A partial answer to this general problem uses the notion of dominated splitting. Let $X \subset M$ be an $F$-invariant set such that the tangent space of $M$ at the points $x \in X$ admits a $DF$-invariant splitting $T_x(M) = E_1(x) \oplus \cdots E_k(x)$, the dimensions $\dim(E_i(x))$ being independent of $x$. This splitting is dominated if the vectors in $E_{i+1}$ are uniformly more expanded than the vectors in $E_i$: there exists $\ell > 0$ such that, for any $x \in X$, any $i \in \{1, \ldots, k-1\}$ and any unit vectors $u \in E_i(x)$ and $v \in E_{i+1}(x)$, one has

$$\|DF^\ell(u)\| < \tfrac{1}{2}\|DF^\ell(v)\|$$

Dominated splittings are always continuous, extend to the closure of $X$, and persist and vary continuously under $C^1$-perturbation of $F$.

### Dominated Splittings versus Wild Behavior

Let $\{\gamma_i\}$ be a set of hyperbolic periodic orbits. On $X = \bigcup \gamma_i$ one considers the natural splitting $TM|_X = E^s \oplus E^u$ induced by the hyperbolicity of the $\gamma_i$. Mañé (1982) proved: “if there is a $C^1$-neighborhood of $F$ on which each $\gamma_i$ remains hyperbolic, then the splitting $TM|_X = E^s \oplus E^u$ is dominated.”

A generalization of Mañé’s result shows: “if a homoclinic class $H(x)$ has no dominated splitting, then for any $\varepsilon > 0$ there is a periodic orbit $\gamma$ in $H(x)$ whose derivative at the period can be turned into an homothety, by an $\varepsilon$-small perturbation of the derivative of $F$ along the points of $\gamma$”; in particular, this periodic orbit can be turned into a sink or a source. As a consequence, one gets: “for $C^1$-generic diffeomorphisms $F$, any homoclinic class either has a dominated splitting or is contained in the closure of the (infinite) set of sinks and sources.”

This argument has been used in two directions:

- Tame systems must satisfy some hyperbolicity. In fact, using the ergodic closing lemma, one proves that the homoclinic classes $H(x)$ of tame diffeomorphisms are volume hyperbolic, that is, there is a dominated splitting $TM = E_1 \oplus \cdots \oplus E_k$ over $H(x)$ such that $DF$ contracts uniformly the volume in $E_1$ and expands uniformly the volume in $E_k$.
- If $F$ admits a homoclinic class $H(x)$ which is robustly without dominated splittings, then generic diffeomorphisms in the neighborhood of $F$ are wild: at this time this is the unique known way to get wild systems.

# Geometric Analysis and General Relativity

**L Andersson**, University of Miami, Coral Gables, FL, USA and Albert Einstein Institute, Potsdam, Germany

Geometric analysis can be said to originate in the nineteenth century work of Weierstrass, Riemann, Schwarz, and others on minimal surfaces, a problem whose history can be traced at least as far back as the work of Meusnier and Lagrange in the eighteenth century. The experiments performed by Plateau in the mid-19th century, on soap films spanning wire contours, served as an important inspiration for this work, and led to the formulation of the Plateau problem, which concerns the existence and regularity of area-minimizing surfaces in $\mathbb{R}^3$ spanning a given boundary contour. The Plateau problem for area-minimizing disks spanning a curve in $\mathbb{R}^3$ was solved by J Douglas (who shared the first Fields medal with Lars V Ahlfors) and T Rado in the 1930s. Generalizations of Plateau's problem have been an important driving force behind the development of modern geometric analysis. Geometric analysis can be viewed broadly as the study of partial differential equations arising in geometry, and includes many areas of the calculus of variations, as well as the theory of geometric evolution equations. The Einstein equation, which is the central object of general relativity, is one of the most widely studied geometric partial differential equations, and plays an important role in its Riemannian as well as in its Lorentzian form, the Lorentzian being most relevant for general relativity.

The Einstein equation is the Euler–Lagrange equation of a Lagrangian with gauge symmetry and thus in the Lorentzian case it, like the Yang–Mills equation, can be viewed as a system of evolution equations with constraints. After imposing suitable gauge conditions, the Einstein equation becomes a hyperbolic system, in particular using spacetime harmonic coordinates (also known as wave coordinates), the Einstein equation becomes a quasilinear system of wave equations. The constraint equations implied by the Einstein equations can be viewed as a system of elliptic equations in terms of suitably chosen variables. Thus, the Einstein equation leads to both elliptic and hyperbolic problems, arising from the constraint equations and the Cauchy problem, respectively. The groundwork for the mathematical study of the Einstein equation and the global nature of spacetimes was laid by, among others, Choquet-Bruhat, who proved local well-posedness for the Cauchy problem, Lichnerowicz, and later York who provided the basic ideas for the analysis of the constraint equations, and Leray who formalized the notion of global hyperbolicity, which is essential for the global study of spacetimes. An important framework for the mathematical study of the Einstein equations has been provided by the singularity theorems of Penrose and Hawking, as well as the cosmic censorship conjectures of Penrose.

Techniques and ideas from geometric analysis have played, and continue to play, a central role in recent mathematical progress on the problems posed by general relativity. Among the main results are the

proof of the positive mass theorem using the minimal surface technique of Schoen and Yau, and the spinor-based approach of Witten, as well as the proofs of the (Riemannian) Penrose inequality by Huisken and Illmanen, and Bray. The proof of the Yamabe theorem by Schoen has played an important role as a basis for constructing Cauchy data using the conformal method.

The results just mentioned are all essentially Riemannian in nature, and do not involve study of the Cauchy problem for the Einstein equations. There has been great progress recently concerning global results on the Cauchy problem for the Einstein equations, and the cosmic censorship conjectures of Penrose. The results available so far are either small data results (among these the nonlinear stability of Minkowski space proved by Christodoulou and Klainerman) or assume additional symmetries, such as the recent proof by Ringström of strong cosmic censorship for the class of Gowdy spacetimes. However, recent progress concerning quasilinear wave equations and the geometry of spacetimes with low regularity due to, among others, Klainerman and Rodnianski, and Tataru and Smith, appears to show the way towards an improved understanding of the Cauchy problem for the Einstein equations.

Since the constraint equations, the Penrose inequality and the Cauchy problem are discussed in separate articles, the focus of this article will be on the role in general relativity of "critical" and other geometrically defined submanifolds and foliations, such as minimal surfaces, marginally trapped surfaces, constant mean curvature hypersurfaces and null hypersurfaces. In this context it would be natural also to discuss geometrically defined flows such as mean curvature flows, inverse mean curvature flow, and Ricci flow. However, this article restricts the discussion to mean curvature flows, since the inverse mean curvature flow appears naturally in the context of the Penrose inequality and the Ricci flow has so far mainly served as a source of inspiration for research on the Einstein equations rather than an important tool. Other topics which would fit well under the heading "General relativity and geometric analysis" are spin geometry (the Witten proof of the Positive mass theorem), the Yamabe theorem and related results concerning the Einstein constraint equations, gluing and other techniques of "spacetime engineering." These are all discussed in other articles. Some techniques which have only recently come into use and for which applications in general relativity have not been much explored, such as Cheeger–Gromov compactness, are not discussed.

## Minimal and Related Surfaces

Consider a hypersurface $N$ in Euclidean space $\mathbb{R}^n$ which is a graph $x_n = u(x_1, \ldots, x_{n-1})$ with respect to the function $u$. The area of $N$ is given by $\mathcal{A}(N) = \int \sqrt{1 + |Du|^2}\, dx^1 \cdots dx^{n-1}$. $N$ is stationary with respect to $\mathcal{A}$ if $u$ satisfies the equation

$$\sum_i D_i \left( \frac{D_i u}{\sqrt{1 + |Du|^2}} \right) = 0 \qquad [1]$$

A hypersurface $N$ defined as a graph of $u$ solving [1] minimizes area with respect to compactly supported deformations, and hence is called a minimal surface. For $n \leq 7$, a solution to eqn [1] defined on all of $\mathbb{R}^{n-1}$ must be an affine function. This fact is known as a Bernstein principle. Equation [1], and more generally, the prescribed mean curvature equation which will be discussed below, is a quasilinear, uniformly elliptic second-order equation. The book by Gilbarg and Trudinger (1983) is an excellent general reference for such equations.

The theory of rectifiable currents, developed by Federer and Fleming, is a basic tool in the modern approach to the Plateau problem and related variational problems. A rectifiable current is a countable union of Lipschitz submanifolds, counted with integer multiplicity, and satisfying certain regularity conditions. Hausdorff measure gives a notion of area for these objects. One may therefore approach the study of minimal surfaces via rectifiable currents which are stationary with respect to variations of area. Suitable generalizations of familiar notions from smooth differential geometry such as tangent plane, normal vector, extrinsic curvature can be introduced. The book by Federer (1969) is a classic treatise on the subject. Further information concerning minimal surfaces and related variational problems can be found in Lawson, Jr. (1980) and Simon (1997). Note, however, that unless otherwise stated, all fields and manifolds considered in this article are assumed to be smooth. For the Plateau problem in a Riemannian ambient space, we have the following existence and regularity result.

**Theorem 1** (Existence of embedded solutions for Plateau problem). *Let $M$ be a complete Riemannian manifold of dimension $n \leq 7$ and let $\Gamma$ be a compact $(n-2)$-dimensional submanifold in $M$ which bounds. Then there is an $(n-1)$-dimensional area-minimizing hypersurface $N$ with $\Gamma$ as its boundary. $N$ is a smooth, embedded manifold in its interior.*

If the dimension of the ambient space is $>7$, solutions to the Plateau problem will in general have a singular set of dimension $n-8$. Let $N$ be an oriented hypersurface of a Riemannian manifold $M$

with covariant derivative $D$. Let $\eta$ be the unit normal of $N$ and define the second fundamental form and mean curvature of $N$ by $A_{ij} = \langle D_{e_i}\eta, e_j\rangle$ and $H = \mathrm{tr}A$. Define the action functional $\mathcal{E}(N) = \mathcal{A}(N) - \int_{M;N} H_0$, where $H_0$ is a function defined on $M$, and $\int_{M;N}$ denotes the integral over the volume bounded by $N$ in $M$. The problem of minimizing $\mathcal{E}$ is a useful generalization of the minimization problem for $\mathcal{A}$.

**Theorem 2** (Existence of minimizers in homology). *Let M be a compact Riemannian manifold of dimension* $\leq 7$, *and let* $\alpha$ *be an integral homology class on M of codimension* 1. *Then there is a smooth minimizer for* $\mathcal{E}$ *representing* $[\alpha]$.

Again, in higher dimensions, the minimizers will in general have singularities. The general form of this result deals with elliptic functionals. For surfaces in 3-manifolds, the problem of minimizing area within homotopy classes has been studied. Results in this direction played a central role in the approach of Schoen and Yau to manifolds with non-negative scalar curvature.

If $M$ is not compact, it is in general necessary to use barriers to control the minimizers, or consider some version of the Plateau problem. Barriers can be used due to the strong maximum principle, which holds for the mean curvature operator since it is quasilinear elliptic. Consider two hypersurfaces $N_1, N_2$ which intersect at a point $p$ and assume that $N_1$ lies on one side of $N_2$ with the normal pointing towards $N_1$. If the mean curvatures $H_1, H_2$ of the hypersurfaces, defined with respect to consistently oriented normals, satisfy $H_1 \leq \lambda \leq H_2$ for some constant $\lambda$, then $N_1$ and $N_2$ coincide near $p$ and have mean curvatures equal to $\lambda$. This result requires only mild regularity conditions on the hypersurfaces. Generalizations hold also for the case of spacelike or null hypersurfaces in a Lorentzian ambient space, see Andersson *et al.* (1998) and Galloway (2000).

Let $\phi$ be a smooth compactly supported function on $N$. The variation $\mathcal{E}' = \delta_{\phi\eta}\mathcal{E}$ of $\mathcal{E}$ under a deformation $\phi\eta$ is

$$\mathcal{E}' = \int_N \phi(H - H_0)$$

Thus, $N$ is stationary with respect to $\mathcal{E}$ if and only if $N$ solves the prescribed mean curvature equation $H(x) = H_0(x)$ for $x \in N$. Supposing that $N$ is stationary and $H_0$ is constant, the second variation $\mathcal{E}'' = \delta_{\phi\eta}\mathcal{E}'$ of $\mathcal{E}$ is of the form

$$\mathcal{E}'' = \int_N \phi(J\phi)$$

where $J$ is the second-variation operator, a second-order elliptic operator. A calculation, using the Gauss equation and the second-variation equation shows

$$J\phi = -\Delta_N\phi - \tfrac{1}{2}[(\mathrm{Scal}_M - \mathrm{Scal}_N) + H^2 + |A|^2]\phi \quad [2]$$

where $\Delta_N, \mathrm{Scal}_M, \mathrm{Scal}_N$ denote the Laplace–Beltrami operator of $N$, and the scalar curvatures of $M$ and $N$, respectively. If $J$ is positive semidefinite, $N$ is called stable.

To set the context where we will apply the above, let $(M, g_{ij})$ be a connected, asymptotically Euclidean three-dimensional Riemannian manifold with covariant derivative, and let $k_{ij}$ be a symmetric tensor on $M$. Suppose $(M, g_{ij}, K_{ij})$ is imbedded isometrically as a spacelike hypersurface in a spacetime $(V, \gamma_{\alpha\beta})$ with $g_{ij}, K_{ij}$ the first and second fundamental forms induced on $M$ from $V$, in particular $K_{ij} = \langle D_{e_i}T, e_j\rangle$ where $T$ is the timelike normal of $M$ in the ambient spacetime $V$, and $D$ is the ambient covariant derivative. We will refer to $(M, g_{ij}, K_{ij})$ as a Cauchy data set for the Einstein equations. Although many of the results which will be discussed below generalize to the case of a nonzero cosmological constant $\Lambda$, we will discuss only the case $\Lambda = 0$ in this article. $G_{\alpha\beta} = \mathrm{Ric}_{V\alpha\beta} - (1/2)\mathrm{Scal}_V\gamma_{\alpha\beta}$ be the Einstein tensor of $V$, and let $\rho = G_{\alpha\beta}T^\alpha T^\beta, \mu_j = G_{j\alpha}T^\alpha$. Then the fields $(g_{ij}, K_{ij})$ satisfy the Einstein constraint equations

$$R + \mathrm{tr}\ K^2 - |K|^2 = 2\rho \quad [3]$$

$$\nabla_j \mathrm{tr}\ K - \nabla^i K_{ij} = \mu_j \quad [4]$$

We assume that the dominant energy condition (DEC)

$$\rho \geq \left(\sum_i \mu_i\mu^i\right)^{1/2} \quad [5]$$

holds. We will sometimes make use of the null energy condition (NEC), $G_{\alpha\beta}L^\alpha L^\beta \geq 0$ for null vectors $L$, and the strong energy condition (SEC), $\mathrm{Ric}_{V\alpha\beta}v^\alpha v^\beta \geq 0$ for causal vectors $v$. $M$ will be assumed to satisfy the fall-off conditions

$$g_{ij} = \left(1 + \frac{2m}{r}\right)\delta_{ij} + O(1/r^2) \quad [6a]$$

$$K_{ij} = O(1/r^2) \quad [6b]$$

as well as suitable conditions for the fall-off of derivatives of $g_{ij}, K_{ij}$. Here $m$ is the ADM (Arnowitt, Deser, Misner) mass of $(M, g_{ij}, K_{ij})$.

## Minimal Surfaces and Positive Mass

Perhaps the most important application of the theory of minimal surfaces in general relativity is in the

Schoen–Yau proof of the positive-mass theorem, which states that $m \geq 0$, and $m = 0$ only if $(M, g, K)$ can be embedded as a hypersurface in Minkowski space. Consider an asymptotically Euclidean manifold $(M, g)$ with $g$ satisfying [6a] and with non-negative scalar curvature. By using Jang's equation, see below, the general situation is reduced to the case of a time symmetric data set, with $K = 0$. In this case, the DEC implies that $(M, g)$ has non-negative scalar curvature.

Assuming $m < 0$ one may, after applying a conformal deformation, assume that $\mathrm{Scal}_M > 0$ in the complement of a compact set. Due to the asymptotic conditions, level sets for sufficiently large values of one of the coordinate functions, say $x^3$, can be used as barriers for minimal surfaces in $M$. By solving a sequence of Plateau problems with boundaries tending to infinity, a stable entire minimal surface $N$ homeomorphic to the plane is constructed. Stability implies using [2],

$$\int_N \left( \frac{1}{2}\, \mathrm{Scal}_M - \kappa + \frac{1}{2}|A|^2 \right) \leq 0$$

where $\kappa = (1/2)\mathrm{Scal}_N$ is the Gauss curvature of $N$. Since by construction $\mathrm{Scal}_M \geq 0, \mathrm{Scal}_M > 0$ outside a compact set, this gives $\int_N \kappa > 0$. Next, one uses the identity, related to the Cohn–Vossen inequality

$$\int_N \kappa = 2\pi - \lim_i \frac{L_i^2}{2A_i}$$

where $A_i, L_i$ are the area and circumference of a sequence of large discs. Estimates using the fact that $M$ is asymptotically Euclidean show that $\lim_i (L_i^2/2A_i) \geq 2\pi$ which gives a contradiction and shows that the minimal surface constructed cannot exist. It follows that $m \geq 0$. It remains to show that the case $m = 0$ is rigid. To do this proves that for an asymptotically Euclidean metric with non-negative scalar curvature, which is positive near infinity, there is a conformally related metric with vanishing scalar curvature and strictly smaller mass. Applying this argument in case $m = 0$ gives a contradiction to the fact that $m \geq 0$. Therefore, $m = 0$ only if the scalar curvature vanishes identically. Suppose now that $(M, g)$ has vanishing scalar curvature but nonvanishing Ricci curvature $\mathrm{Ric}_M$. Then using a deformation of $g$ in the direction of $\mathrm{Ric}_M$, one constructs a metric close to $g$ with negative mass, which leads to a contradiction.

This technique generalizes to Cauchy surfaces of dimension $n \leq 7$. The proof involves induction on dimension. For $n > 7$ minimal hypersurfaces are singular in general and this approach runs into problems. The Witten proof using spinor techniques does not suffer from this limitation but instead requires that $M$ be spin.

## Marginally Trapped Surfaces

Consider a Cauchy data set $(M, g_{ij}, K_{ij})$ as above and let $N$ be a compact surface in $M$ with normal $\eta$, second fundamental form $A$ and mean curvature $H$. Then considering $N$ as a surface in an ambient Lorentzian space $V$ containing $M$, $N$ has two null normal fields which after a rescaling can be taken to be $L_\pm = T \pm \eta$. Here, $T$ is the future-directed time-like unit normal of $M$ in $V$. The null mean curvatures (or null expansions) corresponding to $L_\pm$ can be defined in terms of the variation of the area element $\mu_N$ of $N$ as $\delta_{L_\pm}\mu_N = \theta_\pm \mu_N$ or

$$\theta_\pm = \mathrm{tr}_N K \pm H$$

where $\mathrm{tr}_N K$ denotes the trace of the projection of $K_{ij}$ to $N$. Suppose $L_+$ is the outgoing null normal. $N$ is called outer trapped (marginally trapped, untrapped) if $\theta_+ < 0 (\theta_+ = 0, \theta_+ > 0)$. An asymptotically flat spacetime which contains a trapped surface with $\theta_- < 0, \theta_+ < 0$ is causally incomplete. In the following we will for simplicity drop the word outer from our terminology.

Consider a Cauchy surface $M$. The boundary of the region in $M$ containing trapped surfaces is, if it is sufficiently smooth, a marginally trapped surface. The equation $\theta_+ = 0$ is an equation analogous to the prescribed curvature equation, in particular it is a quasilinear elliptic equation of second order. Marginally trapped surfaces are not variational in the same sense as minimal surfaces. Nevertheless, they are stationary with respect to variations of area within the outgoing light cone. The second variation of area along the outgoing null cone is given, in view of the Raychaudhuri equation, by

$$\delta_{\phi L_+}\theta_+ = -(G_{++} + |\sigma_+|^2)\phi \qquad [7]$$

for a function $\phi$ on $N$. Here $G_{++} = G_{\alpha\beta}L_+^\alpha L_+^\beta$, and $\sigma_+$ denotes the shear of $N$ with respect to $L_+$, that is, the tracefree part of the null second fundamental form with respect to $L_+$. Equation [7] shows that the stability operator in the direction $L_+$ is not elliptic.

In the case of time-symmetric data, $K_{ij} = 0$, the DEC implies $\mathrm{Scal}_M \geq 0$ and marginally trapped surfaces are simply minimal surfaces. A stable compact minimal 2-surface $N$ in a 3-manifold $M$ with non-negative scalar curvature must satisfy

$$2\pi\chi(N) = \int \kappa \geq \frac{1}{2}\int_N \mathrm{Scal}_M + |A|^2 \geq 0$$

and hence by the Gauss–Bonnet theorem, $N$ is diffeomorphic to a sphere or a torus. In case $N$ is a stable minimal torus, the induced geometry is flat and the ambient curvature vanishes at $N$. If, in addition, $N$ minimizes, then $M$ is flat.

For a compact marginally trapped surface $N$ in $M$, analogous results can be proved by studying the stability operator defined with respect to the direction $\eta$. Let $J$ be the operator defined in terms of a variation of $\theta_+$ by $J\phi = \delta_{\phi\eta}\theta_+$. Then

$$J\phi = -\Delta_N\phi + 2s^A D_A\phi + \left(\frac{1}{2}\,\mathrm{Scal}_N - s_A s^A + D_A s^A - \frac{1}{2}|\sigma_+|^2 - G_{+-}\right)\phi$$

Here, $s_A = -(1/2)\langle L_-, D_A L_+\rangle$ and $G_{+-}$ is the Einstein tensor evaluated on $L_+, L_-$. We may call $N$ stable if the real part of the spectrum of $J$ is non-negative. A sufficient condition for $N$ to be stable is that $N$ is locally outermost. This can be formulated, for example, by requiring that a neighborhood of $N$ in $M$ contains no trapped surfaces exterior to $N$. In this case, assuming that the DEC holds, $N$ is a sphere or a torus, and if the real part of the spectrum of $J$ is positive then $N$ is a sphere. If $N$ is a torus, then the ambient curvature and shear vanishes at $N$, $s_A$ is a gradient, and $N$ is flat. One expects that in addition, global rigidity should hold, in analogy with the minimal surface case. This is an open problem. If $N$ satisfies the stronger condition of strict stability, which corresponds to the spectrum of $J$ having positive real part, then $N$ is in the interior of a hypersurface $H$ of the ambient spacetime, with the property that it is foliated by marginally trapped surfaces (Andersson *et al.* 2005). If the NEC holds and $N$ has nonvanishing shear, then $H$ is spacelike at $N$. A hypersurface $H$ with these properties is known as a dynamical horizon.

## Jang's Equation

Consider a Cauchy data set $(M, g_{ij}, K_{ij})$. Extend $K_{ij}$ to a tensor field on $M \times \mathbb{R}$, constant in the vertical direction. Then the equation for a graph

$$N = \{(x, t) \in M \times \mathbb{R}, \quad t = f(x)\}$$

such that $N$ has mean curvature equal to the trace of the projection of $K_{ij}$ to $N$ with respect to the induced metric on $N$, is given by

$$\sum_{i,j}\left(K^{ij} - \frac{\nabla^i\nabla^j f}{(1+|\nabla f|^2)^{1/2}}\right)\left(g_{ij} - \frac{\nabla_i f\nabla_j f}{1+|\nabla f|^2}\right) = 0 \qquad [8]$$

an equation closely related to the equation $\theta_+ = 0$. Equation [8] was introduced by P S Jang (Jang 1978) as part of an attempt to generalize the inverse mean curvature flow method of Geroch from time-symmetric to general Cauchy data.

Existence and regularity for Jang's equation were proved by Schoen and Yau (1981) and used to generalize their proof of the positive-mass theorem from the case of maximal slices to the general case. The solution to Jang's equation is constructed as the limit of the solution to a sequence of regularized problems. The limit consists of a collection $N$ of submanifolds of $M \times \mathbb{R}$. In particular, component near infinity is a graph and has the same mass as $M$. $N$ may contain vertical components which project onto marginally trapped surfaces in $M$, and in fact these constitute the only possibilities for blow-up of the sequence of graphs used to construct $N$. If the DEC is valid, the metric on N has non-negative scalar curvature in the weak sense that

$$\int_N \mathrm{Scal}_N\phi^2 + 2|\nabla\phi|^2 > 0$$

for smooth compactly supported functions $\phi$. If the DEC holds strictly, the strict inequality holds and in this case the metric on $N$ is conformal to a metric with vanishing scalar curvature.

Jang's equation can be applied to prove existence of marginally trapped surfaces, given barriers. Let $(M, g_{ij}, K_{ij})$ be a Cauchy data set containing two compact surfaces $N_1, N_2$ which together bound a compact region $M'$ in $M$. Suppose the surfaces $N_1$ and $N_2$ have $\theta_+ < 0$ on $N_1$ and $\theta_+ > 0$ on $N_2$. Schoen recently proved the following result.

**Theorem 3** (Existence of marginally trapped surfaces). *Let $M', N_1, N_2$ be as above. Then there is a finite collection of compact, marginally trapped surfaces $\{\Sigma_a\}$ contained in the interior of $M'$, such that $\cup\Sigma_a$ is homologous to $N_1$.* If the DEC holds, then $\Sigma_a$ is a collection of spheres and tori.

The proof proceeds by solving a sequence of Dirichlet boundary-value problems for Jang's equation with boundary value on $N_1, N_2$ tending to $-\infty$ and $\infty$, respectively. The assumption on $\theta_+$ is used to show the existence of barriers for Jang's equation. Let $f_k$ be the sequence of solutions to the Dirichlet problems. Jang's equation is invariant under renormalization $f_k \to f_k + c_k$ for some sequence $c_k$ of real numbers. A Harnack inequality for the gradient of the solutions to Jang's equation is used to show that the sequence of solutions $f_k$, possibly after a renormalization, has a subsequence converging to a vertical submanifold of $M' \times \mathbb{R}$, which projects to a collection $\Sigma_a$ of marginally trapped surfaces. By construction, the zero sets of the $f_k$ are homologous to $N_1$ and $N_2$. The estimates on the sequence $\{f_k\}$ show that this holds also in the limit $k \to \infty$. The statement about the topology of the $\Sigma_a$ follows by showing, using the above-mentioned inequality for $\mathrm{Scal}_N$, that if DEC holds, the total Gauss curvature of each surface $\Sigma_a$ is non-negative.

## Center of mass

Since by the positive-mass theorem $m > 0$ unless the ambient spacetime is flat, it makes sense to consider the problem of finding an appropriate notion of center of mass. This problem was solved by Huisken and Yau who showed that under the asymptotic conditions [6] the isoperimetric problem has a unique solution if one considers sufficiently large spheres.

**Theorem 4** (Huisken and Yau 1996). *There is an $H_0 > 0$ and a compact region $B_{H_0}$ such that for each $H \in (0, H_0)$ there is a unique constant mean curvature sphere $S_H$ with mean curvature $H$ contained in $M \backslash B_{H_0}$. The spheres form a foliation.*

The proof involves a study of the evolution equation

$$\frac{\mathrm{d}x}{\mathrm{d}s} = (H - \bar{H})\eta \qquad [9]$$

where $\bar{H}$ is the average mean curvature. This is the gradient flow for the isoperimetric problem of minimizing area keeping the enclosed volume constant. The solutions in Euclidean space are standard spheres. Equation [9] defines a parabolic system, in particular we have

$$\frac{\mathrm{d}}{\mathrm{d}s} H = \Delta H + (\mathrm{Ric}(\eta, \eta) + |A|^2)(H - \bar{H})$$

It follows from the fall-off conditions [6] that the foliation of spheres constructed in Theorem 4 are untrapped surfaces. They can therefore be used as outer barriers in the existence result for marginally trapped surfaces, (Theorem 3).

The mean curvature flow for a spatial hypersurface in a Lorentz manifold is also parabolic. This flow has been applied to construct constant mean curvature Cauchy hypersurfaces in spacetimes.

## Maximal and Related Surfaces

Let $N$ be the hypersurface $x_0 = u(x_1, \ldots, x_n)$ in Minkowski space $\mathbb{R}^{1+n}$ with line element $-\mathrm{d}x_0^2 + \mathrm{d}x_1^2 + \cdots + \mathrm{d}x_n^2$. Assume $|\nabla u| < 1$ so that $N$ is spacelike. Then $N$ is stationary with respect to variations of area if $u$ solves the equation

$$\sum_i \nabla_i \left( \frac{\nabla_i u}{\sqrt{1 - |\nabla u|^2}} \right) = 0 \qquad [10]$$

$N$ maximizes area with respect to compactly supported variations, and hence is called a maximal surface. As in the case of the minimal surface equation, eqn [10] and more generally the Lorentzian prescribed mean curvature equation, is quasilinear elliptic, but it is not uniformly elliptic, which makes the regularity theory more subtle.

A Bernstein principle analogous to the one for the minimal surface equation holds for the maximal surface equation [10]. Suppose that $u$ is a solution to [10] which is defined on all of $\mathbb{R}^n$. Then $u$ is an affine function (Cheng and Yau 1976). An important tool used in the proof is a Bochner type identity, originally due to Calabi, for the norm of the second fundamental form. For a hypersurface in a flat ambient space, the Codazzi equation states $\nabla_i A_{jk} - \nabla_j A_{ik} = 0$. This gives the identity

$$\Delta A_{ij} = \nabla_i \nabla_j H + A_{km} R^{m\ k}_{\ i\ j} + A_{mi} \mathrm{Ric}^m_j \qquad [11]$$

The curvature terms can be rewritten in terms of $A_{ij}$ if the ambient space is flat. Using [11] to compute $\Delta |A|^2$ gives an expression which is quadratic in $\nabla A$, and fourth order in $|A|$, and which allows one to perform maximum principle estimates on $|A|$. Generalizations of this technique for hypersurfaces in general ambient spaces play an important role in the proof of regularity of minimal surfaces, and in the proof of existence for Jang's equation as well as in the analysis of the mean curvature flow used to prove existence of round spheres. The generalization of eqn [11] is known as a Simons identity.

For the case of maximal hypersurfaces of Minkowski space, it follows from further maximum principle estimates that a maximal hypersurface of Minkowski space is convex, in particular, it has nonpositive Ricci curvature. Generalizations of this technique allow one to analyze entire constant mean curvature hypersurfaces of Minkowski space.

Consider a globally hyperbolic Lorentzian manifold $(V, \gamma)$. A $C^0$ hypersurface is said to be weakly spacelike if timelike curves intersect it in at most one point. Call a codimension-2 submanifold $\Gamma \subset V$ a weakly spacelike boundary if it bounds a weakly spacelike hypersurface $N_0$.

**Theorem 5** (Existence for Plateau problem for maximal surfaces (Bartnik 1988)). *Let $V$ be a globally hyperbolic spacetime and assume that the causal structure of $V$ is such that the domain of dependence of any compact domain in $V$ is compact. Given a weakly spacelike boundary $\Gamma$ in $V$, there is a weakly spacelike maximal hypersurface $N$ with $\Gamma$ as its boundary. $N$ is smooth except possibly on null geodesics connecting points of $\Gamma$.*

Here, maximal hypersurface is understood in a weak sense, referring to stationarity with respect to variations. Due to the nonuniform ellipticity for the maximal surface equation, the interior regularity

which holds for minimal surfaces fails to hold in general for the maximal surface equation.

A time-oriented spacetime is said to have a crushing singularity to the past (future) if there is a sequence $\Sigma_n$ of Cauchy surfaces so that the mean curvature function $H_n$ of $\Sigma_n$ diverges uniformly to $-\infty(\infty)$.

**Theorem 6** (Gerhardt 1983). *Suppose that* $(V, \gamma)$ *is globally hyperbolic with compact Cauchy surfaces and satisfies the SEC. Then if* $(V, \gamma)$ *has crushing singularities to the past and future it is globally foliated by constant mean curvature hypersurfaces. The mean curvature* $\tau$ *of these Cauchy surfaces is a global time function.*

The proof involves an application of results from geometric measure theory to an action $\mathcal{E}$ of the form discussed earlier. A barrier argument is used to control the maximizers. Bartnik (1984, theorem 4.1) gave a direct proof of existence of a constant mean curvature (CMC) hypersurface, given barriers. If the spacetime $(V, \gamma)$ is symmetric, so that a compact Lie group acts on $V$ by isometries, then CMC hypersurfaces in $V$ inherit the symmetry. Theorem 6 gives a condition under which a spacetime is globally foliated by CMC hypersurfaces. In general, if the SEC holds in a spatially compact spacetime, then for each $\tau \neq 0$, there is at most one constant mean curvature Cauchy surface with mean curvature $\tau$. In case $V$ is vacuum, $\mathrm{Ric}_V = 0$, and $3+1$ dimensional, then each point $x \in V$ is on at most one hypersurface of constant mean curvature unless $V$ is flat and splits as a metric product.

There are vacuum spacetimes with compact Cauchy surface which contain no CMC hypersurface (Chrusciel *et al.* 2004). The proof is carried out by constructing Cauchy data, using a gluing argument, on the connected sum of two tori, such that the resulting Cauchy data set $(M, g_{ij}, K_{ij})$ has an involution which reverses the sign of $K_{ij}$. The involution extends to the maximal vacuum development $V$ of the Cauchy data set. Existence of a CMC surface in $V$ gives, in view of the involution, barriers which allow one to construct a maximal Cauchy surface homeomorphic to $M$. This leads to a contradiction, since the connected sum of two tori does not carry a metric of positive scalar curvature, and therefore, in view of the constraint equations, cannot be imbedded as a maximal Cauchy surface in a vacuum spacetime. The maximal vacuum development $V$ is causally geodesically incomplete. However, in view of the existence proof for CMC Cauchy surfaces (cf. Theorem 6), these spacetimes cannot have a crushing singularity. It would be interesting to settle the open question whether there are stable examples of this type.

In the case of a spacetime $V$ which has an expanding end, one does not expect in general that the spacetime is globally foliated by CMC hypersurfaces even if $V$ is vacuum and contains a CMC Cauchy surface. This expectation is based on the phenomenon known as the collapse of the lapse; for example, the Schwarzschild spacetime does not contain a global foliation by maximal Cauchy surfaces (Beig and Murchadha 1998). However, no counterexample is known in the spatially compact case. In spite of these caveats, many examples of spacetimes with global CMC foliations are known, and the CMC condition, or more generally prescribed mean curvature, is an important gauge condition for general relativity.

Some examples of situations where global constant or prescribed mean curvature foliations are known to exist in vacuum or with some types of matter are spatially homogeneous spacetimes, and spacetimes with two commuting Killing fields. Small data global existence for the Einstein equations with CMC time gauge have been proved for spacetimes with one Killing field, with Cauchy surface a circle bundle over a surface of genus $>1$, by Choquet-Bruhat and Moncrief. Further, for $(3+1)$-dimensional spacetimes with Cauchy surface admitting a hyperbolic metric, small data global existence in the expanding direction has been proved by Andersson and Moncrief. See Andersson (2004) and Rendall (2002) for surveys on the Cauchy problem in general relativity.

## Null Hypersurfaces

Consider an asymptotically flat spacetime containing a black hole, that is, a region $B$ such that future causal curves starting in $B$ cannot reach observers at infinity. The boundary of the trapped region is called the event horizon $\mathcal{H}$. This is a null hypersurface, which under reasonable conditions on causality has null generators which are complete to the future. Due to the completeness, assuming that $\mathcal{H}$ is smooth, one can use the Raychaudhuri equation [7] to show that the null expansion $\theta_+$ of a spatial cross section of $\mathcal{H}$ must satisfy $\theta_+ \geq 0$, and hence that the area of cross sections of $\mathcal{H}$ grows monotonously to the future. A related statement is that null generators can enter $\mathcal{H}$ but may not leave it. This was first proved by Hawking for the case of smooth horizons, using essentially the Raychaudhuri equation. In general $\mathcal{H}$ can fail to be smooth. However, from the definition of $\mathcal{H}$ as the boundary of the trapped region it follows that it has support hypersurfaces, which are past light cones. This property allows one to prove that $\mathcal{H}$ is Lipschitz and hence smooth almost everywhere. At smooth points of $\mathcal{H}$, the calculations in the proof of

Hawking apply, and the monotonicity of the area of cross sections follows.

**Theorem 7** (Area theorem (Chrusciel *et al.* 2001)). *Let $\mathcal{H}$ be a black hole event horizon in a smooth spacetime $(M, g)$. Suppose that the generators are future complete and the NEC holds on $\mathcal{H}$. Let $S_a, a = 1, 2$, be two spacelike cross sections of $\mathcal{H}$ and suppose that $S_2$ is to the future of $S_1$. Then $\mathcal{A}(S_2) \geq \mathcal{A}(S_1)$.*

The eikonal equation $\nabla^\alpha u \nabla_\alpha u = 0$ plays a central role in geometric optics. Level sets of a solution $u$ are null hypersurfaces which correspond to wave fronts. Much of the recent progress on rough solutions to the Cauchy problem for quasilinear wave equations is based on understanding the influence of the geometry of these wave fronts on the evolution of high-frequency modes ‘in the background spacetime. In this analysis many objects familiar from general relativity, such as the structure equations for null hypersurfaces, the Raychaudhuri equation, and the Bianchi identities play an important role, together with novel techniques of geometric analysis used to control the geometry of cross sections of the wave fronts and to estimate the connection coefficients in a rough spacetime geometry. These techniques show great promise and can be expected to have a significant impact on our understanding of the Einstein equations and general relativity.

# Geometric Flows and the Penrose Inequality

**H Bray**, Duke University, Durham, NC, USA

This article was originally published as "Black holes, geometric flows, and the Penrose inequality in general relativity." Notices of the *American Mathematical Society*, 49(2002), 1372–1381.

## Introduction

In a paper, R Penrose (1973) made a physical argument that the total mass of a spacetime which contains black holes with event horizons of total area $A$ should be at least $\sqrt{A/16\pi}$. An important special case of this physical statement translates into a very beautiful mathematical inequality in Riemannian geometry known as the Riemannian Penrose inequality. The Riemannian Penrose inequality was first proved by Huisken and Ilmanen (1997) for a single black hole and then by the author in 1999 for any number of black holes. The two approaches use two different geometric flow techniques. The most general version of the Penrose inequality is still open.

A natural interpretation of the Penrose inequality is that the mass contributed by a collection of black holes is (at least) $\sqrt{A/16\pi}$. More generally, the question "How much matter is in a given region of a spacetime?" is still very much an open problem. (Christodoulou and Yau 1988). In this paper, we will discuss some of the qualitative aspects of mass in general relativity, look at examples which are informative, and describe the two very geometric proofs of the Riemannian Penrose inequality.

### Total Mass in General Relativity

Two notions of mass which are well understood in general relativity are local energy density at a point and the total mass of an asymptotically flat spacetime. However, defining the mass of a region larger than a point but smaller than the entire universe is not very well understood at all.

Suppose $(M^3, g)$ is a Riemannian 3-manifold isometrically embedded in a $(3+1)$-dimensional Lorentzian spacetime $N^4$. Suppose that $M^3$ has zero-second fundamental form in the spacetime. This is a simplifying assumption which allows us to think of $(M^3, g)$ as a "$t=0$" slice of the spacetime. (Recall that the second fundamental form is a measure of how much $M^3$ curves inside $N^4$. $M^3$ is also sometimes called "totally geodesic" since geodesics of $N^4$ which are tangent to $M^3$ at a point stay inside $M^3$ forever.) The Penrose inequality (which allows for $M^3$ to have general second fundamental form) is known as the Riemannian Penrose inequality when the second fundamental form is set to zero.

We also want to only consider $(M^3, g)$ that are asymptotically flat at infinity, which means that for some compact set $K$, the "end" $M^3 \backslash K$ is diffeomorphic to $\boldsymbol{R}^3 \backslash B_1(0)$, where the metric $g$ is asymptotically approaching (with certain decay conditions) the standard flat metric $\delta_{ij}$ on $\boldsymbol{R}^3$ at infinity. The simplest example of an asymptotically flat manifold is $(\boldsymbol{R}^3, \delta_{ij})$ itself. Other good examples are the conformal metrics $(\boldsymbol{R}^3, u(x)^4\delta_{ij})$, where $u(x)$ approaches a constant sufficiently rapidly at infinity. (Also, sometimes it is convenient to allow $(M^3, g)$ to have multiple asymptotically flat ends, in which case each connected component of $M^3 \backslash K$ must have the property described above.) A qualitative picture of an asympotically flat 3-manifold is shown in Figure 1.

The purpose of these assumptions on the asymptotic behavior of $(M^3, g)$ at infinity is that they imply the existence of the limit

$$m = \frac{1}{16\pi} \lim_{\sigma\to\infty} \int_{S_\sigma} \sum_{i,j} (g_{ij,i}\nu_j - g_{ii,j}\nu_j)\, \mathrm{d}\mu$$

where $S_\sigma$ is the coordinate sphere of radius $\sigma, \nu$ is the unit normal to $S_\sigma$, and $\mathrm{d}\mu$ is the area element of $S_\sigma$ in the coordinate chart. The quantity $m$ is called the "total mass" (or ADM mass) of $(M^3, g)$ and does not depend on the choice of asymptotically flat coordinate chart.

The above equation is where many people would stop reading an article like this. But before you do, we will promise not to use this definition of the total mass in this paper. In fact, it turns out that total mass can be quite well understood with an example. Going back to the example $(\boldsymbol{R}^3, u(x)^4\delta_{ij})$, if we suppose that $u(x) > 0$ has the asymptotics at infinity

$$u(x) = a + b/|x| + \mathcal{O}(1/|x|^2) \qquad [1]$$

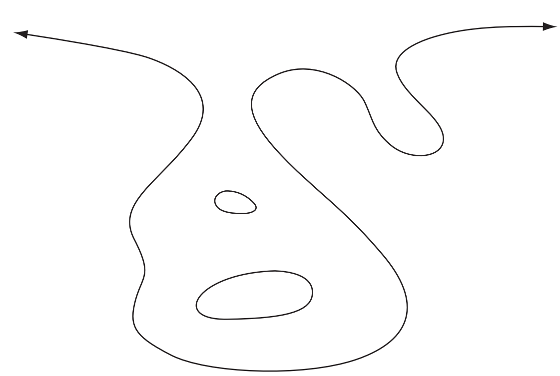

**Figure 1** A qualitative picture of an asymptotically flat 3-manifold.

(and derivatives of the $\mathcal{O}(1/|x|^2)$ term are $\mathcal{O}(1/|x|^3)$), then the total mass of $(M^3, g)$ is

$$m = 2ab \qquad [2]$$

Furthermore, suppose $(M^3, g)$ is any metric whose "end" is isometric to $(\boldsymbol{R}^3 \backslash K, u(x)^4 \delta_{ij})$, where $u(x)$ is harmonic in the coordinate chart of the end $(\boldsymbol{R}^3 \backslash K, \delta_{ij})$ and goes to a constant at infinity. Then expanding $u(x)$ in terms of spherical harmonics demonstrates that $u(x)$ satisfies condition [1]. We will call these Riemannian manifolds $(M^3, g)$ "harmonically flat at infinity," and we note that the total mass of these manifolds is also given by eqn [2].

A very nice lemma by Schoen and Yau is that, given any $\epsilon > 0$, it is always possible to perturb an asymptotically flat manifold to become harmonically flat at infinity such that the total mass changes less than $\epsilon$ and the metric changes less than $\epsilon$ pointwise, all while maintaining non-negative scalar curvature. Hence, it happens that to prove the theorems in this paper, we only need to consider harmonically flat manifolds! Thus, we can use eqn [2] as our definition of total mass. As an example, note that $(\boldsymbol{R}^3, \delta_{ij})$ has zero total mass. Also, note that, qualitatively, the total mass of an asymptotically flat or harmonically flat manifold is the $1/r$ rate at which the metric becomes flat at infinity.

### The Phenomenon of Gravitational Attraction

What do the above definitions of total mass have to do with anything physical? That is, if the total mass is the $1/r$ rate at which the metric becomes flat at infinity, what does this have to do with our real-world intuitive idea of mass?

The answer to this question is very nice. Given a Schwarzschild spacetime metric

$$\left(\boldsymbol{R}^4, \left(1 + \frac{m}{2|x|}\right)^4 (\mathrm{d}x_1^2 + \mathrm{d}x_2^2 + \mathrm{d}x_3^2) - \left(\frac{1 - m/2|x|}{1 + m/2|x|}\right)^2 \mathrm{d}t^2\right)$$

$|x| > m/2$, for example, note that the $t = 0$ slice (which has zero-second fundamental form) is the spacelike Schwarzschild metric

$$\left(\boldsymbol{R}^3 \setminus B_{m/2}(0), \left(1 + \frac{m}{2|x|}\right)^4 \delta_{ij}\right)$$

(discussed more later). Note that according to eqn [2], the parameter $m$ is in fact the total mass of this 3-manifold.

On the other hand, suppose we were to release a small test particle, initially at rest, a large distance $r$ from the center of the Schwarzschild spacetime. If this particle is not acted upon by external forces, then it should follow a geodesic in the spacetime. It turns out that with respect to the asymptotically flat coordinate chart, these geodesics "accelerate" towards the middle of the Schwarzschild metric proportional to $m/r^2$ (in the limit as $r$ goes to infinity). Thus, our Newtonian notion of mass also suggests that the total mass of the spacetime is $m$.

### Local Energy Density

Another quantification of mass which is well understood is local energy density. In fact, in this setting, the local energy density at each point is

$$\mu = \frac{1}{16\pi} R$$

where $R$ is the scalar curvature of the 3-manifold (which has zero-second fundamental form in the spacetime) at each point. Note that $(\boldsymbol{R}^3, \delta_{ij})$ has zero energy density at each point as well as zero total mass. This is appropriate since $(\boldsymbol{R}^3, \delta_{ij})$ is in fact a "$t = 0$" slice of Minkowski spacetime, which represents a vacuum. Classically, physicists consider $\mu \geq 0$ to be a physical assumption. Hence, from this point on, we will not only assume that $(M^3, g)$ is asymptotically flat, but also that it has non-negative scalar curvature,

$$R \geq 0$$

This notion of energy density also helps us understand total mass better. After all, we can take any asymptotically flat manifold and then change the metric to be perfectly flat outside a large compact set, thereby giving the new metric zero total mass. However, if we introduce the physical condition that both metrics have non-negative scalar curvature, then it is a beautiful theorem that this is in fact not possible, unless the original metric was already $(\boldsymbol{R}^3, \delta_{ij})$! (This theorem is actually a corollary to the positive mass theorem discussed below.) Thus, the curvature obstruction of having non-negative scalar curvature at each point is a very interesting condition.

Also, notice the indirect connection between the total mass and local energy density. At this point, there does not seem to be much of a connection at all. The total mass is the $1/r$ rate at which the metric becomes flat at infinity, and local energy density is the scalar curvature at each point. Furthermore, if a metric is changed in a compact set, local energy density is changed, but the total mass is unaffected.

The reason for this is that the total mass is "not" the integral of the local energy density over the manifold. In fact, this integral fails to take potential energy into account (which would be expected to

contribute a negative energy) as well as gravitational energy. Hence, it is not initially clear what we should expect the relationship between total mass and local energy density to be, so let us begin with an example.

### Example Using Superharmonic Functions in $\boldsymbol{R}^3$

Once again, let us return to the $(\boldsymbol{R}^3, u(x)^4\delta_{ij})$ example. The formula for the scalar curvature is

$$R = -8u(x)^{-5}\Delta u(x)$$

Hence, since the physical assumption of non-negative energy density implies non-negative scalar curvature, we see that $u(x) > 0$ must be superharmonic ($\Delta u \leq 0$). For simplicity, let us also assume that $u(x)$ is harmonic outside a bounded set so that we can expand $u(x)$ at infinity using spherical harmonics. Hence, $u(x)$ has the asymptotics of eqn [1]. By the maximum principle, it follows that the minimum value for $u(x)$ must be $a$, referring to eqn [1]. Hence, $b \geq 0$, which implies that $m \geq 0$! Thus, we see that the assumption of non-negative energy density at each point of $(\boldsymbol{R}^3, u(x)^4\delta_{ij})$ implies that the total mass is also non-negative, which is what one would hope.

### The Positive Mass Theorem

Why would one hope this? What would be the difference if the total mass were negative? This would mean that a gravitational system of positive energy density could collectively act as a net negative total mass. This phenomenon has not been observed experimentally, and so it is not a property that we would hope to find in general relativity.

More generally, suppose we have any asymptotically flat manifold with non-negative scalar curvature, is it true that the total mass is also non-negative? The answer is yes, and this fact is know as the positive mass theorem, first proved by Schoen and Yau (1979) using minimal surface techniques and then by Witten (1981) using spinors. In the zero-second fundamental form case, the positive mass theorem is known as the Riemannian positive mass theorem and is stated below.

**Theorem 1** (Schoen, Yau). *Let $(M^3, g)$ be any asymptotically flat, complete Riemannian manifold with non-negative scalar curvature. Then the total mass $m \geq 0$, with equality if and only if $(M^3, g)$ is isometric to $(\boldsymbol{R}^3, \delta)$.*

### Gravitational Energy

The previous example neglects to illustrate some of the subtleties of the positive mass theorem. For example, it is easy to construct asymptotically flat manifolds $(M^3, g)$ (not conformal to $\boldsymbol{R}^3$) which have zero scalar curvature everywhere and yet have "nonzero" total mass. By the positive mass theorem, the mass of these manifolds is positive. Physically, this corresponds to a spacetime with zero energy density everywhere which still has positive total mass. From where did this mass come? How can a vacuum have positive total mass?

Physicists refer to this extra energy as gravitational energy. There is no known local definition of the energy density of a gravitational field, and presumably such a definition does not exist. The curious phenomenon, then, is that for some reason, gravitational energy always makes a non-negative contribution to the total mass of the system.

### Black Holes

Another very interesting and natural phenomenon in general relativity is the existence of black holes. Instead of thinking of black holes as singularities in a spacetime, we will think of black holes in terms of their horizons. For example, suppose we are exploring the universe in a spacecraft capable of traveling at any speed less than the speed of light. If we are investigating a black hole, we would want to make sure that we don't get too close and get trapped by the "gravitational forces" of the black hole. In fact, we could imagine a "sphere of no return" beyond which it is impossible to escape from the black hole. This is called the event horizon of a black hole.

However, one limitation of the notion of an event horizon is that it is very hard to determine its location. One way is to let daredevil spacecraft see how close they can get to the black hole and still escape from it eventually. The only problem with this approach (besides the cost in spacecraft) is that it is hard to know when to stop waiting for a daredevil spacecraft to return. Even if it has been 50 years, it could be that this particular daredevil was not trapped by the black hole but got so close that it will take it 1000 or more years to return. Thus, to define the location of an event horizon even mathematically, we need to know the entire evolution of the spacetime. Hence, event horizons can not be computed based only on the local geometry of the spacetime.

This problem is solved (at least for the mathematician) with the notion of apparent horizons of black holes. Given a surface in a spacetime, suppose that it emits an outward shell of light. If the surface area of this shell of light is decreasing everywhere on the surface, then this is called a trapped surface. The outermost boundary of these trapped surfaces is called the apparent horizon of the black hole. Apparent horizons can be computed based on their

local geometry, and an apparent horizon always implies the existence of an event horizon outside of it (Hawking and Ellis 1973).

Now let us return to the case we are considering in this paper where $(M^3, g)$ is a "$t = 0$" slice of a spacetime with zero-second fundamental form. Then it is a very nice geometric fact that apparent horizons of black holes intersected with $M^3$ correspond to the connected components of the outermost minimal surface $\Sigma_0$ of $(M^3, g)$.

All of the surfaces we are considering in this paper will be required to be smooth boundaries of open bounded regions, so that outermost is well defined with respect to a chosen end of the manifold. A minimal surface in $(M^3, g)$ is a surface which is a critical point of the area function with respect to any smooth variation of the surface. The first variational calculation implies that minimal surfaces have zero mean curvature. The surface $\Sigma_0$ of $(M^3, g)$ is defined as the boundary of the union of the open regions bounded by all of the minimal surfaces in $(M^3, g)$. It turns out that $\Sigma_0$ also has to be a minimal surface, so we call $\Sigma_0$ the "outermost minimal surface." A qualitative sketch of an outermost minimal surface of a 3-manifold is shown in **Figure 2**.

We will also define a surface to be "(strictly) outer minimizing" if every surface which encloses it has (strictly) greater area. Note that outermost minimal surfaces are strictly outer minimizing. Also, we define a "horizon" in our context to be any minimal surface which is the boundary of a bounded open region.

It also follows from a stability argument (using the Gauss–Bonnet theorem interestingly) that each component of an outermost minimal surface (in a 3-manifold with non-negative scalar curvature) must have the topology of a sphere. Furthermore, there is a physical argument, based on Penrose (1973), which suggests that the mass contributed by the black holes (thought of as the connected components of $\Sigma_0$) should be defined to be $\sqrt{A_0/16\pi}$,

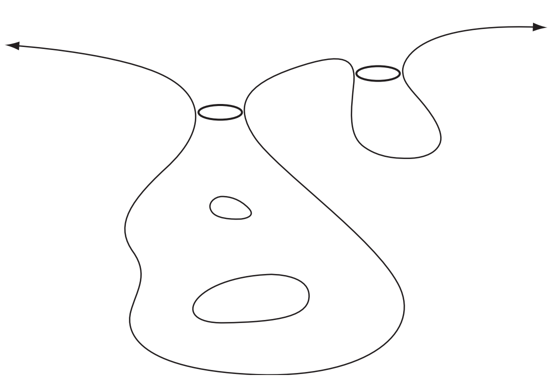

**Figure 2** A qualitative sketch of an outermost minimal surface of a 3-manifold.

where $A_0$ is the area of $\Sigma_0$. Hence, the physical argument that the total mass should be greater than or equal to the mass contributed by the black holes yields the following geometric statement.

**The Riemannian Penrose Inequality** Let $(M^3, g)$ be a complete, smooth, 3-manifold with non-negative scalar curvature which is harmonically flat at infinity with total mass $m$ and which has an outermost minimal surface $\Sigma_0$ of area $A_0$. Then,

$$m \geq \sqrt{\frac{A_0}{16\pi}} \qquad [3]$$

with equality if and only if $(M^3, g)$ is isometric to the Schwarzschild metric

$$\left(\mathbf{R}^3 \backslash \{0\}, \left(1 + \frac{m}{2|x|}\right)^4 \delta_{ij}\right)$$

outside their respective outermost minimal surfaces.

The above statement has been proved by the present author, and Huisken and Ilmanen proved it when $A_0$ is defined instead to be the area of the largest connected component of $\Sigma_0$. We will discuss both approaches in this paper, which are very different, although they both involve flowing surfaces and/or metrics.

We also clarify that the above statement is with respect to a chosen end of $(M^3, g)$, since both the total mass and the definition of outermost refer to a particular end. In fact, nothing very important is gained by considering manifolds with more than one end, since extra ends can always be compactified by connect summing them (around a neighborhood of infinity) with large spheres while still preserving non-negative scalar curvature, for example. Hence, we will typically consider manifolds with just one end. In the case that the manifold has multiple ends, we will require every surface (which could have multiple connected components) in this paper to enclose all of the ends of the manifold except the chosen end.

## The Schwarzschild Metric

The Schwarzschild metric

$$\left(\mathbf{R}^3 \setminus \{0\}, \left(1 + \frac{m}{2|x|}\right)^4 \delta_{ij}\right)$$

referred to in the above statement of the Riemannian Penrose inequality, is a particularly important example to consider, and corresponds to a zero-second fundamental form, spacelike slice of the usual $(3+1)$-dimensional Schwarzschild metric (which represents a spherically symmetric static black hole in vacuum). The three-dimensional

Schwarzschild metrics have total mass $m > 0$ and are characterized by being the only spherically symmetric, geodesically complete, zero scalar curvature 3-metrics, other than $(\mathbf{R}^3, \delta_{ij})$. They can also be embedded in four-dimensional Euclidean space $(x, y, z, w)$ as the set of points satisfying

$$|(x, y, z)| = (w^2/8m) + 2m$$

which is a parabola rotated around an $S^2$. This last picture allows us to see that the Schwarzschild metric, which has two ends, has a $Z_2$ symmetry which fixes the sphere with $w = 0$ and $|(x, y, z)| = 2m$, which is clearly minimal. Furthermore, the area of this sphere is $4\pi(2m)^2$, giving equality in the Riemannian Penrose inequality.

## A Brief History of the Problem

The Riemannian Penrose inequality has a rich history spanning nearly three decades and has motivated much interesting mathematics and physics. In 1973, R Penrose in effect conjectured an even more general version of inequality [3] using a very clever physical argument, which we will not have room to repeat here (Penrose 1973). His observation was that a counterexample to inequality [3] would yield Cauchy data for solving the Einstein equations, the solution to which would likely violate the cosmic censor conjecture (which says that singularities generically do not form in a spacetime unless they are inside a black hole).

Jang and Wald (1977), extending ideas of Geroch, gave a heuristic proof of inequality [3] by defining a flow of 2-surfaces in $(M^3, g)$ in which the surfaces flow in the outward normal direction at a rate equal to the inverse of their mean curvatures at each point. The Hawking mass of a surface (which is supposed to estimate the total amount of energy inside the surface) is defined to be

$$m_{\text{Hawking}}(\Sigma) = \sqrt{\frac{|\Sigma|}{16\pi}}\left(1 - \frac{1}{16\pi}\int_\Sigma H^2\right)$$

(where $|\Sigma|$ is the area of $\Sigma$ and $H$ is the mean curvature of $\Sigma$ in $(M^3, g)$) and, amazingly, is nondecreasing under this "inverse mean curvature flow." This is seen by the fact that under inverse mean curvature flow, it follows from the Gauss equation and the second variation formula that

$$\frac{\mathrm{d}}{\mathrm{d}t} m_{\text{Hawking}}(\Sigma) = \sqrt{\frac{|\Sigma|}{16\pi}}\left[\frac{1}{2} + \frac{1}{16\pi}\int_\Sigma 2\frac{|\nabla_\Sigma H|^2}{H^2} + R - 2K + \frac{1}{2}(\lambda_1 - \lambda_2)^2\right]$$

when the flow is smooth, where $R$ is the scalar curvature of $(M^3, g)$, $K$ is the Gauss curvature of the surface $\Sigma$, and $\lambda_1$ and $\lambda_2$ are the eigenvalues of the second fundamental form of $\Sigma$, or principle curvatures. Hence,

$$R \geq 0$$

and

$$\int_\Sigma K \leq 4\pi \qquad [4]$$

(which is true for any connected surface by the Gauss–Bonnet theorem) imply

$$\frac{\mathrm{d}}{\mathrm{d}t} m_{\text{Hawking}}(\Sigma) \geq 0 \qquad [5]$$

Furthermore,

$$m_{\text{Hawking}}(\Sigma_0) = \sqrt{\frac{|\Sigma_0|}{16\pi}}$$

since $\Sigma_0$ is a minimal surface and has zero mean curvature. In addition, the Hawking mass of sufficiently round spheres at infinity in the asymptotically flat end of $(M^3, g)$ approaches the total mass $m$. Hence, if inverse mean curvature flow beginning with $\Sigma_0$ eventually flows to sufficiently round spheres at infinity, inequality [3] follows from inequality [5].

As noted by Jang and Wald, this argument only works when inverse mean curvature flow exists and is smooth, which is generally not expected to be the case. In fact, it is not hard to construct manifolds which do not admit a smooth inverse mean curvature flow. The problem is that if the mean curvature of the evolving surface becomes zero or is negative, it is not clear how to define the flow.

For 20 years, this heuristic argument lay dormant until the work of Huisken and Ilmanen in 1997. With a very clever new approach, Huisken and Ilmanen discovered how to reformulate inverse mean curvature flow using an energy minimization principle in such a way that the new generalized inverse mean curvature flow always exists. The added twist is that the surface sometimes jumps outward. However, when the flow is smooth, it equals the original inverse mean curvature flow, and the Hawking mass is still monotone. Hence, as will be described in the next section, their new flow produced the first complete proof of inequality [3] for a single black hole.

Coincidentally, the author found another proof of inequality [3], submitted in 1999, which works for any number of black holes. The approach involves flowing the original metric to a Schwarzschild metric (outside the horizon) in such a way that the area of the outermost minimal surface does not change and the

total mass is nonincreasing. Then, since the Schwarzschild metric gives equality in inequality [3], the inequality follows for the original metric.

Fortunately, the flow of metrics which is defined is relatively simple, and in fact stays inside the conformal class of the original metric. The outermost minimal surface flows outwards in this conformal flow of metrics, and encloses any compact set (and hence all of the topology of the original metric) in a finite amount of time. Furthermore, this conformal flow of metrics preserves nonnegative scalar curvature. We will describe this approach later in the paper.

Other contributions on the Penrose conjecture have also been made by Herzlich using the Dirac operator which Witten used to prove the positive mass theorem, by Gibbons in the special case of collapsing shells, by Tod, by Bartnik for quasi-spherical metrics, and by the present author using isoperimetric surfaces. There is also some interesting work of Ludvigsen and Vickers using spinors and Bergqvist, both concerning the Penrose inequality for null slices of a spacetime.

## Inverse Mean Curvature Flow

Geometrically, Huisken and Ilmanen's idea can be described as follows. Let $\Sigma(t)$ be the surface resulting from inverse mean curvature flow for time $t$ beginning with the minimal surface $\Sigma_0$. Define $\bar{\Sigma}(t)$ to be the outermost minimal area enclosure of $\Sigma(t)$. Typically, $\Sigma(t) = \bar{\Sigma}(t)$ in the flow, but in the case that the two surfaces are not equal, immediately replace $\Sigma(t)$ with $\bar{\Sigma}(t)$ and then continue flowing by inverse mean curvature.

An immediate consequence of this modified flow is that the mean curvature of $\bar{\Sigma}(t)$ is always non-negative by the first variation formula, since otherwise $\bar{\Sigma}(t)$ would be enclosed by a surface with less area. This is because if we flow a surface $\Sigma$ in the outward direction with speed $\eta$, the first variation of the area is $\int_\Sigma H\eta$, where $H$ is the mean curvature of $\Sigma$.

Furthermore, by stability, it follows that in the regions where $\bar{\Sigma}(t)$ has zero mean curvature, it is always possible to flow the surface out slightly to have positive mean curvature, allowing inverse mean curvature flow to be defined, at least heuristically at this point.

Furthermore, the Hawking mass is still monotone under this new modified flow. Notice that when $\Sigma(t)$ jumps outwards to $\bar{\Sigma}(t)$,

$$\int_{\bar{\Sigma}(t)} H^2 \leq \int_{\Sigma(t)} H^2$$

since $\bar{\Sigma}(t)$ has zero mean curvature where the two surfaces do not touch. Furthermore,

$$|\bar{\Sigma}(t)| = |\Sigma(t)|$$

since (this is a neat argument) $|\bar{\Sigma}(t)| \leq |\Sigma(t)|$ (since $\bar{\Sigma}(t)$ is a minimal area enclosure of $\Sigma(t)$) and we cannot have $|\bar{\Sigma}(t)| < |\Sigma(t)|$ since $\Sigma(t)$ would have jumped outwards at some earlier time. This is only a heuristic argument, but we can then see that the Hawking mass is nondecreasing during a jump by the above two equations.

This new flow can be rigorously defined, always exists, and the Hawking mass is monotone. Huisken and Ilmanen define $\Sigma(t)$ to be the level sets of a scalar valued function $u(x)$ defined on $(M^3, g)$ such that $u(x) = 0$ on the original surface $\Sigma_0$ and satisfies

$$\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) = |\nabla u| \qquad [6]$$

in an appropriate weak sense. Since the left-hand side of the above equation is the mean curvature of the level sets of $u(x)$ and the right-hand side is the reciprocal of the flow rate, the above equation implies inverse mean curvature flow for the level sets of $u(x)$ when $|\nabla u(x)| \neq 0$.

Huisken and Ilmanen use an energy minimization principle to define weak solutions to eqn [6]. Equation [6] is said to be weakly satisfied in $\Omega$ by the locally Lipschitz function $u$ if for all locally Lipschitz $v$ with $\{v \neq u\} \subset\subset \Omega$,

$$J_u(u) \leq J_u(v)$$

where

$$J_u(v) := \int_\Omega |\nabla v| + v|\nabla u|$$

It can then be seen that the Euler–Lagrange equation of the above energy functional yields eqn [6].

In order to prove that a solution $u$ exists to the above two equations, Huisken and Ilmanen regularize the degenerate elliptic equation 6 to the elliptic equation

$$\operatorname{div}\left(\frac{\nabla u}{\sqrt{|\nabla u|^2 + \epsilon^2}}\right) = \sqrt{|\nabla u|^2 + \epsilon^2}$$

Solutions to the above equation are then shown to exist using the existence of a subsolution, and then taking the limit as $\epsilon$ goes to zero yields a weak solution to eqn [6]. There are many details which we are skipping here, but these are the main ideas.

As it turns out, weak solutions $u(x)$ to eqn [6] often have flat regions where $u(x)$ equals a constant. Hence, the level sets $\Sigma(t)$ of $u(x)$ will be

discontinuous in $t$ in this case, which corresponds to the "jumping out" phenomenon referred to at the beginning of this section.

We also note that since the Hawking mass of the level sets of $u(x)$ is monotone, this inverse mean curvature flow technique not only proves the Riemannian Penrose inequality, but also gives a new proof of the positive mass theorem in dimension 3. This is seen by letting the initial surface be a very small, round sphere (which will have approximately zero Hawking mass) and then flowing by inverse mean curvature, thereby proving $m \geq 0$.

The Huisken and Ilmanen inverse mean curvature flow also seems ideally suited for proving Penrose inequalities for 3-manifolds which have $R \geq -6$ and which are asymptotically hyperbolic. This situation occurs if $(M^3, g)$ is chosen to be a constant mean curvature slice of the spacetime or if the spacetime is defined to solve the Einstein equation with nonzero cosmological constant. In these cases, there exists a modified Hawking mass which in monotone under inverse mean curvature flow which is the usual Hawking mass plus $4(|\Sigma|/16\pi)^{3/2}$. However, because the monotonicity of the Hawking mass relies on the Gauss–Bonnet theorem, these arguments do not work in higher dimensions, at least so far. Also, because of the need for eqn [4], inverse mean curvature flow only proves the Riemannian Penrose inequality for a single black hole. In the next section, we present a technique which proves the Riemannian Penrose inequality for any number of black holes, and which can likely be generalized to higher dimensions.

## The Conformal Flow of Metrics

Given any initial Riemannian manifold $(M^3, g_0)$ which has non-negative scalar curvature and which is harmonically flat at infinity, we will define a continuous, one-parameter family of metrics $(M^3, g_t)$, $0 \leq t < \infty$. This family of metrics will converge to a three-dimensional Schwarzschild metric and will have other special properties which will allow us to prove the Riemannian Penrose inequality for the original metric $(M^3, g_0)$.

In particular, let $\Sigma_0$ be the outermost minimal surface of $(M^3, g_0)$ with area $A_0$. Then, we will also define a family of surfaces $\Sigma(t)$ with $\Sigma(0) = \Sigma_0$ such that $\Sigma(t)$ is minimal in $(M^3, g_t)$. This is natural since as the metric $g_t$ changes, we expect that the location of the horizon $\Sigma(t)$ will also change. Then, the interesting quantities to keep track of in this flow are $A(t)$, the total area of the horizon $\Sigma(t)$ in $(M^3, g_t)$, and $m(t)$, the total mass of $(M^3, g_t)$ in the chosen end.

In addition to all of the metrics $g_t$ having non-negative scalar curvature, we will also have the very nice properties that

$$A'(t) = 0$$
$$m'(t) \leq 0$$

for all $t \geq 0$. Then, since $(M^3, g_t)$ converges to a Schwarzschild metric (in an appropriate sense) which gives equality in the Riemannian Penrose inequality as described in the introduction,

$$m(0) \geq m(\infty) = \sqrt{\frac{A(\infty)}{16\pi}} = \sqrt{\frac{A(0)}{16\pi}} \qquad [7]$$

which proves the Riemannian Penrose inequality for the original metric $(M^3, g_0)$. The hard part, then, is to find a flow of metrics which preserves non-negative scalar curvature and the area of the horizon, decreases total mass, and converges to a Schwarzschild metric as $t$ goes to infinity.

### The Definition of the Flow

In fact, the metrics $g_t$ will all be conformal to $g_0$. This conformal flow of metrics can be thought of as the solution to a first-order ODE in $t$ defined by eqns [8]–[11]. Let

$$g_t = u_t(x)^4 g_0 \qquad [8]$$

and $u_0(x) \equiv 1$. Given the metric $g_t$, define

$$\Sigma(t) = \text{the outermost minimal area enclosure of } \Sigma_0 \text{ in } (M^3, g_t) \qquad [9]$$

where $\Sigma_0$ is the original outer minimizing horizon in $(M^3, g_0)$. In the cases in which we are interested, $\Sigma(t)$ will not touch $\Sigma_0$, from which it follows that $\Sigma(t)$ is actually a strictly outer minimizing horizon of $(M^3, g_t)$. Then given the horizon $\Sigma(t)$, define $v_t(x)$ such that

$$\begin{cases} \Delta_{g_0} v_t(x) \equiv 0 & \text{outside } \Sigma(t) \\ v_t(x) = 0 & \text{on } \Sigma(t) \\ \lim_{x\to\infty} v_t(x) = -\mathrm{e}^{-t} & \end{cases} \qquad [10]$$

and $v_t(x) \equiv 0$ inside $\Sigma(t)$. Finally, given $v_t(x)$, define

$$u_t(x) = 1 + \int_0^t v_s(x)\,\mathrm{d}s \qquad [11]$$

so that $u_t(x)$ is continuous in $t$ and has $u_0(x) \equiv 1$.

Note that eqn [11] implies that the first-order rate of change of $u_t(x)$ is given by $v_t(x)$. Hence, the first-order rate of change of $g_t$ is a function of itself, $g_0$, and $v_t(x)$ which is a function of $g_0$, $t$, and $\Sigma(t)$ which is in turn a function of $g_t$ and $\Sigma_0$. Thus, the first-order rate of change of $g_t$ is a function of $t, g_t, g_0$, and $\Sigma_0$.

**Theorem 2** *Taken together, eqns [8]–[11] define a first-order ODE in t for $u_t(x)$ which has a solution which is Lipschitz in the t variable, $C^1$ in the x variable everywhere, and smooth in the x variable outside $\Sigma(t)$. Furthermore, $\Sigma(t)$ is a smooth, strictly outer minimizing horizon in $(M^3, g_t)$ for all $t \geq 0$, and $\Sigma(t_2)$ encloses but does not touch $\Sigma(t_1)$ for all $t_2 > t_1 \geq 0$.*

Since $v_t(x)$ is a superharmonic function in $(M^3, g_0)$ (harmonic everywhere except on $\Sigma(t)$, where it is weakly superharmonic), it follows that $u_t(x)$ is superharmonic as well. Thus, from eqn [11] we see that $\lim_{x\to\infty} u_t(x) = \mathrm{e}^{-t}$ and consequently that $u_t(x) > 0$ for all $t$ by the maximum principle. Then, since

$$R(g_t) = u_t(x)^{-5}(-8\Delta_{g_0} + R(g_0))u_t(x) \qquad [12]$$

it follows that $(M^3, g_t)$ is an asymptotically flat manifold with non-negative scalar curvature.

Even so, it still may not seem like $g_t$ is particularly naturally defined since the rate of change of $g_t$ appears to depend on $t$ and the original metric $g_0$ in eqn [10]. We would prefer a flow where the rate of change of $g_t$ can be defined purely as a function of $g_t$ (and $\Sigma_0$ perhaps), and interestingly enough this actually does turn out to be the case! The present author has proved this very important fact and defined a new equivalence class of metrics called the harmonic conformal class. Then, once we decide to find a flow of metrics which stays inside the harmonic conformal class of the original metric (outside the horizon) and keeps the area of the horizon $\Sigma(t)$ constant, then we are basically forced to choose the particular conformal flow of metrics defined above.

**Theorem 3** *The function $A(t)$ is constant in t and $m(t)$ is nonincreasing in t, for all $t \geq 0$.*

The fact that $A'(t) = 0$ follows from the fact that to first order the metric is not changing on $\Sigma(t)$ (since $v_t(x) = 0$ there) and from the fact that to first order the area of $\Sigma(t)$ does not change as it moves outward since $\Sigma(t)$ is a critical point for area in $(M^3, g_t)$. Hence, the interesting part of Theorem 3 is proving that $m'(t) \leq 0$. Curiously, this follows from a nice trick using the Riemannian positive mass theorem, which we describe later.

Another important aspect of this conformal flow of the metric is that outside the horizon $\Sigma(t)$, the manifold $(M^3, g_t)$ becomes more and more spherically symmetric and "approaches" a Schwarzschild manifold $(\boldsymbol{R}^3\backslash\{0\}, s)$ in the limit as $t$ goes to $\infty$. More precisely,

**Theorem 4** *For sufficiently large t, there exists a diffeomorphism $\phi_t$ between $(M^3, g_t)$ outside the horizon $\Sigma(t)$ and a fixed Schwarzschild manifold $(\boldsymbol{R}^3\backslash\{0\}, s)$ outside its horizon. Furthermore, for all $\epsilon > 0$, there exists a T such that for all $t > T$, the metrics $g_t$ and $\phi_t^*(s)$ (when determining the lengths of unit vectors of $(M^3, g_t)$) are within $\epsilon$ of each other and the total masses of the 2-manifolds are within $\epsilon$ of each other. Hence,*

$$\lim_{t\to\infty} \frac{m(t)}{\sqrt{A(t)}} = \sqrt{\frac{1}{16\pi}}$$

Theorem 4 is not that surprising really although a careful proof is reasonably long. However, if one is willing to believe that the flow of metrics converges to a spherically symmetric metric outside the horizon, then Theorem 4 follows from two facts. The first fact is that the scalar curvature of $(M^3, g_t)$ eventually becomes identically zero outside the horizon $\Sigma(t)$ (assuming $(M^3, g_0)$ is harmonically flat). This follows from the facts that $\Sigma(t)$ encloses any compact set in a finite amount of time, that harmonically flat manifolds have zero scalar curvature outside a compact set, that $u_t(x)$ is harmonic outside $\Sigma(t)$, and eqn [12]. The second fact is that the Schwarzschild metrics are the only complete, spherically symmetric 3-manifolds with zero scalar curvature (except for the flat metric on $R^3$).

The Riemannian Penrose inequality, inequality [3], then follows from eqn [7] using Theorems 2–4, for harmonically flat manifolds. Since asymptotically flat manifolds can be approximated arbitrarily well by harmonically flat manifolds while changing the relevant quantities arbitrarily little, the asymptotically flat case also follows. Finally, the case of equality of the Penrose inequality follows from a more careful analysis of these same arguments.

### Qualitative Discussion

Figures 3 and 4 are meant to help illustrate some of the properties of the conformal flow of the metric. Figure 3 is the original metric which has a strictly outer minimizing horizon $\Sigma_0$. As $t$ increases, $\Sigma(t)$ moves outwards, but never inwards. In Figure 4, we can observe one of the consequences of the fact that $A(t) = A_0$ is constant in $t$. Since the metric is not changing inside $\Sigma(t)$, all of the horizons $\Sigma(s)$, $0 \leq s \leq t$

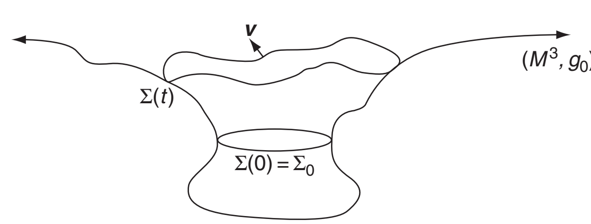

**Figure 3** Original metric having a strictly outer minimizing horizon $\Sigma_0$.

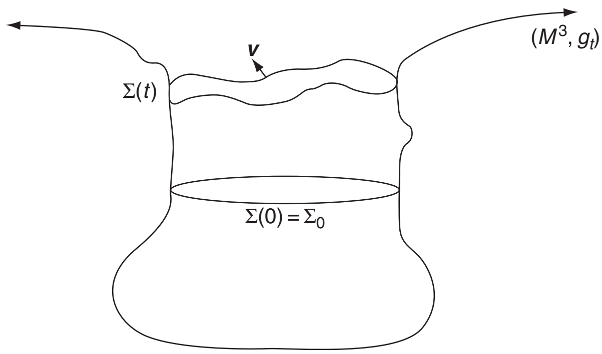

**Figure 4** Metric after time *t*.

have area $A_0$ in $(M^3, g_t)$. Hence, inside $\Sigma(t)$, the manifold $(M^3, g_t)$ becomes cylinder-like in the sense that it is laminated (i.e., foliated but with some gaps allowed) by all of the previous horizons which all have the same area $A_0$ with respect to the metric $g_t$.

Now let us suppose that the original horizon $\Sigma_0$ of $(M^3, g)$ had two components, for example. Then each of the components of the horizon will move outwards as $t$ increases, and at some point before they touch they will suddenly jump outwards to form a horizon with a single component enclosing the previous horizon with two components. Even horizons with only one component will sometimes jump outwards, but no more than a countable number of times. It is interesting that this phenomenon of surfaces jumping is also found in the Huisken–Ilmanen approach to the Penrose conjecture using their generalized $1/H$ flow.

### Proof that $m'(t) \leq 0$

The most surprising aspect of the flow defined earlier is that $m'(t) \leq 0$. As mentioned in that section, this important fact follows from a nice trick using the Riemannian positive mass theorem.

The first step is to realize that while the rate of change of $g_t$ appears to depend on $t$ and $g_0$, this is in fact an illusion. As described in detail by Bray, the rate of change of $g_t$ can be described purely in terms of $g_t$ (and $\Sigma_0$). It is also true that the rate of change of $g_t$ depends only on $g_t$ and $\Sigma(t)$. Hence, there is no special value of $t$, so proving $m'(t) \leq 0$ is equivalent to proving $m'(0) \leq 0$. Thus, without loss of generality, we take $t = 0$ for convenience.

Now expand the harmonic function $v_0(x)$, defined in eqn [10], using spherical harmonics at infinity, to get

$$v_0(x) = -1 + \frac{c}{|x|} + \mathcal{O}\left(\frac{1}{|x|^2}\right) \qquad [13]$$

for some constant $c$. Since the rate of change of the metric $g_t$ at $t = 0$ is given by $v_0(x)$ and since the total mass $m(t)$ depends on the $1/r$ rate at which the metric $g_t$ becomes flat at infinity (see eqn [2]), it is not surprising that direct calculation gives us that

$$m'(0) = 2(c - m(0))$$

Hence, to show that $m'(0) \leq 0$, we need to show that

$$c \leq m(0) \qquad [14]$$

In fact, counterexamples to eqn [14] can be found if we remove either of the requirements that $\Sigma(0)$ (which is used in the definition of $v_0(x)$) be a minimal surface or that $(M^3, g_0)$ have non-negative scalar curvature. Hence, we quickly see that eqn [14] is a fairly deep conjecture which says something quite interesting about manifold with non-negative scalar curvature. Well, the Riemannian positive mass theorem is also a deep conjecture which says something quite interesting about manifolds with non-negative scalar curvature. Hence, it is natural to try to use the Riemannian positive mass theorem to prove eqn [14].

Thus, we want to create a manifold whose total mass depends on $c$ from eqn [13]. The idea is to use a reflection trick similar to one used by Bunting and Masood-ul-Alam (1987) for another purpose. First, remove the region of $M^3$ inside $\Sigma(0)$ and then reflect the remainder of $(M^3, g_0)$ through $\Sigma(0)$. Define the resulting Riemannian manifold to be $(\bar{M}^3, \bar{g}_0)$ which has two asymptotically flat ends since $(M^3, g_0)$ has exactly one asymptotically flat end not contained by $\Sigma(0)$. Note that $(\bar{M}^3, \bar{g}_0)$ has non-negative scalar curvature everywhere except on $\Sigma(0)$ where the metric has corners. In fact, the fact that $\Sigma(0)$ has zero mean curvature (since it is a minimal surface) implies that $(\bar{M}^3, \bar{g}_0)$ has "distributional" non-negative scalar curvature everywhere, even on $\Sigma(0)$. This notion is made rigorous by Bray. Thus, we have used the fact that $\Sigma(0)$ is minimal in a critical way.

Recall from eqn [10] that $v_0(x)$ was defined to be the harmonic function equal to zero on $\Sigma(0)$ which goes to –1 at infinity. We want to reflect $v_0(x)$ to be defined on all of $(\bar{M}^3, \bar{g}_0)$. The trick here is to define $v_0(x)$ on $(\bar{M}^3, \bar{g}_0)$ to be the harmonic function which goes to –1 at infinity in the original end and goes to 1 at infinity in the reflect end. By symmetry, $v_0(x)$ equals 0 on $\Sigma(0)$ and so agrees with its original definition on $(M^3, g_0)$.

The next step is to compactify one end of $(\bar{M}^3, \bar{g}_0)$. By the maximum principle, we know that $v_0(x) > -1$ and $c > 0$, so the new Riemannian manifold $(\bar{M}^3, (v_0(x) + 1)^4 \bar{g}_0)$ does the job quite nicely and compactifies the original end to a point. In fact, the compactified point at infinity and the metric there

can be filled in smoothly (using the fact that $(M^3, g_0)$ is harmonically flat). It then follows from eqn [12] that this new compactified manifold has non-negative scalar curvature since $v_0(x) + 1$ is harmonic.

The last step is simply to apply the Riemannian positive mass theorem to $(\bar{M}^3, (v_0(x) + 1)^4 \bar{g}_0)$. It is not surprising that the total mass $\tilde{m}(0)$ of this manifold involves $c$, but it is quite lucky that direct calculation yields

$$\tilde{m}(0) = -4(c - m(0))$$

which must be positive by the Riemannian positive mass theorem. Thus, we have that

$$m'(0) = 2(c - m(0)) = -\tfrac{1}{2}\tilde{m}(0) \leq 0$$

## Open Questions and Applications

Now that the Riemannian Penrose conjecture has been proved, what are the next interesting directions? What applications can be found? Is this subject only of physical interest, or are there possibly broader applications to other problems in mathematics?

Clearly, the most natural open problem is to find a way to prove the general Penrose inequality in which $M^3$ is allowed to have any second fundamental form in the spacetime. There is good reason to think that this may follow from the Riemannian Penrose inequality, although this is a bit delicate. On the other hand, the general positive mass theorem followed from the Riemannian positive mass theorem as was originally shown by Schoen and Yau using an idea due to Jang. For physicists, this problem is definitely a top priority since most spacetimes do not even admit zero-second fundamental form spacelike slices.

Another interesting question is to ask these same questions in higher dimensions. The author is currently working on a paper to prove the Riemannian Penrose inequality in dimensions $<8$. Dimension 8 and higher are harder because of the surprising fact that minimal hypersurfaces (and hence apparent horizons of black holes) can have codimension 7 singularities (points where the hypersurface is not smooth). This curious technicality is also the reason that the positive mass conjecture is still open in dimensions 8 and higher for manifolds which are not spin.

Naturally, it is harder to tell what the applications of these techniques might be to other problems, but already there have been some. One application is to the famous Yamabe problem: given a compact 3-manifold $M^3$, define $E(g) = \int_{M^3} R_g \, dV_g$ where $g$ is scaled so that the total volume of $(M^3, g)$ is 1, $R_g$ is the scalar curvature at each point, and $dV_g$ is the volume form. An idea due to Yamabe was to try to construct canonical metrics on $M^3$ by finding critical points of this energy functional on the space of metrics. Define $C(g)$ to be the infimum of $E(\bar{g})$ over all metrics $\bar{g}$ conformal to $g$. Then the (topological) Yamabe invariant of $M^3$, denoted here as $Y(M^3)$, is defined to be the supremum of $C(g)$ over all metrics $g$. $Y(S^3) = 6 \cdot (2\pi^2)^{2/3} \equiv Y_1$ is known to be the largest possible value for Yamabe invariants of 3-manifolds. It is also known that $Y(T^3) = 0$ and $Y(S^2 \times S^1) = Y_1 = Y(S^2 \tilde{\times} S^1)$, where $S^2 \tilde{\times} S^1$ is the nonorientable $S^2$ bundle over $S^1$.

The author, working with Andre Neves on a problem suggested by Richard Schoen, recently was able to compute the Yamabe invariant of $RP^3$ using inverse mean curvature flow techniques and found that $Y(RP^3) = Y_1/2^{2/3} \equiv Y_2$. A corollary is $Y(RP^2 \times S^1) = Y_2$ as well. These techniques also yield the surprisingly strong result that the only prime 3-manifolds with Yamabe invariant larger than $RP^3$ are $S^3, S^2 \times S^1$, and $S^2 \tilde{\times} S^1$. The Poincare conjecture for 3-manifolds with Yamabe invariant greater than $RP^3$ is therefore a corollary. Furthermore, the problem of classifying 3-manifolds is known to reduce to the problem of classifying prime 3-manifolds. The Yamabe approach then would be to make a list of prime 3-manifolds ordered by Y. The first five prime 3-manifolds on this list are therefore $S^3, S^2 \times S^1, S^2 \tilde{\times} S^1, RP^3$, and $RP^2 \times S^1$.

# Geometric Measure Theory

**G Alberti**, Università di Pisa, Pisa, Italy

## Introduction

The aim of these pages is to give a brief, self-contained introduction to that part of geometric measure theory which is more directly related to the calculus of variations, namely the theory of currents and its applications to the solution of Plateau problem. (The theory of finite-perimeter sets, which is closely related to currents and to the Plateau problem, is treated in the article Free Interfaces and Free Discontinuities: Variational Problems in the Encyclopedia.)

Named after the Belgian physicist J A F Plateau (1801–1883), this problem was originally formulated as follows: find the surface of minimal area spanning a given curve in the space. Nowadays, it is mostly intended in the sense of developing a mathematical framework where the existence of $k$-dimensional surfaces of minimal volume that span a prescribed boundary can be rigorously proved. Indeed, several solutions have been proposed in the last century, none of which is completely satisfactory.

One difficulty is that the infimum of the area among all smooth surfaces with a certain boundary may not be attained. More precisely, it may happen that all minimizing sequences (i.e., sequences of smooth surfaces whose area approaches the infimum) converge to a singular surface. Therefore, one is forced to consider a larger class of admissible surfaces than just smooth ones (in fact, one might want to do this also for modeling reasons – this is indeed the case with soap films, soap bubbles, and other capillarity problems). But what does it mean that a set "spans" a given curve? and what should we intend by area of a set which is not a smooth surface?

The theory of integral currents developed by Federer and Fleming (1960) provides a class of generalized (oriented) surfaces with well-defined notions of boundary and area (called mass) where the existence of minimizers can be proved by direct methods. More precisely, this class is large enough to have good compactness properties with respect to a topology that makes the mass a lower-semicontinuous functional. This approach turned out to be quite powerful and flexible, and in the last decades the theory of currents has found applications in several different areas, from dynamical systems (in particular, Mather theory) to the theory of foliations, to optimal transport problems.

## Hausdorff Measures, Dimension, and Rectifiability

The volume of a smooth $d$-dimensional surface in $\mathbb{R}^n$ is usually defined using parametrizations by subsets of $\mathbb{R}^d$. The notion of Hausdorff measure allows to compute the $d$-dimensional volume using coverings instead of parametrizations, and, what is more important, applies to all sets in $\mathbb{R}^n$, and makes sense even if $d$ is not an integer. Attached to Hausdorff measure is the notion of Hausdorff dimension. Again, it can be defined for all sets in $\mathbb{R}^n$ and is not necessarily an integer. The last fundamental notion is rectifiability: $k$-rectifiable sets can be roughly understood as the largest class of $k$-dimensional sets for which it is still possible to define a $k$-dimensional tangent bundle, even if only in a very weak sense. They are essential to the construction of integral currents.

### Hausdorff Measure

Let $d \geq 0$ be a positive real number. Given a set $E$ in $\mathbb{R}^n$, for every $\delta > 0$ we set

$$\mathscr{H}^d_\delta(E) := \frac{\omega_d}{2^d} \inf \left\{ \sum_j (\operatorname{diam}(E_j))^d \right\} \qquad [1]$$

where $\omega_d$ is the $d$-dimensional volume of the unit ball in $\mathbb{R}^d$ whenever $d$ is an integer (there is no canonical choice for $\omega_d$ when $d$ is not an integer; a convenient one is $\omega_d = 2^d$), and the infimum is taken over all countable families of sets $\{E_j\}$ that cover $E$ and whose diameters satisfy $\operatorname{diam}(E_j) \leq \delta$. The $d$-dimensional Hausdorff measure of $E$ is

$$\mathscr{H}^d(E) := \lim_{\delta \to 0} \mathscr{H}^d_\delta(E) \qquad [2]$$

(the limit exists because $\mathscr{H}^d_\delta(E)$ is decreasing in $\delta$).

#### Remarks

(i) $\mathscr{H}^d$ is called $d$-dimensional because of its scaling behavior: if $E_\lambda$ is a copy of $E$ scaled homothetically by a factor $\lambda$, then

$$\mathscr{H}^d(E_\lambda) = \lambda^d \mathscr{H}^d(E)$$

Thus, $\mathscr{H}^1$ scales like the length, $\mathscr{H}^2$ scales like the area, and so on.

(ii) The measure $\mathscr{H}^d$ is clearly invariant under rigid motions (translations and rotations). This implies that $\mathscr{H}^d$ agrees on $\mathbb{R}^d$ with the Lebesgue measure up to some constant factor; the renormalization constant $\omega_d/2^d$ in [1] makes this factor equal to 1. Thus, $\mathscr{H}^d(E)$ agrees with the usual $d$-dimensional volume for every set $E$ in $\mathbb{R}^d$, and the area formula shows that the same is true if $E$ is (a subset of) a $d$-dimensional surface of class $C^1$ in $\mathbb{R}^n$.

(iii) Besides the Hausdorff measure, there are several other, less popular notions of $d$-dimensional measure: all of them are invariant under rigid motion, scale in the expected way, and agree with $\mathscr{H}^d$ for sets contained in $\mathbb{R}^d$ or in a $d$-dimensional surface of class $C^1$, and yet they differ for other sets (for further details, see Federer (1996, section 2.10)).

(iv) The definition of $\mathscr{H}^d(E)$ uses only the notion of diameter, and therefore makes sense when $E$ is a subset of an arbitrary metric space. Note that $\mathscr{H}^d(E)$ depends only on the restriction of the metric to $E$, and not on the ambient space.

(v) The measure $\mathscr{H}^d$ is countably additive on the $\sigma$-algebra of Borel sets in $\mathbb{R}^n$, but not on all sets; to avoid pathological situations, we shall always assume that sets and maps are Borel measurable.

### Hausdorff Dimension

According to intuition, the length of a surface should be infinite, while the area of a curve should be null. These are indeed particular cases of the following implications:

$$\mathscr{H}^d(E) > 0 \;\Rightarrow\; \mathscr{H}^{d'}(E) = \infty \quad \text{for } d' < d$$
$$\mathscr{H}^d(E) < \infty \;\Rightarrow\; \mathscr{H}^{d'}(E) = 0 \quad \text{for } d' > d$$

Hence, the infimum of all $d$ such that $\mathscr{H}^d(E) = 0$ and the supremum of all $d$ such that $\mathscr{H}^d(E) = \infty$ coincide. This number is called Hausdorff dimension of $E$, and denoted by $\dim_{\mathrm{H}}(E)$. For surface of class $C^1$, the notion of Hausdorff dimension agrees with the usual one. Example of sets with nonintegral dimension are described in the next subsection.

#### Remarks

(i) Note that $\mathscr{H}^d(E)$ may be 0 or $\infty$ even for $d = \dim_{\mathrm{H}}(E)$.

(ii) The Hausdorff dimension of a set $E$ is strictly related to the metric on $E$, and not just to the topology. Indeed, it is preserved under diffeomorphisms but not under homeomorphisms, and it does not always agree with the topological dimension. For instance, the Hausdorff dimension of the graph of a continuous function $f: \mathbb{R} \to \mathbb{R}$ can be any number between 1 and 2 (included).

(iii) For nonsmooth sets, the Hausdorff dimension does not always conform to intuition: for example, the dimension of a Cartesian product $E \times F$ of compact sets does not agree in general with the sum of the dimensions of $E$ and $F$.

(iv) There are many other notions of dimension besides Hausdorff and topological ones. Among these, packing dimension and box-counting dimension have interesting applications (see Falconer (2003, chapters 3 and 4)).

### Self-Similar Fractals

Interesting examples of sets with nonintegral dimension are self-similar fractals. We present here a simplified version of a construction due to Hutchinson (Falconer 2003, chapter 9). Let $\{\Psi_i\}$ be a finite set of similitudes of $\mathbb{R}^n$ with scaling factor $\lambda_i < 1$, and assume that there exists a bounded open set $V$ such that the sets $V_i := \Psi_i(V)$ are pairwise disjoint and contained in $V$. The self-similar fractal associated with the system $\{\Psi_i\}$ is the compact set $C$ that satisfies

$$C = \bigcup_i \Psi_i(C) \qquad [3]$$

The term "self-similar" follows by the fact that $C$ can be written as a union of scaled copies of itself.

The existence (and uniqueness) of such a $C$ follows from a standard fixed-point argument applied to the map $C \mapsto \bigcup \Psi_i(C)$. The dimension $d$ of $C$ is the unique solution of the equation

$$\sum_i \lambda_i^d = 1 \qquad [4]$$

Formula [4] can be easily justified: if the sets $\Psi_i(C)$ are disjoint – and the assumption on $V$ implies that this almost the case – then [3] implies $\mathscr{H}^d(C) = \Sigma \mathscr{H}^d(\Psi_i(C)) = \Sigma \lambda_i^d \mathscr{H}^d(C)$, and therefore $\mathscr{H}^d(C)$ can be positive and finite if and only if $d$ satisfies [4].

An example of this construction is the usual Cantor set in $\mathbb{R}$, which is given by the similitudes

$$\Psi_1(x) := \tfrac{1}{3}x \text{ and } \Psi_2(x) := \tfrac{2}{3} + \tfrac{1}{3}x$$

By [4], its dimension is $d = \log 2/\log 3$. Other examples are described in **Figures 1–3**.

### Rectifiable Sets

Given an integer $k = 1, \ldots, n$, we say that a set $E$ in $\mathbb{R}^n$ is $k$-rectifiable if it can be covered by a countable family of sets $\{S_j\}$ such that $S_0$ is $\mathscr{H}^k$-negligible (i.e., $\mathscr{H}^k(S_0) = 0$) and $S_j$ is a $k$-dimensional surface of class $C^1$ for $j = 1, 2, \ldots$ Note that $\dim_H(E) \le k$ because each $S_j$ has dimension $k$.

A $k$-rectifiable set $E$ bears little resemblance to smooth surfaces (it can be everywhere dense!), but it still admits a suitably weak notion of tangent bundle.

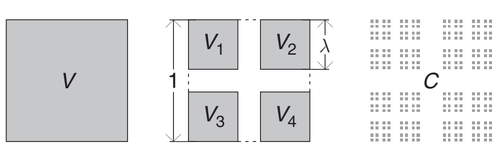

**Figure 1** The maps $\Psi_i, i = 1, \ldots, 4$, take the square $V$ into the squares $V_i$ at the corners of $V$. The scaling factor is $\lambda$ for all $i$, hence $\dim_H(C) = \log 4/(-\log \lambda)$. Note that $\dim_H(C)$ can be any number between 0 and 2, including 1.

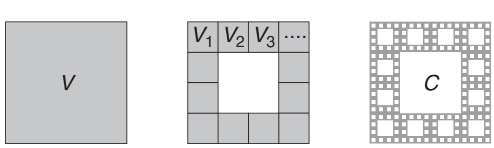

**Figure 2** A self-similar fractal with more complicated topology. The scaling factor is 1/4 for all twelve similitudes, hence $\dim_H(C) = \log 12/\log 4$.

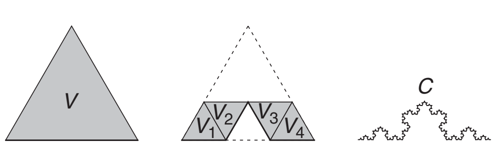

**Figure 3** The von Koch curve (or snowflake). The scaling factor is 1/3 for all four similitudes, hence $\dim_H(C) = \log 4/\log 3$.

More precisely, it is possible to associate with every $x \in E$ a $k$-dimensional subspace of $\mathbb{R}^n$, denoted by $\mathrm{Tan}(E, x)$, so that for every $k$-dimensional surface $S$ of class $C^1$ in $\mathbb{R}^n$ there holds

$$\mathrm{Tan}(E, x) = \mathrm{Tan}(S, x) \quad \text{for } \mathscr{H}^k\text{-a.e. } x \in E \cap S \qquad [5]$$

where $\mathrm{Tan}(S, x)$ is the tangent space to $S$ at $x$ according to the usual definition.

It is not difficult to see that $\mathrm{Tan}(E, x)$ is uniquely determined by [5] up to an $\mathscr{H}^k$-negligible amount of points $x \in E$, and if $E$ is a surface of class $C^1$, then it agrees with the usual tangent space for $\mathscr{H}^k$-almost all points of $E$.

**Remarks**

(i) In the original definition of rectifiability, the sets $S_j$ with $j > 0$ are Lipschitz images of $\mathbb{R}^k$, that is, $S_j := f_j(\mathbb{R}^k)$, where $f_j : \mathbb{R}^k \to \mathbb{R}^n$ is a Lipschitz map. It can be shown that this definition is equivalent to the one above.

(ii) The construction of the tangent bundle is straightforward: Let $\{S_j\}$ be a covering of $E$ as earlier, and set $\mathrm{Tan}(E, x) := \mathrm{Tan}(S_j, x)$, where $j$ is the smallest positive integer such that $x \in S_j$. Then [5] is an immediate corollary of the following lemma: if $S$ and $S'$ are $k$-dimensional surfaces of class $C^1$ in $\mathbb{R}^n$, then $\mathrm{Tan}(S, x) = \mathrm{Tan}(S', x)$ for $\mathscr{H}^k$-almost every $x \in S \cap S'$.

(iii) A set $E$ in $\mathbb{R}^n$ is called purely $k$-unrectifiable if it contains no $k$-rectifiable subset with positive $k$-dimensional measure, or, equivalently, if $\mathscr{H}^k(E \cap S) = 0$ for every $k$-dimensional surface $S$ of class $C^1$. For instance, every product $E := E_1 \times E_2$, where $E_1$ and $E_2$ are $\mathscr{H}^1$-negligible sets in $\mathbb{R}$ is a purely 1-unrectifiable set in $\mathbb{R}^2$ (it suffices to show that $\mathscr{H}^1(E \cap S) = 0$ whenever $S$ is the graph of a function $f : \mathbb{R} \to \mathbb{R}$ of class $C^1$, and this follows by the usual formula for the length of the graph). Note that the Hausdorff dimension of such product sets can be any number between 0 and 2, hence rectifiability is not related to dimension. The self-similar fractals described in **Figures 1 and 3** are both purely 1-unrectifiable.

### Rectifiable Sets with Finite Measure

If $E$ is a $k$-rectifiable set with finite (or locally finite) $k$-dimensional measure, then $\mathrm{Tan}(E, x)$ can be related to the behavior of $E$ close to the point $x$.

Let $B(x, r)$ be the open ball in $\mathbb{R}^n$ with center $x$ and radius $r$, and let $C(x, T, a)$ be the cone with center $x$, axis $T$ – a $k$-dimensional subspace of $\mathbb{R}^n$ – and amplitude $\alpha = \arcsin a$, that is,

$$C(x, T, a) := \{x' \in \mathbb{R}^n\colon\ \mathrm{dist}(x' - x, T) \le a|x' - x|\}$$

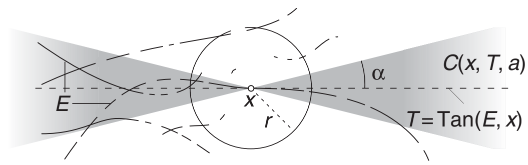

**Figure 4** A rectifiable set $E$ close to a point $x$ of approximate tangency. The part of $E$ contained in the ball $B(x, r)$ but not in the cone $C(x, T, a)$ is not empty, but only small in measure.

For $\mathscr{H}^k$-almost every $x \in E$, the measure of $E \cap B(x, r)$ is asymptotically equivalent, as $r \to 0$, to the measure of a flat disk of radius $r$, that is,

$$\mathscr{H}^k(E \cap B(x, r)) \sim \omega_k r^k$$

Moreover, the part of $E$ contained in $B(x, r)$ is mostly located close to the tangent plane $\mathrm{Tan}(E, x)$, that is,

$$\mathscr{H}^k(E \cap B(x, r) \cap C(x, \mathrm{Tan}(E, x), a)) \sim \omega_k r^k \quad \text{for every } a > 0$$

When this condition holds, $\mathrm{Tan}(E, x)$ is called the approximate tangent space to $E$ at $x$ (see Figure 4).

### The Area Formula

The area formula allows to compute the measure $\mathscr{H}^k(\Phi(E))$ of the image of a set $E$ in $\mathbb{R}^k$ as the integral over $E$ of a suitably defined Jacobian determinant of $\Phi$. When $\Phi$ is injective and takes values in $\mathbb{R}^k$, we recover the usual change of variable formula for multiple integrals.

We consider first the linear case. If $L$ is a linear map from $\mathbb{R}^k$ to $\mathbb{R}^m$ with $m \geq k$, the volume ratio $\rho := \mathscr{H}^k(L(E))/\mathscr{H}^k(E)$ does not depend on $E$, and agrees with $|\det(PL)|$, where $P$ is any linear isometry from the image of $L$ into $\mathbb{R}^k$, and $\det(PL)$ is the determinant of the $k \times k$ matrix associated with $PL$. The volume ratio $\rho$ can be computed using one of the following identities:

$$\rho = \sqrt{\det(L^* L)} = \sqrt{\sum (\det M)^2} \qquad [6]$$

where $L^*$ is the adjoint of $L$ (thus, $L^* L$ is a linear map from $\mathbb{R}^k$ into $\mathbb{R}^k$), and the sum in the last term is taken over all $k \times k$ minors $M$ of the matrix associated with $L$.

Let $\Phi : \mathbb{R}^k \to \mathbb{R}^m$ be a map of class $C^1$ with $m \geq k$, and $E$ a set in $\mathbb{R}^k$. Then

$$\int_{\Phi(E)} \#(\Phi^{-1}(y) \cap E) \, \mathrm{d}\mathscr{H}^k(y) = \int_E J(x) \, \mathrm{d}\mathscr{H}^k(x) \qquad [7]$$

where $\#A$ stands for the number of elements of $A$, and the Jacobian $J$ is

$$J(x) := \sqrt{\det(\nabla\Phi(x)^* \nabla\Phi(x))} \qquad [8]$$

Note that the left-hand side of [7] is $\mathscr{H}^k(\Phi(E))$ when $\Phi$ is injective.

**Remark**

Formula [7] holds even if $E$ is a $k$-rectifiable set in $\mathbb{R}^n$. In this case, the gradient $\nabla\Phi(x)$ in [8] should be replaced by the tangential derivative of $\Phi$ at $x$ (viewed as a linear map from $\mathrm{Tan}(E, x)$ into $\mathbb{R}^m$). No version of formula [7] is available when $E$ is not rectifiable.

## Vectors, Covectors, and Differential Forms

In this section, we review some basic notions of multilinear algebra. We have chosen a definition of $k$-vectors and $k$-covectors in $\mathbb{R}^n$, and of the corresponding exterior products, which is quite convenient for computations, even though not as satisfactory from the formal viewpoint. The main drawback is that it depends on the choice of a standard basis of $\mathbb{R}^n$, and therefore cannot be used to define forms (and currents) when the ambient space is a general manifold.

### *k*-Vectors and Exterior Product

Let $\{e_1, \ldots, e_n\}$ be the standard basis of $\mathbb{R}^n$. Given an integer $k \leq n$, $I(n, k)$ is the set of all multi-indices $\boldsymbol{i} = (i_1, \ldots, i_k)$ with $1 \leq i_1 < i_2 < \cdots < i_k \leq n$, and for every $\boldsymbol{i} \in I(n, k)$ we introduce the expression

$$e_{\boldsymbol{i}} = e_{i_1} \wedge e_{i_2} \wedge \cdots \wedge e_{i_k}$$

A $k$-vector in $\mathbb{R}^n$ is any formal linear combination $\Sigma \alpha_{\boldsymbol{i}} e_{\boldsymbol{i}}$ with $\alpha_{\boldsymbol{i}} \in \mathbb{R}$ for every $\boldsymbol{i} \in I(n, k)$. The space of $k$-vectors is denoted by $\wedge_k(\mathbb{R}^n)$; in particular, $\wedge_1(\mathbb{R}^n) = \mathbb{R}^n$. For reasons of formal convenience, we set $\wedge_0(\mathbb{R}^n) := \mathbb{R}$ and $\wedge_k(\mathbb{R}^n) := \{0\}$ for $k > n$.

We denote by $|\cdot|$ the Euclidean norm on $\wedge_k(\mathbb{R}^n)$.

The exterior product $v \wedge w \in \wedge_{k+h}(\mathbb{R}^n)$ is defined for every $v \in \wedge_k(\mathbb{R}^n)$ and $w \in \wedge_h(\mathbb{R}^n)$, and is completely determined by the following properties: (1) associativity, (2) linearity in both arguments, and (3) $e_i \wedge e_j = -e_j \wedge e_i$ for every $i \neq j$ and $e_i \wedge e_i = 0$ for every $i$.

### Simple Vectors and Orientation

A simple $k$-vector is any $v$ in $\wedge_k(\mathbb{R}^n)$ that can be written as a product of 1-vectors, that is,

$$v = v_1 \wedge v_2 \wedge \cdots \wedge v_k$$

It can be shown that $v$ is null if and only if the vectors $\{v_i\}$ are linearly dependent. If $v$ is not null,

then it is uniquely determined by the following objects: (1) the $k$-dimensional space $M$ spanned by $\{v_i\}$; (2) the orientation of $M$ associated with the basis $\{v_i\}$; (3) the euclidean norm $|v|$. In particular, $M$ does not depend on the choice of the vectors $v_i$. Note that $|v|$ is equal to the $k$-dimensional volume of the parallelogram spanned by $\{v_i\}$.

Hence, the map $v \mapsto M$ is a one-to-one correspondence between the class of simple $k$-vectors with norm $|v| = 1$ and the Grassmann manifold of oriented k-dimensional subspaces of $\mathbb{R}^n$.

This remark paves the way to the following definition: if $S$ is a $k$-dimensional surface of class $C^1$ in $\mathbb{R}^n$, possibly with boundary, an orientation of $S$ is a continuous map $\tau_S : S \to \wedge_k(\mathbb{R}^n)$ such that $\tau_S(x)$ is a simple $k$-vector with norm 1 that spans $\mathrm{Tan}(S, x)$ for every $x$. With every orientation of $S$ (if any exists) is canonically associated the orientation of the boundary $\partial S$ that satisfies

$$\tau_S(x) = \eta(x) \wedge \tau_{\partial S}(x) \quad \text{for every } x \in \partial S \qquad [9]$$

where $\eta(x)$ is the inner normal to $\partial S$ at $x$.

### *k*-Covectors

The standard basis of the dual of $\mathbb{R}^n$ is $\{dx_1, \ldots, dx_n\}$, where $dx_i : \mathbb{R}^n \to \mathbb{R}$ is the linear functional that takes every $x = (x_1, \ldots, x_n)$ into the $i$th component $x_i$. For every $\boldsymbol{i} \in I(n, k)$ we set

$$dx_{\boldsymbol{i}} = dx_{i_1} \wedge dx_{i_2} \wedge \cdots \wedge dx_{i_k}$$

and the space $\wedge^k(\mathbb{R}^n)$ of $k$-covectors consists of all formal linear combinations $\Sigma \alpha_{\boldsymbol{i}} dx_{\boldsymbol{i}}$. The exterior product of covectors is defined as that for vectors. The space $\wedge^k(\mathbb{R}^n)$ is dual to $\wedge_k(\mathbb{R}^n)$ via the duality pairing $\langle\, ;\, \rangle$ defined by the relations $\langle dx_{\boldsymbol{i}}; e_{\boldsymbol{j}} \rangle := \delta_{\boldsymbol{ij}}$ (that is, 1 if $\boldsymbol{i} = \boldsymbol{j}$ and 0 otherwise).

### Differential Forms and Stokes Theorem

A differential form of order $k$ on $\mathbb{R}^n$ is a map $\omega : \mathbb{R}^n \to \wedge^k(\mathbb{R}^n)$. Using the canonical basis of $\wedge^k(\mathbb{R}^n)$, we can write $\omega$ as

$$\omega(x) = \sum_{\boldsymbol{i} \in I(n,k)} \omega_{\boldsymbol{i}}(x) dx_{\boldsymbol{i}}$$

where the coordinates $\omega_{\boldsymbol{i}}$ are real functions on $\mathbb{R}^n$. The exterior derivative of a $k$-form $\omega$ of class $C^1$ is the $(k+1)$-form

$$d\omega(x) := \sum_{\boldsymbol{i} \in I(n,k)} d\omega_{\boldsymbol{i}}(x) \wedge dx_{\boldsymbol{i}}$$

where, for every scalar function $f$, $df$ is the 1-form

$$df(x) := \sum_{i=1}^{n} \frac{\partial f}{\partial x_i}(x) dx_i$$

If $S$ is a $k$-dimensional oriented surface, the integral of a $k$-form $\omega$ on $S$ is naturally defined by

$$\int_S \omega := \int_S \langle \omega(x); \tau_S(x) \rangle \, \mathrm{d}\mathscr{H}^k(x)$$

Stokes theorem states that for every $(k-1)$-form $\omega$ of class $C^1$ there holds

$$\int_{\partial S} \omega = \int_S \mathrm{d}\omega \qquad [10]$$

provided that $\partial S$ is endowed with the orientation $\tau_{\partial S}$ that satisfies [9].

## Currents

The definition of $k$-dimensional currents closely resembles that of distributions: they are the dual of smooth $k$-forms with compact support. Since every oriented $k$-dimensional surface defines by integration a linear functional on forms, currents can be regarded as generalized oriented surfaces. As every distribution admits a derivative, so every current admits a boundary. Indeed, many other basic notions of homology theory can be naturally extended to currents – this was actually one of the motivations behind the introduction of currents, due to de Rham.

For the applications to variational problems, smaller classes of currents are usually considered; the most relevant to the Plateau problem is that of integral currents. Note that the definitions of the spaces of normal, rectifiable, and integral currents and the symbols used to denote them vary, sometimes more than slightly, depending on the author.

### Currents, Boundary, and Mass

Let $n, k$ be integers with $n \geq k$. The space of $k$-dimensional currents on $\mathbb{R}^n$, denoted by $\mathscr{D}_k(\mathbb{R}^n)$, is the dual of the space $\mathscr{D}^k(\mathbb{R}^n)$ of smooth $k$-forms with compact support in $\mathbb{R}^n$. For $k \geq 1$, the boundary of a $k$-current $T$ is the $(k-1)$-current $\partial T$ defined by

$$\langle \partial T; \omega \rangle := \langle T; \mathrm{d}\omega \rangle \quad \text{for every } \omega \in \mathscr{D}^{k-1}(\mathbb{R}^n) \qquad [11]$$

while the boundary of a 0-current is set equal to 0. The mass of $T$ is the number

$$\mathbb{M}(T) := \sup\Big\{ \langle T; \omega \rangle : \ \omega \in \mathscr{D}^k(\mathbb{R}^n), |\omega| \leq 1 \Big\} \qquad [12]$$

Fundamental examples of $k$-currents are oriented $k$-dimensional surfaces: with each oriented surface $S$ of class $C^1$ is canonically associated the current $\langle T; \mathrm{d}\omega \rangle := \int_S \omega$ (in fact, $S$ is completely determined by the action on forms, i.e., by the associated

current). By Stokes theorem, the boundary of $T$ is the current associated with the boundary of $S$; thus, the notion of boundary for currents is compatible with the classical one for oriented surfaces. A simple computation shows that $\mathbb{M}(T) = \mathscr{H}^k(S)$; therefore, the mass provides a natural extension of the notion of $k$-dimensional volume to $k$-currents.

### Remarks

(i) Not all $k$-currents look like $k$-dimensional surfaces. For example, every $k$-vectorfield $v : \mathbb{R}^n \to \wedge_k(\mathbb{R}^n)$ defines by duality the $k$-current

$$\langle T;\omega\rangle := \int \langle \omega(x); v(x)\rangle \,\mathrm{d}\mathscr{H}^n(x)$$

The mass of $T$ is $\int |v| \mathrm{d}\mathscr{H}^n$, and the boundary is represented by a similar integral formula involving the partial derivatives of $v$ (in particular, for 1-vectorfields, the boundary is the 0-current associated with the divergence of $v$). Note that the dimension of such $T$ is $k$ because $k$-vectorfields act on $k$-forms, and there is no relation with the dimension of the support of $T$, which is $n$.

(ii) To be precise, $\mathscr{D}^k(\mathbb{R}^n)$ is a locally convex topological vector space, and $\mathscr{D}_k(\mathbb{R}^n)$ is its topological dual. As such, $\mathscr{D}_k(\mathbb{R}^n)$ is endowed with a dual (or weak$^*$) topology. We say that a sequence of $k$-currents $(T_j)$ converge to $T$ if they converge in the dual topology, that is,

$$\langle T_j;\omega\rangle \to \langle T;\omega\rangle \quad \text{for every } \omega \in \mathscr{D}^k(\mathbb{R}^n) \qquad [13]$$

Recalling the definition of mass, it is easy to show that it is lower-semicontinuous with respect the dual topology, and in particular

$$\liminf \mathbb{M}(T_j) \geq \mathbb{M}(T) \qquad [14]$$

### Currents with Finite Mass

By definition, a $k$-current $T$ with finite mass is a linear functional on $k$-forms which is bounded with respect to the supremum norm, and by Riesz theorem it can be represented as a bounded measure with values in $\wedge_k(\mathbb{R}^n)$. In other words, there exist a finite positive measure $\mu$ on $\mathbb{R}^n$ and a density function $\tau : \mathbb{R}^n \to \wedge_k(\mathbb{R}^n)$ such that $|\tau(x)| = 1$ for every $x$ and

$$\langle T;\omega\rangle = \int \langle \omega(x); \tau(x)\rangle \,\mathrm{d}\mu(x)$$

The fact that currents are the dual of a separable space yields the following compactness result: a sequence of $k$-currents $(T_j)$ with uniformly bounded masses $\mathbb{M}(T_j)$ admits a subsequence that converges to a current with finite mass.

### Normal Currents

A $k$-current $T$ is called normal if both $T$ and $\partial T$ have finite mass. The compactness result stated in the previous paragraph implies the following compactness theorem for normal currents: a sequence of normal currents $(T_j)$ with $\mathbb{M}(T_j)$ and $\mathbb{M}(\partial T_j)$ uniformly bounded admits a subsequence that converges to a normal current.

### Rectifiable Currents

A $k$-current $T$ is called rectifiable if it can represented as

$$\langle T;\omega\rangle = \int_E \langle \omega(x); \tau(x)\rangle \theta(x) \,\mathrm{d}\mathscr{H}^k(x)$$

where $E$ is a $k$-rectifiable set $E$, $\tau$ is an orientation of $E$ – that is, $\tau(x)$ is a simple unit $k$-vector that spans $\mathrm{Tan}(E,x)$ for $\mathscr{H}^k$-almost every $x \in E$ – and $\theta$ is a real function such that $\int_E |\theta| \mathrm{d}\mathscr{H}^k$ is finite, called multiplicity. Such $T$ is denoted by $T = [E, \tau, \theta]$. In particular, a rectifiable 0-current can be written as $\langle T;\omega\rangle = \Sigma \theta_i \omega(x_i)$, where $E = \{x_i\}$ is a countable set in $\mathbb{R}^n$ and $\{\theta_i\}$ is a sequence of real numbers with $\Sigma|\theta_i| < +\infty$.

### Integral Currents

If $T$ is a rectifiable current and the multiplicity $\theta$ takes integral values, $T$ is called an integer multiplicity rectifiable current. If both $T$ and $\partial T$ are integer multiplicity rectifiable currents, then $T$ is an integral current.

The first nontrivial result is the boundary rectifiability theorem: if $T$ is an integer multiplicity rectifiable current and $\partial T$ has finite mass, then $\partial T$ is an integer multiplicity rectifiable current, too, and therefore $T$ is an integral current.

The second fundamental result is the compactness theorem for integral currents: a sequence of integral currents $(T_j)$ with $\mathbb{M}(T_j)$ and $\mathbb{M}(\partial T_j)$ uniformly bounded admits a subsequence that converges to an integral current.

### Remarks

(i) The point of the compactness theorem for integral currents is not the existence of a converging subsequence – that being already established by the compactness theorem for normal currents – but the fact that the limit is an integral current. In fact, this result is often referred to as a "closure theorem" rather than a "compactness theorem."

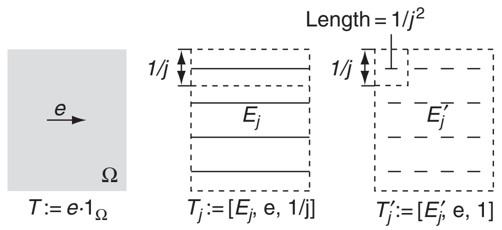

**Figure 5** $T$ is the normal 1-current on $\mathbb{R}^2$ associated with the vectorfield equal to the unit vector $e$ on the unit square $\Omega$, and equal to 0 outside. $T_j$ are the rectifiable currents associated with the sets $E_j$ (middle) and the constant multiplicity $1/j$, and then $\mathbb{M}(T_j) = 1, \mathbb{M}(\partial T_j) = 2$. $T'_j$ are the integral currents associated with the sets $E'_j$ (left) and the constant multiplicity 1, and then $\mathbb{M}(T'_j) = 1, \mathbb{M}(\partial T'_j) = 2j^2$. Both $(T_j)$ and $(T'_j)$ converge to $T$.

(ii) The following observations may clarify the role of assumptions in the compactness theorem: (1) a sequence of integral currents $(T_j)$ with $\mathbb{M}(T_j)$ uniformly bounded – but not $\mathbb{M}(\partial T_j)$ – may converge to any current with finite mass, not necessarily a rectifiable one.
(2) A sequence of rectifiable currents $(T_j)$ with rectifiable boundaries and $\mathbb{M}(T_j), \mathbb{M}(\partial T_j)$ uniformly bounded may converge to any normal current, not necessarily a rectifiable one. Examples of both situations are described in Figure 5.

### Application to the Plateau Problem

The compactness result for integral currents implies the existence of currents with minimal mass: if $\Gamma$ is the boundary of an integral $k$-current in $\mathbb{R}^n, 1 \le k \le n$, then there exists a current $T$ of minimal mass among those that satisfy $\partial T = \Gamma$.

The proof of this existence result is a typical example of the direct method: let $m$ be the infimum of $\mathbb{M}(T)$ among all integral currents with boundary $\Gamma$, and let $(T_j)$ be a minimizing sequence (i.e., a sequence of integral currents with boundary $\Gamma$ such that $\mathbb{M}(T_j)$ converges to $m$). Since $\mathbb{M}(T_j)$ is bounded and $\mathbb{M}(\partial T_j) = \mathbb{M}(\Gamma)$ is constant, we can apply the compactness theorem for integral currents and extract a subsequence of $(T_j)$ that converges to an integral current $T$. By the continuity of the boundary operator, $\partial T = \lim \partial T_j = \Gamma$, and by the semicontinuity of the mass $\mathbb{M}(T) \le \lim \mathbb{M}(T_j) = m$ (cf. [14]). Thus, $T$ is the desired minimal current.

### Remarks

(i) Every integral $(k-1)$-current $\Gamma$ with null boundary and compact support in $\mathbb{R}^n$ is the boundary of an integral current, and therefore is an admissible datum for the previous existence result.

(ii) A mass-minimizing integral current $T$ is more regular than a general integral current. For $k = n-1$, there exists a closed singular set $S$ with $\dim_{\mathrm{H}}(S) \le k-7$ such that $T$ agrees with a smooth surface in the complement of $S$ and of the support of the boundary. In particular, $T$ is smooth away from the boundary for $n \le 7$. For general $k$, it can only be proved that $\dim_{\mathrm{H}}(S) \le k-2$ Both results are optimal: in $\mathbb{R}^4 \times \mathbb{R}^4$, the minimal 7-current with boundary $\Gamma := \{|x| = |y| = 1\}$ – a product of two 3-spheres – is the cone $T := \{|x| = |y| \le 1\}$, and is singular at the origin. In $\mathbb{R}^2 \times \mathbb{R}^2$, the minimal 2-current with boundary $\Gamma := \{x = 0, |y| = 1\} \cup \{y = 0, |x| = 1\}$ – a union of two disjoint circles – is the union of the disks $\{x = 0, |y| \le 1\} \cup \{y = 0, |x| \le 1\}$, and is singular at the origin.

(iii) In certain cases, the mass-minimizing current $T$ may not agree with the solution of the Plateau problem suggested by intuition. The first reason is that currents do not include nonorientable surfaces, which sometimes may be more convenient (Figure 6). Another reason is that the mass of an integral current $T$ associated with a $k$-rectifiable set $E$ does not agree with the measure $\mathscr{H}^k(E)$ – called size of $T$ – because multiplicity must be taken into account, and for certain $\Gamma$ the mass-minimizing current may be not size-minimizing (Figure 7). Unfortunately, proving the existence of size-minimizing currents is much more complicated, due to lack of suitable compactness theorems.

(iv) For $k = 2$, the classical approach to the Plateau problem consists in parametrizing surfaces in $\mathbb{R}^n$ by maps $f$ from a given two-dimensional domain $D$ into $\mathbb{R}^n$, and looking for minimizers of the area functional

$$\int_D \sqrt{\det(\nabla f^* \nabla f)}$$

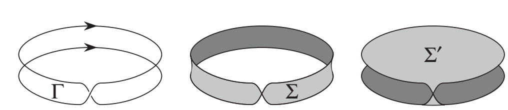

**Figure 6** The surface with minimal area spanning the (oriented) curve $\Gamma$ is the Möbius strip $\Sigma$. However, $\Sigma$ is not orientable, and cannot be viewed as a current. The mass-minimizing current with boundary $\Gamma$ is $\Sigma'$.

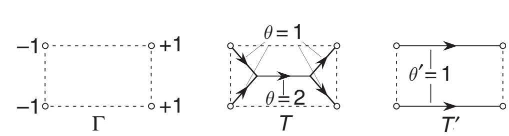

**Figure 7** The boundary $\Gamma$ is a 0-current associated with four oriented points. The size (length) of $T$ is smaller than that of $T'$. However, $\partial T = \Gamma$ implies that the multiplicity of $T$ must be 2 on the central segment and 1 on the others; thus the mass of $T$ is larger than its size. The size-minimizing current with boundary $\Gamma$ is $T$, while the mass-minimizing one is $T'$.

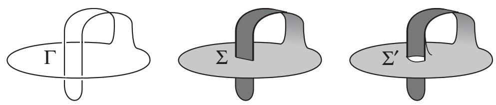

**Figure 8** The surface $\Sigma$ minimizes the area among surfaces parametrized by the disk with boundary $\Gamma$. The mass-minimizing current $\Sigma'$ can only be parametrized by a disk with a handle. Note that $\Sigma$ is a singular surface, while $\Sigma'$ is not.

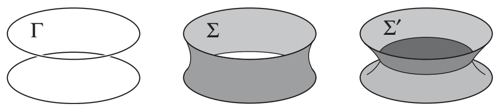

**Figure 9** Two possible soap films spanning the wire $\Gamma$: unlike $\Sigma$, $\Sigma'$ cannot be viewed as a current with multiplicity 1 and boundary $\Gamma$.

(recall the area formula, discussed earlier) under the constraint $f(\partial D) = \Gamma$. In this framework, the choice of the domain $D$ prescribes the topological type of admissible surfaces, and therefore the minimizer may differ substantially from the mass-minimizing current with boundary $\Gamma$ (Figure 8).

(v) For some modeling problems, for instance, those related to soap films and soap bubbles, currents do not provide the right framework (Figure 9). A possible alternative are integral varifolds (cf. Almgren 2001). However, it should be pointed out that this framework does not allow for "easy" application of the direct method, and the existence of minimal varifolds is in general quite difficult to prove.

### Miscellaneous Results and Useful Tools

(i) An important issue, related to the use of currents for solving variational problems, concerns the extent to which integral currents can be approximated by regular objects. For many reasons, the "right" regular class to consider are not smooth surfaces, but integral polyhedral currents, that is, linear combinations with integral coefficients of oriented simplexes. The following approximation theorem holds: for every integral current $T$ in $\mathbb{R}^n$ there exists a sequence of integral polyhedral currents $(T_j)$ such that

$$T_j \to T, \ \partial T_j \to \partial T$$
$$\mathbb{M}(T_j) \to \mathbb{M}(T), \mathbb{M}(\partial T_j) \to \mathbb{M}(\partial T)$$

The proof is based on a quite useful tool, called polyhedral deformation.

(ii) Many geometric operations for surfaces have an equivalent for currents. For instance, it is possible to define the image of a current in $\mathbb{R}^n$ via a smooth proper map $f: \mathbb{R}^n \to \mathbb{R}^m$. Indeed, with every $k$-form $\omega$ on $\mathbb{R}^m$ is canonically associated a $k$-form $f^{\#}\omega$ on $\mathbb{R}^n$, called pullback of $\omega$ according to $f$. The adjoint of the pullback is an operator, called push-forward, that takes every $k$-current $T$ in $\mathbb{R}^n$ into a $k$-current $f_{\#}T$ in $\mathbb{R}^m$. If $T$ is the rectifiable current associated with a rectifiable set $E$ and a multiplicity $\theta$, the push-forward $f_{\#}T$ is the rectifiable current associated with $f(E)$ – and a multiplicity $\theta'(y)$ which is computed by adding up with the right sign all $\theta(x)$ with $x \in f^{-1}(y)$. As one might expect, the boundary of the push-forward is the push-forward of the boundary.

(iii) In general, it is not possible to give a meaning to the intersection of two currents, and not even of a current and a smooth surface. However, it is possible to define the intersection of a normal $k$-current $T$ and a level surface $f^{-1}(y)$ of a smooth map $f: \mathbb{R}^n \to \mathbb{R}^h$ (with $k \le h \le n$) for almost every $y$, resulting in a current $T_y$ with the expected dimension $h - k$. This operation is called slicing.

(iv) When working with currents, a quite useful notion is that of flat norm:

$$\mathbb{F}(T) := \inf\{\mathbb{M}(R) + \mathbb{M}(S): \ T = R + \partial S\}$$

where $T$ and $R$ are $k$-currents, and $S$ is a $(k+1)$-current. The relevance of this notion lies in the fact that a sequence $(T_j)$ that converges with respect to the flat norm converges also in the dual topology, and the converse holds if the masses $\mathbb{M}(T_j)$ and $\mathbb{M}(\partial T_j)$ are uniformly bounded. Hence, the flat norm metrizes the dual topology of currents (at least on sets of currents where the mass and the mass of the boundary are bounded).

Since $\mathbb{F}(T)$ can be explicitly estimated from above, it can be quite useful in proving that a sequence of currents converges to a certain limit. Finally, the flat norm gives a (geometrically significant) measure of how far apart two currents are: for instance, given the 0-currents $\delta_x$ and $\delta_y$ (the Dirac masses at $x$ and $y$, respectively), then $\mathbb{F}(\delta_x - \delta_y)$ is exactly the distance between $x$ and $y$.

# Geometric Phases

**P Lévay**, Budapest University of Technology and Economics, Budapest, Hungary

## Introduction

We invite the reader to perform the following simple experiment. Put your arm out in front of you keeping your thumb pointing up perpendicular to your arm. Move your arm up over your head, then bring it down to your side, and at last bring the arm back in front of you again. In this experiment an object (your thumb) was taken along a closed path traced by another object (your arm) in a way that a simple local law of transport was applied. In this case the local law consisted of two ingredients: (1) preserve the orthogonality of your thumb with respect to your arm and (2) do not rotate the thumb about its instantaneous axis (i.e., your arm). Performing the experiment in this way, you will manage to avoid rotations of your thumb locally; however, in the end you will experience a rotation of $90^\circ$ globally.

The experiment above can be regarded as the archetypical example of the phenomenon called anholonomy by physicists and holonomy by mathematicians. In this article, we consider the manifestation of this phenomenon in the realm of quantum theory. The objects to be transported along closed paths in suitable manifolds will be wave functions representing quantum systems. After applying local laws dictated by inputs coming from physics, one ends up with a new wave function that has picked up a complex phase factor. Phases of this kind are called geometric phases, with the famous Berry phase being a special case.

## The Space of Rays

Let us consider a quantum system with physical states represented by elements $|\psi\rangle$ of some Hilbert space $\mathcal{H}$ with scalar product $\langle|\rangle:\mathcal{H}\times\mathcal{H}\to \mathbf{C}$. For simplicity, we assume that $\mathcal{H}$ is finite dimensional, $\mathcal{H}\simeq \mathbf{C}^{n+1}$ with $n\geq 1$. The infinite-dimensional case can be studied by taking the inductive limit $n\to\infty$. Let us denote the complex amplitudes characterizing the state $|\psi\rangle$ by $Z^\alpha, \alpha=0,1,\ldots,n$. For a normalized state,

$$\|\psi\|^2=\langle\psi|\psi\rangle\equiv\delta_{\alpha\beta}\bar{Z}^\alpha Z^\beta\equiv\bar{Z}_\alpha Z^\alpha=1 \qquad [1]$$

where summation over repeated indices is understood, indices raised and lowered by $\delta^{\alpha\beta}$ and $\delta_{\alpha\beta}$, respectively, and the overbar refers to complex conjugation. A normalized state lies on the unit sphere $\mathcal{S}\simeq S^{2n+1}$ in $\mathbf{C}^{n+1}$. Two nonzero states $|\psi\rangle$ and $|\varphi\rangle$ are equivalent, $|\psi\rangle\sim|\varphi\rangle$, iff they are related as $|\psi\rangle=\lambda|\varphi\rangle$ for some nonzero complex number $\lambda$. For equivalent states, physically meaningful quantities such as

$$\frac{\langle\psi|\boldsymbol{A}|\psi\rangle}{\langle\psi|\psi\rangle},\qquad \frac{|\langle\psi|\varphi\rangle|^2}{\|\psi\|^2\|\varphi\|^2} \qquad [2]$$

(mean value of a physical quantity represented by a Hermitian operator $A$, transition probability from a physical state represented by $|\psi\rangle$ to one represented by $|\varphi\rangle$) are invariant. Hence, the real space of states representing the physical states of a quantum system unambiguously is the set of equivalence classes $\mathcal{P}\equiv\mathcal{H}/\sim$. $\mathcal{P}$ is called the "space of rays." For $\mathcal{H}\simeq\mathbf{C}^{n+1}$, we have $\mathcal{P}\simeq \boldsymbol{CP}^n$, where $\boldsymbol{CP}^n$ is the $n$-dimensional complex projective space. For normalized states, $|\psi\rangle$ and $|\varphi\rangle$ are equivalent iff $|\psi\rangle=\lambda|\varphi\rangle$, where $|\lambda|=1$, that is, $\lambda\in \mathrm{U}(1)$. Thus, two normalized states are equivalent iff they differ merely in a complex phase. It is well known that $\mathcal{S}$ can be regarded as the total space of a principal bundle over $\mathcal{P}$ with structure group U(1). This means that we have the projection

$$\pi:|\psi\rangle\in\mathcal{S}\subset\mathcal{H}\to|\psi\rangle\langle\psi|\in\mathcal{P} \qquad [3]$$

where the rank-1 projector $|\psi\rangle\langle\psi|$ represents the equivalence class of $|\psi\rangle$. Since we will use this bundle frequently in this article, we call it $\eta_1$ (the meaning of the subscript 1 will be clarified later). Then, we have

$$\eta_1:\mathrm{U}(1)\hookrightarrow\mathcal{S}\xrightarrow{\pi}\mathcal{P} \qquad [4]$$

For $Z^0\neq 0$ the space of rays $\mathcal{P}$ can be given local coordinates

$$w^j\equiv Z^j/Z^0,\quad j=1,\ldots,n \qquad [5]$$

The $w^j$ are inhomogeneous coordinates for $\boldsymbol{CP}^n$ on the coordinate patch $\mathcal{U}_0$ defined by the condition $Z^0 \neq 0$.

$\mathcal{P}$ is a compact complex manifold with a natural Riemannian metric $g$. This metric $g$ is induced from the scalar product on $\mathcal{H}$. Let us consider the construction of $g$ by using the physical input provided by the invariance of the transition probability of [1]. For this we define a distance between $|\psi\rangle\langle\psi|$ and $|\varphi\rangle\langle\varphi|$ in $\mathcal{P}$ as follows:

$$\cos^2(\delta(\psi,\varphi)/2) \equiv \frac{|\langle\psi|\varphi\rangle|^2}{\|\psi\|^2\|\varphi\|^2} \qquad [6]$$

This definition makes sense since, due to the Cauchy–Schwartz inequality, the right-hand side of [6] is non-negative and $\leq 1$. It is equal to 1 iff $|\psi\rangle$ is a nonzero complex multiple of $|\varphi\rangle$, that is, iff they define the same point in $\mathcal{P}$. Hence in this case, $\delta(\psi,\varphi) = 0$ as expected.

Suppose now that $|\psi\rangle$ and $|\varphi\rangle$ are separated by an infinitesimal distance $\mathrm{d}s \equiv \delta(\psi,\varphi)$. Putting this into the definition [6], using the local coordinates $w^j$ of [5] for $|\psi\rangle$ and $w^j + \mathrm{d}w^j$ for $|\varphi\rangle$ after expanding both sides using Taylor series, one gets

$$\mathrm{d}s^2 = 4g_{j\bar{k}}\,\mathrm{d}w^j\,\mathrm{d}w^{\bar{k}}, \quad j,\bar{k} = 1,2,\ldots,n \qquad [7]$$

where

$$g_{j\bar{k}} \equiv \frac{(1+\bar{w}_l w^l)\delta_{jk} - \bar{w}_j w_k}{(1+\bar{w}_m w^m)^2} \qquad [8]$$

with $\mathrm{d}w^{\bar{k}} \equiv \mathrm{d}\bar{w}^k$. The line element [7] defines the Fubini–Study metric for $\mathcal{P}$.

## The Pancharatnam Connection

Having defined the basic entity, the space of rays $\mathcal{P}$, and the principal U(1) bundle $\eta_1$, now we define a connection giving rise to a local law of parallel transport. This approach gives rise to a very general definition of the geometric phase. In the mathematical literature, the connection defined below is called the "canonical connection" on the principal bundle. However, since the motivation is coming from physics, we are going to rediscover this construction using merely physical information provided by quantum theory alone.

The information needed is an adaptation of Pancharatnam's study of polarized light to quantum mechanics. Let us consider two normalized states $|\psi\rangle$ and $|\varphi\rangle$. When these states belong to the same ray, then we have $|\psi\rangle = \mathrm{e}^{\mathrm{i}\phi}|\varphi\rangle$ for some phase factor $\mathrm{e}^{\mathrm{i}\phi}$; hence, the phase difference between them can be defined to be just $\phi$. How to define the phase difference between $|\psi\rangle$ and $|\varphi\rangle$ (not orthogonal) when these states belong to different rays? To compare the phases of nonorthogonal states belonging to different rays, Pancharatnam employed the following simple rule: two states are "in phase" iff their interference is maximal. In order to find the state $|\varphi\rangle \equiv \mathrm{e}^{\mathrm{i}\phi}|\varphi'\rangle$ from the ray spanned by the representative $|\varphi'\rangle$ which is "in phase" with $|\psi\rangle$, we have to find a $\phi$ modulo $2\pi$ for which the interference term in

$$\|\psi + \mathrm{e}^{\mathrm{i}\phi}\varphi'\|^2 = 2(1 + \mathrm{Re}(\mathrm{e}^{\mathrm{i}\phi}\langle\psi|\varphi'\rangle)) \qquad [9]$$

is maximal. Obviously the interference is maximal iff $\mathrm{e}^{\mathrm{i}\phi}\langle\psi|\varphi'\rangle$ is a real positive number, that is,

$$\mathrm{e}^{\mathrm{i}\phi} = \frac{\langle\varphi'|\psi\rangle}{|\langle\varphi'|\psi\rangle|}, \quad |\varphi\rangle = |\varphi'\rangle\frac{\langle\varphi'|\psi\rangle}{|\langle\varphi'|\psi\rangle|} \qquad [10]$$

Hence for the state $|\varphi\rangle$ "in phase" with $|\psi\rangle$, one has

$$\langle\psi|\varphi\rangle = |\langle\psi|\varphi'\rangle| \in \boldsymbol{R}^+ \qquad [11]$$

When such $|\psi\rangle$ and $|\varphi\rangle \equiv |\psi + \mathrm{d}\psi\rangle$ are infinitesimally separated, from [11] it follows that

$$\mathrm{Im}\langle\psi|\mathrm{d}\psi\rangle = \frac{1}{2\mathrm{i}}\left(\bar{Z}_\alpha\,\mathrm{d}Z^\alpha - \mathrm{d}\bar{Z}_\alpha Z^\alpha\right) = 0 \qquad [12]$$

where $\bar{Z}_\alpha Z^\alpha = \bar{Z}_0 Z^0(1+\bar{w}_j w^j) = 1$ due to normalization. Writing $Z^0 \equiv |Z^0|\mathrm{e}^{\mathrm{i}\Phi}$ using [5], one obtains

$$\mathrm{Im}\langle\psi|\mathrm{d}\psi\rangle = \mathrm{d}\Phi + A = 0, \quad A \equiv \mathrm{Im}\frac{\bar{w}_j\mathrm{d}w^j}{1+\bar{w}_k w^k} \qquad [13]$$

In order to clarify the meaning of the 1-form $A$, notice that the choice

$$|\psi'\rangle \equiv \frac{1}{\sqrt{1+\bar{w}_k w^k}}\begin{pmatrix}1\\ w^j\end{pmatrix} \qquad [14]$$

defines a local section of the bundle $\eta_1$. In terms of this section, the state $|\psi\rangle$ can be expressed as

$$|\psi\rangle = \begin{pmatrix}Z^0\\ Z^j\end{pmatrix} = |Z^0|\mathrm{e}^{\mathrm{i}\Phi}\begin{pmatrix}1\\ w^j\end{pmatrix} = \mathrm{e}^{\mathrm{i}\Phi}|\psi'\rangle \qquad [15]$$

For a path $w^j(t)$ lying entirely in $\mathcal{U}_0 \subset \mathcal{P}$, $|\psi(t)\rangle = \mathrm{e}^{\mathrm{i}\Phi(t)}|\psi'(t)\rangle$ defines a path in $\mathcal{S}$ with a $\Phi(t)$ satisfying the equation $\dot{\Phi} + A = 0$. For a closed path $C$, the equation above defines a (generically) open path $\Gamma$ projecting onto $C$ by the projection $\pi$. It must be clear by now that the process described is the one of parallel transports with respect to a connection with a connection 1-form $\omega$. The pull-back of $\omega$ with respect to the local section in [14] is the 1-form (U(1) gauge field) $A$ in [13]. The curve $\Gamma$ corresponding to $|\psi(t)\rangle$ is the horizontal lift of $C$ in $\mathcal{P}$. The U(1) phase

$$\mathrm{e}^{\mathrm{i}\Phi[C]} \equiv \mathrm{e}^{-\mathrm{i}\oint_C A} \qquad [16]$$

is the holonomy of the connection. We call this connection the "Pancharatnam connection," and its holonomy for a closed path in the space of rays is the geometric phase acquired by the wave function. Now the question of fundamental importance is: how to realize closed paths in $\mathcal{P}$ physically? This question is addressed in the following sections.

## Quantum Jumps

We have seen that physical states of a quantum system are represented by the space of rays $\mathcal{P}$ and normalized states used as representatives for such states form the total space $\mathcal{S}$ of a principal U(1) bundle $\eta_1$ over $\mathcal{P}$. Moreover, in the previous section we have realized that the physical notions of transition probability, and quantum interference naturally lead to the introduction of a Riemannian metric $g$ and an abelian U(1) gauge field $A$ living on $\mathcal{P}$.

An interesting result based on the connection between $g$ and $A$ concerns a nice geometric description of a special type of quantum evolution consisting of a sequence of "quantum jumps."

Consider two nonorthogonal rays $|A\rangle\langle A|$ and $|B\rangle\langle B|$ in $\mathcal{P}$. Let us suppose that the system's normalized wave function initially is $|A\rangle \in \mathcal{S}$, and measure by the "polarizer" $|B\rangle\langle B|$. Then the result of this filtering measurement is $|B\rangle\langle B|A\rangle$, or after projecting back to the set of normalized states we have the "quantum jump"

$$|A\rangle \to |B\rangle \frac{\langle B|A\rangle}{|\langle B|A\rangle|} \qquad [17]$$

Now we have the following theorem:

**Theorem** *The* [17] *jump can be recovered by parallel transporting the normalized state* $|A\rangle$ *according to the Pancharatnam connection along the shortest geodesic* (*with respect to the* [8] *metric*), *connecting* $|A\rangle\langle A|$ *and* $|B\rangle\langle B|$ *in* $\mathcal{P}$.

Let us now consider a cyclic series of filtering measurements with projectors $|A_a\rangle\langle A_a|$, $a = 1, 2, \ldots, N+1$, where $|A_1\rangle\langle A_1| = |A_{N+1}\rangle\langle A_{N+1}|$. Prepare the system in the state $|A_1\rangle \in \mathcal{S}$, and then subject it to the sequence of filtering measurements. Then according to the theorem, the phase

$$\mathrm{e}^{\mathrm{i}\Phi} = \frac{\langle A_1|A_N\rangle\langle A_N|A_{N-1}\rangle\cdots\langle A_2|A_1\rangle}{|\langle A_1|A_N\rangle\langle A_N|A_{N-1}\rangle\cdots\langle A_2|A_1\rangle|} \qquad [18]$$

picked up by the state is equal to the one obtained by parallel transporting $|A_1\rangle$ along a geodesic polygon consisting of the shorter arcs connecting the projectors $|A_a\rangle\langle A_a|$ and $|A_{a+1}\rangle\langle A_{a+1}|$ with $a = 1, 2, \ldots, N$. It is important to realize that this filtering measurement process is not a unitary one; hence, unitarity is not essential for the geometric phase to appear.

In this section we have managed to obtain closed paths in the form of geodesic polygons in $\mathcal{P}$ via the physical process of subjecting the initial state $|A_1\rangle$ to a sequence of filtering measurements. It is clear that for any type of evolution, the geodesics of the Fubini-study metric play a fundamental role since any smooth closed curve in $\mathcal{P}$ can be approximated by geodesic polygons.

Nonunitary evolution provided by the quantum measuring process is only half of the story. In the next section, we start describing closed paths in $\mathcal{P}$ arising also from unitary evolutions generated by parameter-dependent Hamiltonians, the original context where geometric phases were discovered.

## Unitary Evolutions

### Adiabatic Evolution

Suppose that the evolution of our quantum system with $\mathcal{H} \simeq \mathbf{C}^{n+1}$ is generated by a Hermitian Hamiltonian matrix depending on a set of external parameters $x^\mu, \mu = 1, 2, \ldots, M$. Here we assume that the $x^\mu$ are local coordinates on some coordinate patch $\mathcal{V}$ of a smooth $M$-dimensional manifold $\mathcal{M}$. We lable the eigenvalues of $H(x)$ by the numbers $r = 0, 1, 2, \ldots, n$, and assume that the $r$th eigenvalue $E_r(x)$ is nondegenerate:

$$H(x)|r,x\rangle = E_r(x)|r,x\rangle, \quad r = 0, 1, 2, \ldots, n \qquad [19]$$

We assume that $H(x), E_r(x), |r,x\rangle$ are smooth functions of $x$. The rank-1 spectral projectors

$$P_r(x) \equiv |r,x\rangle\langle r,x|, \quad r = 0, 1, 2, \ldots, n \qquad [20]$$

for each $r$ define a map $f_r : \mathcal{M} \to \mathcal{P}$:

$$f_r : x \in \mathcal{V} \subset \mathcal{M} \mapsto P_r(x) \in \mathcal{P} \qquad [21]$$

Recall now that we have the bundle $\eta_1$ over $\mathcal{P}$, at our disposal, and we can pull back $\eta_1$ using the map $f_r$ to construct a new bundle $\xi_1^r$ over the parameter space $\mathcal{M}$. Moreover, we can define a connection on $\xi_1^r$ by pulling back the canonical (Pancharatnam) connection of $\eta_1$. The resulting bundle $\xi_1^r$ is called the Berry–Simon bundle over the parameter space $\mathcal{M}$. Explicitly,

$$\xi_1^r : \mathrm{U}(1) \hookrightarrow \xi_1^r \xrightarrow{\pi_\xi} \mathcal{M} \qquad [22]$$

The states $|r,x\rangle$ of [19] define a local section of $\xi_1^r$. Supressing the index $r$, the relationship between $\eta_1$

and $\xi_1$ can be summarized by the following diagram:

$$\begin{array}{ccc} \xi_1 & \xleftarrow{f^*} & \eta_1 \\ \pi_\xi \big\downarrow & & \pi_\eta \big\downarrow \\ \mathcal{M} & \xrightarrow{f} & \mathcal{P} \end{array} \qquad [23]$$

Here $f^*$ denotes the pullback map, and we have $\xi_1 \equiv f^*(\eta_1)$. (We have denoted the total space $\mathcal{S}$ as $\eta_1$.)

The local section of $\xi_1$ arising as the pullback of [14] an $\eta_1$ is given by

$$|r, x\rangle = \frac{1}{\sqrt{1 + \bar{w}^k(x) w_k(x)}} \begin{pmatrix} 1 \\ w^j(x) \end{pmatrix}, \quad x \in \mathcal{V} \subset \mathcal{M} \qquad [24]$$

with $j = 1, 2, \ldots, n$. The pullback of the Pancharatnam connection $\omega$ on $\eta_1$ is $f^*(\omega)$. We can further pull back $f^*(\omega)$ to $\mathcal{V} \subset \mathcal{M}$ with respect to the local section of [24] to obtain a gauge field living on the parameter space. This gauge field is called the "Berry gauge field" and the corresponding connection is the Berry connection. Thus,

$$\mathcal{A} = f^*(A) = \mathcal{A}_\mu(x) \mathrm{d}x^\mu = (A_j \partial_\mu w^j + A_{\bar{j}} \partial_\mu w^{\bar{j}}) \mathrm{d}x^\mu \qquad [25]$$

here $\partial_\mu \equiv \partial / \partial x^\mu$ and $A$ is given by [13]. When we have a closed curve $\mathcal{C}$ in $\mathcal{M}$, then $f \circ \mathcal{C}$ defines a closed curve C in $\mathcal{P}$. We already know that the holonomy for C in $\mathcal{P}$ can be written in the [16] form; hence,

$$\Phi_B = -\oint_{f \circ \mathcal{C}} A = -\oint_{\mathcal{C}} f^*(A) = -\oint_{\mathcal{C}} \mathcal{A} \qquad [26]$$

This formula states that there is a geometric phase picked up by the eigenstates of a parameter-dependent Hermitian Hamiltonian when we change the parameters along a closed curve. Our formula shows that the geometric phase can be calculated using either the canonical connection on $\eta_1$ or the Berry connection on $\xi_1$.

Let us then change the parameters $x^\mu$ adiabatically. The closed path in parameter space then defines Hamiltonians satisfying $H(x(T)) = H(x(0))$ for some $T \in \boldsymbol{R}^+$. Moreover, there is also the associated closed curve $P_r(x(T)) = P_r(x(0))$ in $\mathcal{P}$. The quantum adiabatic theorem states that if we prepare a state $|\Psi(0)\rangle \equiv |r, x(0)\rangle$ at $t = 0$, which is an eigenstate of the instantaneous Hamiltonian $H(x(0))$, then after changing the parameters infinitely slowly, the time evolution generated by the time-dependent Schrödinger equation

$$\mathrm{i}\hbar \frac{\mathrm{d}}{\mathrm{d}t} |\Psi(t)\rangle = H(t) |\Psi(t)\rangle \qquad [27]$$

takes the form

$$|\Psi(t)\rangle = |r, x(t)\rangle \mathrm{e}^{\mathrm{i}\Lambda_r(t)} \qquad [28]$$

after time $t$, which belongs to the same eigensubspace. The point is that the theorem holds only for cases when the kinetic energy associated with the slow change in the external parameters is much smaller than the energy separation between $E_r(x)$ and $E_{r'}(x)$ for all $x \in \mathcal{M}$. Under this assumption, transitions between adjacent levels are prohibited during evolution. Notice that the adiabatic theorem clearly breaks down in the vicinity of level crossings where the gap is comparable with the magnitude of the kinetic energy of the external parameters.

However, if one takes it for granted that the projector $P_r(t) \equiv P_r(x(t))$ for some $r$ satisfies the Schrödinger–von Neumann equation

$$\mathrm{i}\hbar \frac{\mathrm{d}}{\mathrm{d}t} P_r(t) = [H(t), P_r(t)] \qquad [29]$$

by virtue of [19], we get zero for the right-hand side. This means that $P_r(t)$ is constant; hence, the curve in $\mathcal{P}$ degenerates to a point. The upshot of this is that exact adiabatic cyclic evolutions do not exist. It can be shown, however, that under certain conditions one can find an initial state $|\Psi(0)\rangle \neq |r, x(0)\rangle$ that is "close enough" to $P_r(x(t)) = |r, x(t)\rangle\langle r, x(t)|$. Then, we can say that the projector analog of [28] only approximately holds

$$|\Psi(t)\rangle\langle\Psi(t)| \simeq |r, x(t)\rangle\langle r, x(t)| \qquad [30]$$

This means that the use of the bundle picture for the generation of closed curves for $\mathcal{P}$ via the adiabatic evolution can merely be used as an approximation.

## Berry's Phase

The straightforward calculation after substituting [28] into [27] shows that

$$\exp(\mathrm{i}\Lambda_r(T)) \exp\left(-\frac{\mathrm{i}}{\hbar} \int_0^T E_r(t) \mathrm{d}t\right) \exp\left(-\mathrm{i} \oint_{\mathcal{C}} \mathcal{A}^{(r)}\right) \qquad [31]$$

where $\mathcal{C}$ is a closed curve lying entirely in $\mathcal{V} \subset \mathcal{M}$. The first phase factor is the dynamical and the second is the celebrated Berry phase. Notice that the index $r$ labeling the eigensubspace in question

should now be included in the definition of $\mathcal{A}$ (see eqn [25]).

As an explicit example, let us take the Hamiltonian

$$H(\boldsymbol{X}(t)) = -\omega_0 \boldsymbol{J}\boldsymbol{X}(t), \qquad \omega_0 \equiv \frac{Bge}{2mc}, \\ \boldsymbol{X} \in \boldsymbol{R}^3, \quad |\boldsymbol{X}| = 1 \qquad [32]$$

where $e$, $m$, and $g$ are the charge, mass, and Landé factor of a particle, $c$ is the speed of light, and $B$ is the (constant) magnitude of an applied magnetic field. The three components of $\boldsymbol{J}$ are $(2J+1)\times(2J+1)$-dimensional spin matrices satisfying $\boldsymbol{J}\times\boldsymbol{J} = \mathrm{i}\hbar\boldsymbol{J}$. The Hamiltonian (eqn [32]) describes a spin $J$ particle moving in a magnetic field with slowly varying direction. It is obvious that the parameter space is a 2-sphere. Introducing polar coordinates $0 \leq \theta < \pi$, $0 \leq \chi < 2\pi$ for the patch $\mathcal{V}$ of $S^2$ excluding the south pole, we have $x^1 \equiv \theta$, $x^2 \equiv \chi$.

As an illustration, let us consider the spin 1/2 case. Then $H$ can be expressed in terms of the $2\times 2$ Pauli matrices. The eigenvalues are $E_0 = -\omega_0\hbar/2$ and $E_1 = \omega_0\hbar/2$ $(r = 0, 1)$. For the ground state, the mapping $f_0$ of [21] from $\mathcal{V} \subset \mathcal{M} \simeq S^2$ to $\mathcal{P} \simeq \boldsymbol{CP}^1$ is given by

$$w(\theta,\chi) \equiv \tan\left(\frac{\theta}{2}\right)\mathrm{e}^{\mathrm{i}\chi} \qquad [33]$$

which is stereographic projection of $S^2$ from the south pole onto the complex plane corresponding to the coordinate patch $\mathcal{U}_0 \subset \boldsymbol{CP}^1$. Using [13] and [25], one can calculate the pullback gauge field and its curvature $\mathcal{F}^{(0)} \equiv \mathrm{d}\mathcal{A}^{(0)}$, where

$$\mathcal{A}^{(0)} = \frac{1}{2}(1-\cos\theta)\mathrm{d}\chi, \qquad \mathcal{F}^{(0)} = \frac{1}{2}\sin\theta\mathrm{d}\theta\wedge\mathrm{d}\chi \quad [34]$$

Notice that $\mathcal{F}^{(0)}$ is the field strength of a magnetic monopole of strength 1/2 living on $\mathcal{M}$. Using Stokes theorem, from [26] one can calculate Berry's phase

$$\Phi^{(0)}[\mathcal{C}] = -\oint_{\mathcal{C}} \mathcal{A}^{(0)} = -\int_S \mathcal{F}^{(0)} = -\frac{1}{2}\Omega[\mathcal{C}] \qquad [35]$$

where $S$ is the surface bounded by the loop $\mathcal{C}$ and $\Omega[\mathcal{C}]$ is the solid angle subtended by the curve $\mathcal{C}$ at $\boldsymbol{X} = \boldsymbol{0}$.

The above result can be generalized for arbitrary spin $J$. Then, we have the eigenvalues $E_r = -\omega_0\hbar(J-r)$, where $0 \leq r \leq 2J$. The final result in this case is

$$\Phi^{(r)}[\mathcal{C}] = -(J-r)\Omega[\mathcal{C}], \quad 0 \leq r \leq 2J \qquad [36]$$

## The Aharonov–Anandan Phase

We have seen that the quantum adiabatic theorem can only be used approximately for generating closed curves in $\mathcal{P}$. This section, describes as to how such curves can be generated exactly.

Let us consider the Schrödinger equation with a time-dependent Hamiltonian (eqn [27]). Then we call its solution $|\Psi(t)\rangle$ cyclic if the state of the system returns, after a period $T$, to its original state. This means that the projector $|\Psi(t)\rangle\langle\Psi(t)|$ traverses a closed path $C$ in $\mathcal{P}$. In order to realize this situation, we have to find solutions of [27] for which $|\Psi(T)\rangle = \mathrm{e}^{\mathrm{i}\Delta_\Psi}|\Psi(0)\rangle$ for some $\Delta_\Psi$.

Taking for granted the existence of such a solution, let us first explore its consequences. First, we remove the dynamical phase from the cyclic solution $|\Psi(t)\rangle$

$$|\psi(t)\rangle \equiv \exp\left(\frac{\mathrm{i}}{\hbar}\int_0^t \langle\Psi(t')|H(t)|\Psi(t')\rangle \mathrm{d}t'\right)|\Psi(t)\rangle \quad [37]$$

Then, $|\psi(t)\rangle$ satisfies [12], that is, it defines a unique horizontal lift of the closed curve $C$ in $\mathcal{P}$. Following the same steps as in section describing the Pancharatnam condition, we see that the phase

$$\Phi_{AA}[C] = -\oint_C A \\ = \Delta_\Psi + \frac{1}{\hbar}\int_0^T \langle\Psi(t)|H(t)|\Psi(t)\rangle\,\mathrm{d}t \quad [38]$$

is purely geometric in origin. It is called the Aharonov–Anandan (AA) phase.

Let us now turn back to the question of finding cyclic states satisfying $|\Psi(T)\rangle = \mathrm{e}^{\mathrm{i}\Delta_\Psi}|\Psi(0)\rangle$. One possible solution is as follows. Suppose that $H$ depends on time through some not necessarily slowly changing parameters $x$. Let us find a partner Hamiltonian $h$ for our $H$ by defining a smooth mapping $\sigma: \mathcal{M} \to \mathcal{M}$, such that

$$h(x) \equiv H(\sigma(x)), \quad x \in \mathcal{V} \subset \mathcal{M} \qquad [39]$$

For the special class we study here, the cyclic vectors are eigenvectors of $h(x)$. Hence, the projectors $p_r$ and $P_r$ of $h$ and $H$ are related as $p_r(x) = P_r(\sigma(x))$; this means that we have a map $g_r: \mathcal{M} \to \mathcal{P}$,

$$g_r \equiv f_r \circ \sigma : x \in \mathcal{V} \subset \mathcal{M} \to p_r(x) \in \mathcal{P} \qquad [40]$$

which associates with every $x$ an eigenstate of $h(x)$. Moreover, $g_r$ associates with a closed curve $\mathcal{C}$ in $\mathcal{M}$ a closed curve $C$ in $\mathcal{P}$. Notice that generically $[h(x), H(x)] \neq 0$; hence, cyclic states are not eigenstates of the instanteneous Hamiltonian.

It should be clear by now that we can repeat the construction as discussed in the adiabatic case with $g_r$ replacing $f_r$. In particular, we can construct a new bundle $\zeta_1$ over the parameter space via the usual

pullback procedure. More precisely, we have the corresponding diagram

$$\begin{array}{ccc} \zeta_1 & \xleftarrow{g^*} & \eta_1 \\ \pi_\zeta \downarrow & & \pi_\eta \downarrow \\ \mathcal{M} & \xrightarrow{g} & \mathcal{P} \end{array} \qquad [41]$$

The AA connection can be obtained by pulling back the Pancharatnam connection:

$$a \equiv g^*(A) = \sigma^* \circ f^*(A) = \sigma^*(\mathcal{A}) \qquad [42]$$

where the last equality relates the AA connection with the Berry connection. Now the AA phase is

$$\Phi_{AA} = -\oint_{g\circ\mathcal{C}} A = -\oint_{\mathcal{C}} g^*(A) = -\oint_{\mathcal{C}} a \qquad [43]$$

As an example, let us take the Hamiltonian [32] with the curve $\mathcal{C}$ on $\mathcal{M} \equiv S^2$:

$$\boldsymbol{X}(t) = (\sin\theta\cos(\chi+\omega t), \sin\theta\sin(\chi+\omega t), \cos\theta) \quad [44]$$

Here $\theta$ and $\chi$ are the polar coordinates of a fixed point in $S^2$ where the motion starts. The curve $\mathcal{C}$ is a circle of fixed latitude and is traversed with an arbitrary speed. This model can be solved exactly and it can be shown that the mapping $\sigma_s$: $S^2 \to S^2$ is given by

$$\sigma : (u, \chi) \mapsto \left( \frac{u - s}{\sqrt{s^2 - 2us + 1}}, \chi \right),$$

$$u \equiv \cos\theta, \quad s \equiv \frac{\omega}{\omega_0} \qquad [45]$$

One can prove that for $0 \leq s < 1, \sigma_s$ is a diffeomorphism. In the $s \to 0$ (the adiabatic) limit, the mapping $g_{r,s} \equiv f_{r,s} \circ \sigma_s$ is continuously deformed to $f_r$. Moreover, $h(x)$ as defined above commutes with the time evolution operator; hence, cyclic states are indeed eigenstates of $h(x)$.

Using [42], [43], and [45], the explicit form of $\sigma_s$, we get for the AA phase

$$\Phi_{AA}^{(\mathrm{r,s})}[\mathcal{C}] = -2\pi(J - r)\left(1 - \frac{u - s}{\sqrt{s^2 - 2us + 1}}\right) \qquad [46]$$

In the adiabatic limit, the result goes to $-2\pi(J - r)(1 - u)$ which is just $-(J - r)$ times the solid angle of the path of fixed latitude, as it has to be.

## Generalization

In the sequence of examples, we have shown that geometric phases are related to the geometric structures on the bundle $\eta_1$. The Berry and AA phases are special cases arising from Pancharatnam's phase via a pullback procedure with respect to suitable maps defined by the physical situation in question. Hence, the Pancharatnam connection in this sense is universal. The root of this universality rests in a deep theorem of mathematics concerning the existence of universal bundles and their universal connections. In order to elaborate the insight provided by this theorem into the geometry of quantum evolution, let us first make a further generalization.

In our study of time-dependent Hamiltonians we have assumed that the eigenvalues of [19] were nondegenerate. Let us now relax this assumption. Fix an integer $N \geq 1$, the degeneracy of the eigensubspace corresponding to the eigenvalue $E_r$. One can then form a U($N$) principal bundle $\xi_N$ over $\mathcal{M}$, furnished with a connection, that is a natural generalization of the Berry connection. The pullback of this connection to a patch of $\mathcal{M}$ is a U($N$)-valued gauge field and its holonomy along a loop in $\mathcal{M}$ gives rise to a U($N$) matrix generalization of the U(1) Berry phase.

The natural description of this connection and its AA analog is as follows. Take the complex Grassmannian $Gr(n+1, N)$ of $N$ planes in $\mathbf{C}^{n+1}$. Obviously, $Gr(n+1, 1) \equiv \mathcal{P}$. Each point of $Gr(n+1, N)$ corresponds to an $N$ plane through the origin represented by a rank-$N$ projector. This projector can be written in terms of $N$ orthonormal basis vectors in an infinite number of ways. This ambiguity of choosing orthonormal frames is captured by the U($N$) gauge symmetry, the analog of the U(1) (phase) ambiguity in defining a normalized state as the representative of the rank-1 projector. This bundle of frames is the Stiefel bundle $V(n+1, N)$ alternatively denoted by $\eta_N$. $V(n+1, N)$ is a principal U($N$) bundle over $Gr(n+1, N)$ equipped with a canonical connection $\omega_N$ which is the U($N$) analog of Pancharatnam's connection.

Now according to the powerful theorem of Narasimhan and Ramanan if we have a U($N$) bundle $\xi_N$ over the $M$-dimensional parameter space $\mathcal{M}$, then there exists an integer $n_0(N, M)$ such that for $n \leq n_0$ there exists a map $f$: $\mathcal{M} \to Gr(n+1, N)$ such that $\eta_N = f^*(V(n+1, N))$. Moreover, given any two such maps $f$ and $g$, the corresponding pullback bundles are isomorphic if and only if $f$ is homotopic to $g$.

For the examples of the sections "Berry's phase" and "The Aharonov–Anandan phase," we have $N=1, n=1$, and $M=2$. Since the maps $f_r$ and $g_{r,s}$ defined by the rank-1 spectral projectors of $H(x)$ and $h(x)$ for $0 \leq s < 1$ are homotopic, the corresponding pullback bundles $\xi_1$ and $\zeta_1$ are isomorphic. Moreover, the Berry and AA connections are the pullbacks of the universal connection on $V(n+1, 1) \equiv \eta_1$ which is just Pancharatnam's connection.

For the infinite-dimensional case, one can define $Gr(\infty, N)$ by taking the union of the natural inclusion maps of $Gr(n, N)$ into $Gr(n+1, N)$.

We denote this universal classifying bundle $V(\infty, N)$ as $\eta$. Then, we see that given an $N$-dimensional eigensubspace bundle over $\mathcal{M}$ and a map $f_r : x \in \mathcal{M} \mapsto P_r(x) \in Gr(\infty, N)$ defined by the physical situation, the geometry of evolving eigensubspaces can be understood in terms of the holonomy of the pullback of the universal connection on $\eta$.

## Conclusions

In this article, we elucidate the mathematical origin of geometric phases. We have seen that the key observation is the fact that the space of rays $\mathcal{P}$ represents unambiguously the physical states of a quantum system. The particular representatives of a class in $\mathcal{P}$ belonging to the usual Hilbert space $\mathcal{H}$ form (local) sections of a U(1) bundle $\eta_1$. Based on the physical notions of transition probability and interference, $\eta_1$ can be furnished with extra structures: the metric and the connection, the latter giving rise to a natural definition of parallel transport. We have seen that the geodesics of $\mathcal{P}$ with respect to the metric play a fundamental role in approximating evolutions of any kind, giving rise to a curve in $\mathcal{P}$.

The geometric structures of $\eta_1$ induce similar structures for pullback bundles. These bundles encapsulate the geometric details of time evolutions generated by Hamiltonians that depend on a set of parameters $x$ belonging to a manifold $\mathcal{M}$. It was shown that the famous examples of Berry and AA phases arise as an important special case in this formalism. A generalization of evolving $N$-dimensional subspaces based on the theory of universal connections can also be given. This shows that the basic structure responsible for the occurrence of anholonomy effects in evolving quantum systems is the universal bundle $\eta$ which is the bundle of subspaces of arbitrary dimension $N$ in a Hilbert space.

The important issue of applying the idea of anholonomy to physical problems has not been dealt with in this article. There are spectacular applications such as holonomic quantum computation, the gauge kinematics of deformable bodies, quantum Hall-effect, fractional spin and statistics. The interested reader should consult the vast literature on the subject or as a first glance, the book of Shapere and Wilczek (1989).

# Geophysical Dynamics

**M B Ziane**, University of Southern California, Los Angeles, CA, USA

## Introduction

The equations of geophysical fluid dynamics are the equations governing the motion of the atmosphere and the ocean, and are derived from the conservation equations from physics, namely conservation of mass, momentum, energy, and some other components such as salt for the ocean, humidity (or chemical pollutants) for the atmosphere.

The first assumption used in any circulation model is the well-accepted Boussinesq approximation, that is, the density differences are neglected in the system except in the buoyancy term and in the equation of state. The resulting system is the so-called Boussinesq equations (Pedlosky 1987). Due to the extremely high accuracy of this approximation, these equations are considered as the basic equations

in geophysical dynamics. From the computational point of view, however, the Boussinesq equations are still not accessible.

Owing to the difference of sizes of the vertical and horizontal dimensions, both in the atmosphere and in the ocean (10–20 km versus several thousands of kilometers), the second approximation is based on the smallness of the vertical length scales with respect to the horizontal length scales, that is, oceans (and the atmosphere) compose very thin layers. The scale analysis ensures that the dominant forces in the vertical-momentum equation come from the pressure gradient and the gravity. This leads to the so-called hydrostatic approximation, which amounts to replacing the vertical component of the momentum equation by the hydrostatic balance equation, and hence leading to the well-accepted primitive equations (PEs) (Washington and Parkinson 1986). As far as we know, the primitive equations were first considered by L F Richardson (1922); when it appeared that they were still too complicated they were left out and, instead, attention was focused on even simpler models, the geostrophic and quasigeostrophic models, considered in the late 1940s by J von Neumann and his collaborators, in particular J G Charney. With the increase of computing power, interest eventually returned to the PEs, which are now the core of many global circulation models (GCMs) or ocean global circulation models (OGCMs), available at the National Center for Atmospheric Research (NCAR) and elsewhere. GCMs and OGCMs are very complex models which contain many components, but still, the PEs are the central component for the dynamics of the air or the water. Further approximations based on the fast rotation of the Earth implying the smallness of the Rossby number lead to the quasigeostrophic and geostrophic equations (Pedlosky 1987).

The mathematical study of the PEs was initiated by Lions, Temam, and Wang in the early 1990s. They produced a mathematical formulation of the PEs which resembles that of the Navier–Stokes due to Leray, and obtained the existence, for all time, of weak solutions (see Lions *et al.* 1992a, b, 1993, 1995). Further works conducted during the 1990s have improved and supplemented these early results bringing the mathematical theory of the PEs to that of the three-dimensional incompressible Navier–Stokes equations (Constantin and Foias 1998, Teman 2001). In summary, the following results are now available which will be presented in this article:

1. existence of weak solutions for all time;
2. existence of strong solutions in space dimension three, local in time;
3. existence and uniqueness of a strong solution in space dimension two, for all time; and
4. uniqueness of weak solutions in space dimension two.

## The PEs of the Ocean

The ocean is made up of a slightly compressible fluid subject to a Coriolis force. The full set of equations of the large-scale ocean are the following: the conservation of momentum equation, the continuity equation (conservation of mass), the thermodynamics equation, the equation of state and the equation of diffusion for the salinity $S$:

$$\rho\frac{\mathrm{d}\boldsymbol{V}_3}{\mathrm{d}t} + 2\rho\boldsymbol{\Omega}\times\boldsymbol{V}_3 + \nabla_3 p + \rho\boldsymbol{g} = D \qquad [1]$$

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} + \rho\,\mathrm{div}_3\boldsymbol{V}_3 = 0 \qquad [2]$$

$$\frac{\mathrm{d}T}{\mathrm{d}t} = Q_T \qquad [3]$$

$$\frac{\mathrm{d}S}{\mathrm{d}t} = Q_S \qquad [4]$$

$$\rho = f(T,S,p) \qquad [5]$$

Here $\boldsymbol{V}_3$ is the three-dimensional velocity vector, $\boldsymbol{V}_3 = (u,v,w)$, $\rho$, $p$, $T$ are respectively, the density, pressure, and temperature, and $S$ is the concentration of salinity; $\boldsymbol{g} = (0,0,g)$ is the gravity vector, $D$ the molecular dissipation, $Q_T$ and $Q_S$ are the heat and salinity diffusions, respectively.

**Remark 1** The equation of state for the oceans is derived on a phenomenological basis. Only empirical forms of the function $f(T,S,\rho)$ are known (see Washington and Parkinson (1986)). It is natural, however, to expect that $\rho$ decreases if $T$ increases and that $\rho$ increases if $S$ increases. The simplest law is

$$\rho = \rho_0(1 - \beta_T(T - T_\mathrm{r}) + \beta_S(S - S_\mathrm{r})) \qquad [6]$$

corresponding to a linearization around reference values $\rho_0$, $T_\mathrm{r}$, $S_\mathrm{r}$ of respectively, the density, temperature, and the salinity, $\beta_T$ and $\beta_S$ are positive expansion coefficients.

The Mach number for the flow in the ocean is not large and, therefore, as a starting point, we can make the so-called Boussinesq approximation in which the density is assumed constant, $\rho = \rho_0$, except in the buoyancy term and in the equation of state. This amounts to replacing [1], [2] by

$$\rho_0\frac{\mathrm{d}\boldsymbol{V}_3}{\mathrm{d}t} + 2\rho_0\Omega\times\boldsymbol{V}_3 + \nabla_3 p + \rho\boldsymbol{g} = D \qquad [7]$$

$$\mathrm{div}_3\boldsymbol{V}_3 = 0 \qquad [8]$$

Furthermore, since for large-scale ocean, the horizontal scale is much larger than the vertical one, a scale analysis (Pedlosky 1987) shows that $\partial p/\partial z$ and $\rho g$ are

the dominant terms in the vertical-momentum equation, leading to the hydrostatic approximation

$$\frac{\partial p}{\partial z} = -\rho g \qquad [9]$$

For mid-latitude regional studies, it is usual to consider the beta-plane approximation of the equations. Thus, we assume that the ocean fills a domain $\mathcal{M}_\varepsilon$ of $\mathbb{R}^3$. The top of the ocean is a domain $\Gamma_i$ included in the surface of the earth $S_a$ (sphere of radius $a$ centered at 0). The bottom $\Gamma_b$ of the ocean is defined by $(z = x_3 = r - a)$, $z = -\varepsilon h(\theta, \varphi)$, where $\varepsilon > 0$ is a positive parameter. It is introduced to take into consideration the smallness of the vertical scales compared to the horizontal scales. $h$ is a function of class $\mathcal{C}^2$ at least on $\bar{\Gamma}_i$; it is assumed also that $h$ is bounded from below, that is, $0 < \underline{h} \le h(\theta, \varphi) \le \underline{h}$, $(\theta, \varphi) \in \Gamma_i$. The lateral surface $\Gamma_l$ consists of the part of cylinder $\{(\theta, \varphi) \in \partial\Gamma_i, -\varepsilon h(\theta, \varphi) \le r \le 0\}$. The PEs of the ocean are given by

$$\frac{\partial \boldsymbol{v}}{\partial t} + \nabla_v \boldsymbol{v} + w\frac{\partial \boldsymbol{v}}{\partial z} + \frac{1}{\rho_0}\nabla p + 2\Omega \sin\theta \boldsymbol{k} \times \boldsymbol{v} - \mu_v \Delta \boldsymbol{v} - \nu_v \frac{\partial^2 \boldsymbol{v}}{\partial z^2} = F_v \qquad [10]$$

$$\frac{\partial p}{\partial z} = -\rho, \qquad \operatorname{div} \boldsymbol{v} + \frac{\partial w}{\partial z} = 0 \qquad [11]$$

$$\frac{\partial T}{\partial t} + \nabla_{\boldsymbol{v}} T + w\frac{\partial T}{\partial z} - \mu_T \Delta T - \nu_T \frac{\partial^2 T}{\partial z^2} = F_T \qquad [12]$$

$$\frac{\partial S}{\partial t} + \nabla_{\boldsymbol{v}} S + w\frac{\partial S}{\partial z} - \mu_S \Delta S - \nu_S \frac{\partial^2 S}{\partial z^2} = F_S \qquad [13]$$

$$\operatorname{div} \int_{-h}^{0} \boldsymbol{v}\, dz = 0 \qquad [14]$$

$$p = p_s + P, \qquad P = P(T, S) = g \int_z^0 p\, dz' \qquad [15]$$

$$\rho = \rho_0(1 - \beta_T(T - T_r) + \beta_S(S - S_r)) \qquad [16]$$

$$\int_{\mathcal{M}_\varepsilon} S\, d\mathcal{M}_\varepsilon = 0 \qquad [17]$$

where $\boldsymbol{v}$ is the horizontal velocity of the water, $w$ is the vertical velocity, and $T_r$, $S_r$ are averaged (or reference) values of $T$ and $S$. The diffusion coefficients $\mu_v$, $\mu_T$, $\mu_S$ and $\nu_v$, $\nu_T$, $\nu_S$ are different in the horizontal and vertical directions, accounting for some eddy diffusions in the sense of Smagorinsky (1962). Note that $F_v$, $F_T$, and $F_S$ correspond to volumic sources of horizontal momentum, heat, and salt, respectively.

### Boundary conditions

There are several sets of natural boundary conditions that one can associate to the PEs; for instance, the following:

**On the top of the ocean** $\Gamma_i(z = 0)$

$$\nu_v \frac{\partial \boldsymbol{v}}{\partial z} + \alpha_v(\boldsymbol{v} - \boldsymbol{v}_a) = \tau_v, \qquad w = 0$$
$$\nu_T \frac{\partial T}{\partial z} + \alpha_T(T - T_a) = 0, \qquad \frac{\partial S}{\partial z} = 0 \qquad [18]$$

**At the bottom of the ocean** $\Gamma_b(z = -h(\theta, \varphi))$

$$\boldsymbol{v} = 0, \; w = 0, \; \frac{\partial T}{\partial \boldsymbol{n}_T} = 0, \; \frac{\partial S}{\partial \boldsymbol{n}_S} = 0 \qquad [19]$$

**On the lateral boundary** $\Gamma_l = \{-h(\theta, \varphi) < z < 0, (\theta, \varphi) \in \partial\Gamma_i\}$

$$\boldsymbol{v} = 0, \; w = 0, \; \frac{\partial T}{\partial \boldsymbol{n}_T} = 0, \; \frac{\partial S}{\partial \boldsymbol{n}_S} = 0 \qquad [20]$$

Here $\boldsymbol{n} = (n_H, n_z)$ is the unit outward normal on $\partial\mathcal{M}_\varepsilon$ decomposed into its horizontal and vertical components; the conormal derivatives $\partial/\partial \boldsymbol{n}_T$ and $\partial/\partial \boldsymbol{n}_S$ are those associated with the linear (temperature and salinity) operators,

$$\frac{\partial}{\partial \boldsymbol{n}_T} = \mu_T n_H \cdot \nabla + \nu_T n_z \frac{\partial}{\partial z}$$
$$\frac{\partial}{\partial \boldsymbol{n}_S} = \mu_S n_H \cdot \nabla + \nu_S n_z \frac{\partial}{\partial z} \qquad [21]$$

Equations [10]–[17] with boundary conditions [18]–[20] are supplemented with the initial conditions

$$\boldsymbol{v}|_{t=0} = \boldsymbol{v}_0, \; T|_{t=0} = T_0, \; S|_{t=0} = S_0 \qquad [22]$$

where $\boldsymbol{v}_0, T_0, S_0$ are given initial data.

Following the work of Lions *et al.* (1992a, b, 1993, 1995) (see also Temam and Ziane (2004)), we introduce the following function spaces $V = V_1 \times V_2 \times V_3$, $H = H_1 \times H_2 \times H_3$, where

$$V_1 = \left\{\boldsymbol{v} \in H^1(\mathcal{M})^2, \operatorname{div} \int_{-h}^{0} \boldsymbol{v} dz = 0, \; \boldsymbol{v} = 0 \text{ on } \Gamma_b \cup \Gamma_l\right\}$$

$$V_2 = H^1(\mathcal{M})$$

$$V_3 = \dot{H}^1(\mathcal{M}) = \left\{S \in H^1(\mathcal{M}), \int_{\mathcal{M}} S d\mathcal{M} = 0\right\}$$

$$H_1 = \left\{\boldsymbol{v} \in L^2(\mathcal{M})^2, \operatorname{div} \int_{-h}^{0} \boldsymbol{v}\, dz = 0, \; n_H \cdot \int_{-h}^{0} \boldsymbol{v}\, dz = 0 \text{ on } \partial\Gamma_i \text{ (i.e., on } \Gamma_l)\right\}$$

$$H_2 = L^2(\mathcal{M})$$

$$H_3 = \dot{L}^2(\mathcal{M}) = \left\{S \in L^2(\mathcal{M}), \int_{\mathcal{M}} S d\mathcal{M} = 0\right\}$$

The global existence of weak solutions is established in Lions *et al.* (1992b), using the Galerkin method and assuming the $H^2$-regularity of the GFD–Stokes problem, which was established in Ziane

(1995). A more general global existence result based on the method of finite differences in time and independent of the $H^2$-regularity is established in Temam and Ziane (2004), which we state here.

**Theorem 2** *Given $t_1 > 0$, $U_0$ in $H$, and $F = (F_v, F_T, F_S)$ in $L^2(0, t_1; H)$; $g = g_v$, $g_T$ is given in $L^2(0, t_1; (L^2(\Gamma_i)^3)$. Then there exists*

$$U \in L^\infty(0, t_1; H) \cap L^2(0, t_1; V) \qquad [23]$$

*which is a weak solution of* [10]–[17] and [18]–[20], [22]; *furthermore, $U$ is weakly continuous from $[0, t_1]$ into $H$.*

### Strong Solutions

The local existence and uniqueness of strong solutions of the primitive equations of the ocean relies on the $H^2$-regularity of the stationary linear primitive equations associated to [10]–[17]:

$$\frac{1}{\rho_0}\nabla p + 2\Omega \sin\theta \boldsymbol{k} \times \boldsymbol{v} - \mu_v \Delta \boldsymbol{v} - \nu_v \frac{\partial^2 \boldsymbol{v}}{\partial z^2} = F_v$$
$$\int_{-h}^{0} \operatorname{div} \boldsymbol{v}\, \mathrm{d}z = 0 \qquad [24]$$

$$-\mu_T \Delta T - \nu_T \frac{\partial^2 T}{\partial z^2} = F_T$$
$$-\mu_S \Delta S - \nu_S \frac{\partial^2 S}{\partial z^2} = F_S \qquad [25]$$

$$p = p_s + P, \quad P = P(T, S) = g\int_z^0 p\, \mathrm{d}z' \qquad [26]$$

with boundary conditions [18]–[20]. Here $F_v, F_T, F_S$ are independent of time. We have the following $H^2$-regularity of solutions (Ziane 1995, Hu *et al.* 2002, Temam and Ziane 2004).

**Theorem 3** *Assume that $h$ is in $\mathcal{C}^4(\bar{\Gamma}_i), h \ge \underline{h} > 0$, $F_v, F_T, F_S \in (\mathbb{L}^2(\mathcal{M}_\varepsilon))^4$ and $g_v = \tau_v + \alpha_v \boldsymbol{v}_a$, $g_T = \alpha_a T_a \in (\mathbb{H}_0^1(\Gamma_i))^4$. Let $(v, T, S; p) \in (\mathbb{H}^1(M_\varepsilon))^4 \times L^2(\Gamma_i)$ be a weak solution of* [24]–[26]. *Then*

$$(v, p) \in \left(\mathbb{H}^2(\mathcal{M}_\varepsilon)\right)^2 \times H^1(\mathcal{M}_\varepsilon)$$
$$(T, S) \in \left(\mathbb{H}^2(\mathcal{M}_\varepsilon)\right)^2 \qquad [27]$$

*Moreover, the following inequalities hold:*

$$|v|^2_{\mathbb{H}^2(\mathcal{M}_\varepsilon)} + \varepsilon |p|^2_{H^1(\Gamma_i)} \le C\Big[|F_v|^2_\varepsilon + |g_v|^2_{L^2(\Gamma_i)} + \varepsilon|\nabla g_v|^2_{L^2(\Gamma_i)}\Big]$$

$$|T|^2_{\mathbb{H}^2(\mathcal{M}_\varepsilon)} \le C\Big[|F_T|^2 + |g_T|^2_{L^2(\Gamma_i)} + \varepsilon|\nabla g_T|^2_{L^2(\Gamma_i)}\Big]$$
$$|S|^2_{\mathbb{H}^2(\mathcal{M}_\varepsilon)} \le C|F_S|^2$$

*where $C$ is a positive constant independent of $\varepsilon$.*

We now turn our attention to the nonlinear time-dependent PEs. The local-in-time existence and uniqueness of strong solutions is obtained in Temam and Ziane (2004); see also Hu *et al.* (2003) and Guillén-González *et al.* (2001). The proof is more involved than that of the three-dimensional Navier–Stokes equations. It consists of several steps. In the first step, one proves the global existence of strong solutions to the linearized time-dependent problem. In the second step, one uses the solution of the linearized equation in order to reduce the PEs to a nonlinear evolution equation with zero initial data and homogeneous boundary conditions. Finally, in the last step, one uses nonisotropic Sobolev inequalities together with Theorem 3. The local existence result is given by the following:

**Theorem 4** *Let $\varepsilon > 0$ be given. We assume that $\Gamma_i$ is of class $\mathcal{C}^3$ and that $h : \bar{\Gamma}_i \to \mathbb{R}_+$ is of class $\mathcal{C}^3$. We are given $U_0$ in $V$, $F = (F_v, F_T, F_S)$ in $L^2(0, t_1; H)$ with $\partial F/\partial t$ in $L^2(0, t_1; L^2(\mathcal{M}_\varepsilon)^4)$, and $g = (g_v, g_T)$ in $L^2(0, t_1; H_0^1(\Gamma_i)^3)$ with $\partial g/\partial t$ in $L^2(0, t_1; H_0^1(\Gamma_i)^3)$. Then there exists $t_* > 0, t_* = t_*(\|U_0\|)$, and there exists a unique solution $U = U(t) = (\boldsymbol{v}(t), T(t), S(t))$ of the PEs* [10]–[17], [18]–[20], *and* [22] *such that*

$$U \in C([0, t_*]; V) \cap L^2(0, t_*, H^2(\mathcal{M}_\varepsilon)^4) \qquad [28]$$

## The PEs of the Atmosphere

In this section we briefly describe the PEs of the atmosphere, for which all the mathematical results obtained for the PEs of the ocean are valid. We start from the conservations equations similar to [1]–[5]; in fact [1] and [2] are the same; the equation of energy conservation (temperature) is slightly different from [3] because of the compressibility of air; the state equation is that of perfect gas instead of [5]; finally, instead of the concentration of salt in the water, we consider the amount of water in air, $q$. Hence, we have

$$\rho \frac{\mathrm{d}\boldsymbol{V}_3}{\mathrm{d}t} + 2\rho\boldsymbol{\Omega} \times \boldsymbol{V}_3 + \nabla_3 p + \rho \boldsymbol{g} = D \qquad [29]$$

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} + \rho \operatorname{div}_3 \boldsymbol{V}_3 = 0 \qquad [30]$$

$$hc_p \frac{\mathrm{d}T}{\mathrm{d}t} - \frac{RT}{p}\frac{\mathrm{d}p}{\mathrm{d}t} = Q_T$$
$$\frac{\mathrm{d}q}{\mathrm{d}t} = 0, \qquad p = RpT \qquad [31]$$

Here $c_p > 0$ is the specific heat of air at constant pressure, and $R$ is the specific gas constant for the air. Proceeding as in the PEs of the ocean, we decompose $\boldsymbol{V}_3$ into its horizontal and vertical components, $\boldsymbol{V}_3 = \boldsymbol{v} + w$; then we use the hydrostatic approximation, replacing the equation of

conservation of vertical momentum by the hydrostatic equation [9]. We find

$$\frac{\partial v}{\partial t} + \nabla_v \boldsymbol{v} + w\frac{\partial \boldsymbol{v}}{\partial z} + \frac{1}{\nabla \rho_0} p + 2\Omega \sin\theta \times \boldsymbol{v} - \mu_v \Delta \boldsymbol{v} - \nu_v \frac{\partial^2 \boldsymbol{v}}{\partial z^2} = 0 \quad [32]$$

$$\frac{\partial p}{\partial z} = -\rho g \quad [33]$$

$$\frac{\partial T}{\partial t} + \nabla_v T + w\frac{\partial T}{\partial z} - \mu_T \Delta T - \nu_T \frac{\partial^2 T}{\partial z^2} - \frac{RT}{p}\frac{\mathrm{d}p}{\mathrm{d}t} = Q_T \quad [34]$$

$$\frac{\partial q}{\partial t} + \nabla_v q + w\frac{\partial q}{\partial z} - \mu_q \Delta q - \nu_q \frac{\partial^2 q}{\partial z^2} = 0 \quad [35]$$

$$p = RpT \quad [36]$$

The right-hand side of [34], represents the solar heating.

### Change of Vertical Coordinate

Since $\rho$ does not vanish, the hydrostatic equation [33] implies that $p$ is a strictly decreasing function of $z$, and we are thus allowed to use $p$ as the vertical coordinate; hence in spherical geometry the independent variables are now $\varphi, \theta, p$, and $t$. By an abuse of notation, we still denote by $\boldsymbol{v}$, $p$, $T$, $q$, $\rho$ these functions expressed in the $\varphi$, $\theta$, $p$, $t$ variables. We denote by $\omega$ the vertical component of the wind in the new variables, and one can show that the PEs of the atmosphere become

$$\frac{\partial \boldsymbol{v}}{\partial t} + \nabla_v \boldsymbol{v} + \omega\frac{\partial \boldsymbol{v}}{\partial p} + 2\Omega \sin\theta k \times \boldsymbol{v} + \nabla\Phi - L_v \boldsymbol{v} = F_v \quad [37]$$

$$\frac{\partial \Phi}{\partial p} + \frac{R}{p} T = 0 \quad [38]$$

$$\operatorname{div} \boldsymbol{v} + \frac{\partial \mathrm{w}}{\partial}\mathrm{z} = 0 \quad [39]$$

$$\frac{\partial T}{\partial t} + \nabla_v T + \omega\frac{\partial T}{\partial p} - \frac{RT}{p}\omega - L_T = F_T \quad [40]$$

$$\frac{\partial q}{\partial t} + \nabla_v q + \omega\frac{\partial q}{\partial z} - L_q q = F_q \quad [41]$$

$$p = R\rho T \quad [42]$$

We have denoted by $\Phi = gz$ the geopotential ($z$ is now function of $\varphi, \theta, p, t$); $L_v, L_T, L_q$ are the Laplace operators, with suitable eddy viscosity coefficients, expressed in the $\varphi$, $\theta$, $p$ variables. Hence, for example,

$$L_v \boldsymbol{v} = \mu_v \Delta \boldsymbol{v} + \nu_v \frac{\partial}{\partial p}\left[\left(\frac{gp}{R\bar{T}}\right)^2 \frac{\partial \boldsymbol{v}}{\partial p}\right] \quad [43]$$

with similar expressions for $L_T$ and $L_q$. Note that $F_T$ corresponds to the heating of the Sun, whereas $F_v$ and $F_q$ (which vanish in reality) are added here for mathematical generality. The change of variable gives, for $\partial^2 \boldsymbol{v}/\partial z^2$, a term different from the coefficient of $\nu_v$. The expression above is simplified for of this coefficient; the simplification is legitimate because $\nu_v$ is a very small coefficient (in particular, $T$ has been replaced by $\bar{T}$ (known) average value of the temperature).

### Pseudogeometrical Domain

For physical and mathematical reasons, we do not allow the pressure to go to zero, and assume that $p \geq p_0$, with $p_0 > 0$ "small." Physically, in the very high atmosphere ($p$ very small), the air is ionized and the equations above are not valid anymore. The pressure is then restricted to an interval $p_0 < p < p_1$, where $p_1$ is a value of the pressure smaller in average than the pressure on Earth, so that the isobar $p = p_1$ is slightly above the Earth and the isobar $p = p_0$ is an isobar high in the sky. We study the motion of the air between these two isobars.

For the whole atmosphere, the boundary of this domain

$$\mathcal{M} = \{(\varphi, \theta, p), p_0 < p < p_1\}$$

consists first of an upper part $\Gamma_{\mathrm{u}}, p = p_0$; the lower part $p = p_1$ is divided into two parts $\Gamma_i$ the part of $p = p_1$ at the interface with the ocean, and $\Gamma_e$ the part of $p = p_1$ above the earth.

### Boundary Conditions

Typically, the boundary conditions are as follows:

**On the top of the atmosphere** $\Gamma_{\mathrm{u}}(p = p_0)$

$$\frac{\partial \boldsymbol{v}}{\partial p} = 0, \ \omega = 0, \ \frac{\partial T}{\partial p} = 0, \ \frac{\partial q}{\partial p} = 0 \quad [44]$$

# Gerbes in Quantum Field Theory

**J Mickelsson**, KTH Physics, Stockholm, Sweden

## Definitions and an Example

A gerbe can be viewed as a next step in a ladder of geometric and topological objects on a manifold which starts from ordinary complex-valued functions and in the second step of sections of complex line bundles.

It is useful to recall the construction of complex line bundles and their connections. Let $M$ be a smooth manifold and $\{U_\alpha\}$ an of open cover of $M$ which trivializes a line bundle $L$ over $M$. Topologically, up to equivalence, the line bundle is completely determined by its Chern class, which is a cohomology class $[c] \in H^2(M, \mathbb{Z})$. On each open set $U_\alpha$ we may write $2\pi i c = \mathrm{d}A_\alpha$, where $A_\alpha$ is a 1-form. On the overlaps $U_{\alpha\beta} = U_\alpha \cap U_\beta$ we can write

$$A_\alpha - A_\beta = f_{\alpha\beta}^{-1} \mathrm{d} f_{\alpha\beta} \qquad [1]$$

at least when $U_{\alpha\beta}$ is contractible, where $f_{\alpha\beta}$ is a circle-valued complex function on the overlap. The data $\{c, A_\alpha, f_{\alpha\beta}\}$ define what is known as a (representative of a) Deligne cohomology class on the open cover $\{U_\alpha\}$. The 1-forms $A_\alpha$ are the local potentials of the curvature form $2\pi i c$ and the $f_{\alpha\beta}$'s are the transition functions of the line bundle $L$. Each of these three different data defines separately the equivalence class of the line bundle but together they define the line bundle with a connection.

The essential thing here is that there is a bijection between the second integral cohomology of $M$ and the set of equivalence classes of complex line bundles over $M$. It is natural to ask whether there is a geometric realization of integral third (or higher) cohomology. In fact, gerbes provide such a realization. Here, we shall restrict to a smooth differential geometric approach which by no means is the most general possible, but it is sufficient for most applications to quantum field theory. However, there are examples of gerbes over orbifolds that do not need to come from finite group action on a manifold, which are not covered by the following definition.

For the examples in this article, it is sufficient to adapt the following definition. A gerbe over a manifold $M$ (without geometry) is simply a principal bundle $\pi: P \to M$ with fiber equal to $PU(H)$, the projective unitary group of a Hilbert space $H$. The Hilbert space may be either finite or infinite dimensional.

The quantum field theory applications discussed in this article are related to the chiral anomaly for

fermions in external fields. The link comes from the fact that the chiral symmetry breaking leads in the generic case to projective representations of the symmetry groups. For this reason, when modding out by the gauge or diffeomorphism symmetries, one is led to study bundles of projective Hilbert spaces. The anomaly is reflected as a nontrivial characteristic class of the projective bundle, known in mathematics literature as the Dixmier–Douady class.

In a suitable open cover, the bundle $P$ has a family of local trivializations with transition functions $g_{\alpha\beta}: U_{\alpha\beta} \to PU(H)$, with the usual cocycle property

$$g_{\alpha\beta} g_{\beta\gamma} g_{\gamma\alpha} = 1 \quad [2]$$

on triple overlaps. Assuming that the overlaps are contractible, we can choose lifts $\hat{g}_{\alpha\beta}: U_{\alpha\beta} \to U(H)$, to the unitary group of the Hilbert space. However,

$$\hat{g}_{\alpha\beta} \hat{g}_{\beta\gamma} \hat{g}_{\gamma\alpha} = f_{\alpha\beta\gamma} \quad [3]$$

where the $f$'s are circle-valued functions on triple overlaps. They satisfy automatically the cocycle property

$$f_{\alpha\beta\gamma} f^{-1}_{\alpha\beta\delta} f_{\alpha\gamma\delta} f^{-1}_{\beta\gamma\delta} = 1 \quad [4]$$

on quadruple overlaps. There is an important difference between the finite- and infinite-dimensional cases. In the finite-dimensional case, the circle bundle $U(H) \to U(H)/S^1 = PU(H)$ reduces to a bundle with fiber $\mathbb{Z}/N\mathbb{Z} = \mathbb{Z}_N$, where $N = \dim H$. This follows from $\mathrm{U}(N)/S^1 = \mathrm{SU}(N)/Z_N$ and the fact that $\mathrm{SU}(N)$ is a subgroup of $\mathrm{U}(N)$. For this reason one can choose the lifts $\hat{g}_{\alpha\beta}$ such that the functions $f_{\alpha\beta\gamma}$ take values in the finite subgroup $\mathbb{Z}_N \subset S^1$.

The functions $f_{\alpha\beta\gamma}$ define an element $a = \{a_{\alpha\beta\gamma\delta}\}$ in the Čech cohomology $H^3(\mathcal{U}, \mathbb{Z})$ by a choice of logarithms,

$$2\pi i a_{\alpha\beta\gamma\delta} = \log f_{\alpha\beta\gamma} - \log f_{\alpha\beta\delta} + \log f_{\alpha\gamma\delta} - \log f_{\beta\gamma\delta} \quad [5]$$

In the finite-dimensional case, the Čech cocycle is necessarily torsion, $Na = 0$, but not so if $H$ is infinite dimensional. In the finite-dimensional case (by passing to a good cover and using the Čech – de Rham equivalence over real or complex numbers), the class is third de Rham cohomology constructed from the transition functions is necessarily zero. Thus, in general one has to work with Čech cohomology to preserve torsion information. One can prove:

**Theorem** *The construction above is a one-to-one map between the set of equivalence classes of* $PU(H)$ *bundles over M and elements of* $H^3(M, \mathbb{Z})$.

The characteristic class in $H^3(M, \mathbb{Z})$ of a $PU(H)$ bundle is called the *Dixmier–Douady class*.

### First example

Let $M$ be an oriented Riemannian manifold and $FM$ its bundle of oriented orthonormal frames. The structure group of $FM$ is the rotation group $\mathrm{SO}(n)$ with $n = \dim M$. The spin bundle (when it exists) is a double covering $\mathrm{Spin}(M)$ of $FM$, with structure group $\mathrm{Spin}(n)$, a double cover of $\mathrm{SO}(n)$. Even when the spin bundle does not exist there is always the bundle $\mathrm{Cl}(M)$ of Clifford algebras over $M$. The fiber at $x \in M$ is the Clifford algebra defined by the metric $g_x$, that is, it is the complex $2^n$-dimensional algebra generated by the tangent vectors $v \in T_x(m)$ with the defining relations

$$\gamma(u)\gamma(v) + \gamma(v)\gamma(u) = 2g_x(u, v)$$

The Clifford algebra has a faithful representation in $N = 2^{[n/2]}$ dimensions ($[x]$ is the integral part of $x$) such that

$$\gamma(a \cdot u) = S(a)\gamma(u)S(a)^{-1}$$

where $S$ is an unitary representation of $\mathrm{Spin}(n)$ in $\mathbb{C}^N$. Since $\mathrm{Spin}(n)$ is a double cover of $\mathrm{SO}(n)$, the representation $S$ may be viewed as a projective representation of $\mathrm{SO}(n)$. Thus again, if the overlaps $U_{\alpha\beta}$ are contractible, we may choose a lift of the frame bundle transition functions $g_{\alpha\beta}$ to unitaries $\hat{g}_{\alpha\beta}$ in $H = \mathbb{C}^N$. In this case, the functions $f_{\alpha\beta\gamma}$ reduce to $\mathbb{Z}_2$-valued functions, and the obstruction to the lifting problem, which is the same as the obstruction to the existence of spin structure, is an element of $H^2(M, \mathbb{Z}_2)$, known as the second Stiefel–Whitney class $w_2$. The image of $w_2$ with respect to the Bockstein map (in this case, given by the formula [5]) gives a 2-torsion element in $H^3(M, \mathbb{Z})$, the Dixmier–Douady class.

Another way to think of a gerbe is the following (we shall see that this arises in a natural way in quantum field theory). There is a canonical complex line bundle $L$ over $PU(H)$, the associated line bundle to the circle bundle $S^1 \to U(H) \to PU(H)$. Pulling back $L$ by the local transition functions $g_{\alpha\beta} \to PU(H)$, we obtain a family of line bundles $L_{\alpha\beta}$ over the open sets $U_{\alpha\beta}$. By the cocycle property [2] we have natural isomorphisms

$$L_{\alpha\beta} \otimes L_{\beta\gamma} = L_{\alpha\gamma} \quad [6]$$

We can take this as a definition of a gerbe over $M$: a collection of line bundles over intersections of open sets in an open cover of $M$, satisfying the cocycle condition [6]. By [6] we have a trivialization

$$L_{\alpha\beta} \otimes L_{\beta\gamma} \otimes L_{\gamma\alpha} = f_{\alpha\beta\gamma} \cdot \mathbf{1} \quad [7]$$

where the $f$'s are circle-valued functions on the triple overlaps. By the theorem above, we conclude

that indeed the data in [6] define (an equivalence class of) a principal $PU(H)$ bundle.

If $L_{\alpha\beta}$ and $L'_{\alpha\beta}$ are two systems of local line bundles over the same cover, then the gerbes are equivalent if there is a system of line bundles $L_\alpha$ over open sets $U_\alpha$ such that

$$L'_{\alpha\beta} = L_{\alpha\beta} \otimes L^*_\alpha \otimes L_\beta \qquad [8]$$

on each $U_{\alpha\beta}$.

A gerbe may come equipped with geometry, encoded in a Deligne cohomology class with respect to a given open covering of $M$. The Deligne class is given by functions $f_{\alpha\beta\gamma}$, 1-forms $A_{\alpha\beta}$, 2-forms $F_\alpha$, and a global 3-form (the Dixmier–Douady class of the gerbe) $\Omega$, subject to the conditions

$$\begin{aligned} dF_\alpha &= 2\pi i\Omega \\ F_\alpha - F_\beta &= dA_{\alpha\beta} \\ A_{\alpha\beta} - A_{\alpha\gamma} + A_{\beta\gamma} &= f^{-1}_{\alpha\beta\gamma} df_{\alpha\beta\gamma} \end{aligned} \qquad [9]$$

## Gerbes from Canonical Quantization

Let $D_x$ be a family of self-adjoint Fredholm operators in a complex Hilbert space $H$ parametrized by $x \in M$. This situation arises in quantum field theory, for example, when $M$ is some space of external fields, coupled to Dirac operator $D$ on a compact manifold. The space $M$ might consist of gauge potentials (modulo gauge transformations) or $M$ might be the moduli space of Riemann metrics. In these examples, the essential spectrum of $D_x$ is both positive and negative and the family $D_x$ defines an element of $K^1(M)$. In fact, one of the definitions of $K^1(M)$ is that its elements are homotopy classes of maps from $M$ to the space $\mathcal{F}_*$ of self-adjoint Fredholm operators with both positive and negative essential spectrum. In physics applications, one deals most often with unbounded Hamiltonians, and the operator norm topology must be replaced by something else; popular choices are the Riesz topology defined by the map $F \mapsto F/(|F|+1)$ to bounded operators or the gap topology defined by graph metric.

The space $\mathcal{F}_*$ is homotopy equivalent to the group $G = U_1(H)$ of unitary operators $g$ in $H$ such that $g-1$ is a trace-class operator. This space is a classifying space for principal $U_{res}$ bundles, where $U_{res}$ is the group of unitary operators $g$ in a polarized complex Hilbert space $\mathcal{H} = \mathcal{H}_+ \oplus \mathcal{H}_-$ such that the off-diagonal blocks of $g$ are Hilbert–Schmidt operators. This is related to Bott periodicity. There is a natural principal bundle $P$ over $G = U_1(H)$ with fiber equal to the group $\Omega G$ of based loops in $G$. The total space $P$ consists of smooth paths $f(t)$ in $G$ starting from the neutral element such that $f^{-1}df$ is smooth and periodic. The projection $P \to G$ is the evaluation at the end point $f(1)$. The fiber is clearly $\Omega G$. By Bott periodicity, the homotopy groups of $\Omega G$ are shifted from those of $G$ by one dimension, that is,

$$\pi_n \Omega G = \pi_{n+1} G$$

The latter are zero in even dimensions and equal to $\mathbb{Z}$ in odd dimensions. On the other hand, it is known that the even homotopy groups of $U_{res}(\mathcal{H})$ are equal to $\mathbb{Z}$ and the odd ones vanish. In fact, with a little more effort, one can show that the embedding of $\Omega G$ to $U_{res}(\mathcal{H})$ is a homotopy equivalence, when $\mathcal{H} = L^2(S^1, H)$, the polarization being the splitting to nonnegative and negative Fourier modes and the action of $\Omega G$ is the pointwise multiplication on $H$-valued functions on the circle $S^1$.

Since $P$ is contractible, it is indeed the classifying bundle for $U_{res}$ bundles. Thus, we conclude that "$K^1(M)$ = the set of homotopy classes of maps $M \to G$ = the set of equivalence classes of $U_{res}$ bundles over $M$." The relevance of this fact in quantum field theory follows from the properties of representations of the algebra of canonical anticommutation relations ($CAR$). For any complex Hilbert space $H$, this algebra is the algebra generated by elements $a(v)$ and $a^*(v)$, with $v \in H$, subject to the relations

$$a^*(u)a(v) + a(v)a^*(u) = 2 < v, u >$$

where the Hilbert space inner product on the right-hand side is antilinear in the first argument, and all other anticommutators vanish. In addition, $a^*(u)$ is linear and $a(v)$ antilinear in its argument.

An irreducible Dirac representation of the CAR algebra is given by a polarization $H = H_+ \oplus H_-$. The representation is characterized by the existence of a vacuum vector $\psi$ in the fermionic Fock space $\mathcal{F}$ such that

$$a^*(u)\psi = 0 = a(v)\psi \quad \text{for } u \in H_-,\ v \in H_+ \qquad [10]$$

A theorem of D Shale and W F Stinespring says that two Dirac representations defined by a pair of polarizations $H_+, H'_+$ are equivalent if and only if there is $g \in U_{res}(H_+ \oplus H_-)$ such that $H'_+ = g \cdot H_+$. In addition, in order that a unitary transformation $g$ is implementable in the Fock space, that is, there is a unitary operator $\hat{g}$ in $\mathcal{F}$ such that

$$\hat{g} a^*(v) \hat{g}^{-1} = a^*(gv), \quad \forall v \in H \qquad [11]$$

and similarly for the $a(v)$'s, one must have $g \in U_{res}$ with respect to the polarization defining the vacuum vector. This condition is both necessary and sufficient.

The polarization of the one-particle Hilbert space comes normally from a spectral projection onto the positive-energy subspace of a Hamilton operator. In the background field problems one studies families of Hamilton operators $D_x$ and then one would like to construct a family of fermionic Fock spaces parametrized by $x \in M$. If none of the Hamilton operators has zero modes, this is unproblematic. However, the presence of zero modes makes it impossible to define the positive-energy subspace $H_+(x)$ as a continuous function of $x$. One way out of this is to weaken the condition for the polarization: each $x \in M$ defines a Grassmann manifold $\mathrm{Gr}_{\mathrm{res}}(x)$ consisting of all subspaces $W \subset H$ such that the projections onto $W$ and $H_+(x)$ differ by Hilbert–Schmidt operators. The definition of $\mathrm{Gr}_{\mathrm{res}}(x)$ is stable with respect to finite-rank perturbations of $D_x/|D_x|$. For example, when $D_x$ is a Dirac operator on a compact manifold then $(D_x - \lambda)/|D_x - \lambda|$ defines the same Grassmannian for all real numbers $\lambda$ because in each finite interval there are only a finite number of eigenvalues (with multiplicities) of $D_x$. From this follows that the Grassmannians form a locally trivial fiber bundle Gr over families of Dirac operators.

If the bundle Gr has a global section $x \mapsto W_x$ then we can define a bundle of Fock space representations for the CAR algebra over the parameter space $M$. However, there are important situations when no global sections exist. It is easier to explain the potential obstruction in terms of a principal $U_{\mathrm{res}}$ bundle $P$ such that Gr is an associated bundle to $P$.

The fiber of $P$ at $x \in M$ is the set of all unitaries $g$ in $H$ such that $g \cdot H_+ \in \mathrm{Gr}_x$ where $H = H_+ \oplus H_-$ is a fixed reference polarization. Then we have

$$\mathrm{Gr} = P \times_{U_{\mathrm{res}}} \mathrm{Gr}_{\mathrm{res}},$$

where the right action of $U_{\mathrm{res}} = U_{\mathrm{res}}(H_+ \oplus H_-)$ in the fibers of $P$ is the right multiplication on unitary operators and the left action on $\mathrm{Gr}_{\mathrm{res}}$ comes from the observation that $\mathrm{Gr}_{\mathrm{res}} = U_{\mathrm{res}}/(U_+ \times U_-)$, where $U_\pm$ are the diagonal block matrices in $U_{\mathrm{res}}$. By a result of N Kuiper, the subgroup $U_- \times U_-$ is contractible and so Gr has a global section if and only if $P$ is trivial.

Thus, when $P$ is trivial we can define the family of Dirac representations of the CAR algebra parametrized by $M$ such that in each of the Fock spaces we have a Dirac vacuum which, in a precise sense, is close to the vacuum defined by the energy polarization. However, the triviality of $P$ is not a necessary condition. Actually, what is needed is that $P$ has a prolongation to a bundle $\hat{P}$ with fiber $\hat{U}_{\mathrm{res}}$. The group $\hat{U}_{\mathrm{res}}$ is a central extension of $U_{\mathrm{res}}$ by the group $S^1$.

The Lie algebra $\hat{\boldsymbol{u}}_{\mathrm{res}}$ is as a vector space the direct sum $\boldsymbol{u}_{\mathrm{res}} \oplus \mathrm{i}\mathbb{R}$, with commutators

$$[X + \lambda, Y + \mu] = [X, Y] + c(X, Y) \qquad [12]$$

where $c$ is the Lie algebra cocycle

$$c(X, Y) = \tfrac{1}{4}\mathrm{tr}\,\epsilon[\epsilon, X][\epsilon, Y] \qquad [13]$$

Here $\epsilon$ is the grading operator with eigenvalues $\pm 1$ on $H_\pm$. The trace exists since the off diagonal blocks of $X, Y$ are Hilbert–Schmidt.

The group $\hat{U}_{\mathrm{res}}$ is a circle bundle over $U_{\mathrm{res}}$. The Chern class of the associated complex line bundle is the generator of $H^2(U_{\mathrm{res}}, \mathbb{Z})$ and is given explicitly at the identity element as the antisymmetric bilinear form $c/2\pi\mathrm{i}$ and at other points on the group manifold through left-translation of $c/2\pi\mathrm{i}$. If $P$ is trivial, then it has an obvious prolongation to the trivial bundle $M \times \hat{U}_{\mathrm{res}}$. In any case, if the prolongation exists we can define the bundle of Fock spaces carrying CAR representations as the associated bundle

$$\mathcal{F} = \hat{P} \times_{\hat{U}_{\mathrm{res}}} \mathcal{F}_0$$

where is $\mathcal{F}_0$ is the fixed Fock space defined by the same polarization $H = H_+ \oplus H_-$ used to define $U_{\mathrm{res}}$. By the Shale–Stinespring theorem, any $g \in U_{\mathrm{res}}$ has an implementation $\hat{g}$ in $\mathcal{F}_0$, but $\hat{g}$ is only defined up to phase, thus the central $S^1$ extension.

The action of the CAR algebra in the fibers is given as follows. For $x \in M$ choose any $\hat{g} \in \hat{P}_x$. Define

$$a^*(v) \cdot (\hat{g}, \psi) = (\hat{g}, a^*(g^{-1}v)\psi)$$

where $\psi \in \mathcal{F}_0$ and $v \in H$; similarly for the operators $a(v)$. It is easy to check that this definition passes to the equivalence classes in $\mathcal{F}$. Note that the representations in different fibers are in general inequivalent because the tranformation $g$ is not implementable in the Fock space $\mathcal{F}_0$.

The potential obstruction to the existence of the prolongation of $P$ is again a 3-cohomology class on the base. Choose a good cover of $M$. On the intersections $U_{\alpha\beta}$ of the open cover the transition functions $g_{\alpha\beta}$ of $P$ can be prolonged to functions $\hat{g}_{\alpha\beta} : U_{\alpha\beta} \to \hat{U}_{\mathrm{res}}$. We have

$$\hat{g}_{\alpha\beta}\hat{g}_{\beta\gamma}\hat{g}_{\gamma\alpha} = f_{\alpha\beta\gamma} \cdot 1 \qquad [14]$$

for functions $f_{\alpha\beta\gamma} : U_{\alpha\beta\gamma} \to S^1$, which by construction satisfy the cocycle property [4]. Since the cocycle is defined on a good cover, it defines an integral Čech cohomology class $\omega \in H^3(M, \mathbb{Z})$.

Let us return to the universal $U_{\mathrm{res}}$ bundle $P$ over $G = U_1(H)$. In this case the prolongation obstruction can be computed relatively easily. It turns out that

the 3-cohomology class is represented by the de Rham class which is the generator of $H^3(G, \mathbb{Z})$. Explicitly,

$$\omega = \frac{1}{24\pi^2} \mathrm{tr}\,(g^{-1}\mathrm{d}g)^3 \qquad [15]$$

Any principal $U_{\mathrm{res}}$ bundle over $M$ comes from a pullback of $P$ with respect to a map $f: M \to G$, so the Dixmier–Douady class in the general case is the pullback $f^*\omega$.

The line bundle construction of the gerbe over the parameter space $M$ for Dirac operators is given by the observation that the spectral subspaces $E_{\lambda\lambda'}(x)$ of $D_x$, corresponding to the open interval $]\lambda,\lambda'[$ in the real line, form finite-rank vector bundles over open sets $U_{\lambda\lambda'} = U_\lambda \cap U_{\lambda'}$. Here $U_\lambda$ is the set of points $x \in M$ such that $\lambda$ does not belong to the spectrum of $D_x$. Then we can define, as top exterior power,

$$L_{\lambda\lambda'} = \bigwedge^{\mathrm{top}}(E_{\lambda\lambda'})$$

as the complex vector bundle over $U_{\lambda\lambda'}$. It follows immediately from the definition that the cocycle property [6] is satisfied.

**Example 1** (Fermions on an interval). Let $K$ be a compact group and $\rho$ its unitary representation in a finite-dimensional vector space $V$. Let $H$ be the Hilbert space of square-integrable $V$-valued functions on the interval $[0, 2\pi]$ of the real axis. For each $g \in K$ let $\mathrm{Dom}_g \subset H$ be the dense subspace of smooth functions $\psi$ with the boundary condition $\psi(2\pi) = \rho(g)\psi(0)$. Denote by $D_g$ the operator $-\mathrm{i}\,\mathrm{d}/\mathrm{d}x$ on this domain. The spectrum of $D_g$ is a function of the eigenvalues $\lambda_k$ of $\rho(g)$, consisting of real numbers $n + \log(\lambda_k)/2\pi\mathrm{i}$ with $n \in \mathbb{Z}$. For this reason the splitting of the one-particle space $H$ to positive and negative modes of the operator $D_g$ is in general not continuous as function of the parameter $g$. This leads to the problems described above. However, the principal $U_{\mathrm{res}}$ bundle can be explicitly constructed. It is the pullback of the universal bundle $P$ with respect to the map $f: K \to G$ defined by the embedding $\rho(K) \subset G$ as $N \times N$ block matrices, $N = \dim V$. Thus, the Dixmier–Douady class in this example is

$$\omega = \frac{1}{24\pi^2} \mathrm{tr}\,(\rho(g)^{-1}\ \mathrm{d}\rho(g))^3 \qquad [16]$$

**Example 2** (Fermions on a circle). Let $H = L^2(S^1, V)$ and $D_A = -\mathrm{i}(\mathrm{d}/\mathrm{d}x + A)$ where $A$ is a smooth vector potential on the circle taking values in the Lie algebra $\boldsymbol{k}$ of $K$. In this case, the domain is fixed, consisting of smooth $V$-valued functions on the circle. The $\boldsymbol{k}$-valued function $A$ is represented as a multiplication operator through the representation $\rho$ of $K$. The parameter space $\mathcal{A}$ of smooth vector potentials is flat; thus, there cannot be any obstruction to the prolongation problem. However, in quantum field theory, one wants to pass to the moduli space $\mathcal{A}/\mathcal{G}$ of gauge potentials. Here $\mathcal{G}$ is the group of smooth based gauge transformations, that is, $\mathcal{G} = \Omega K$. Now the moduli space is the group of holonomies around the circle, $\mathcal{A}/\mathcal{G} = K$. Thus, we are in a similar situation as in Example 1. In fact, these examples are really two different realizations of the same family of self-adjoint Fredholm operators. The operator $D_A$ with $k = \mathrm{holonomy}(A)$ has exactly the same spectrum as $D_k$ in Example 1. For this reason, the Dixmier–Douady class on $K$ is the same as before.

The case of Dirac operators on the circle is simple because all the energy polarizations for different vector potentials are elements in a single Hilbert–Schmidt Grassmannian $\mathrm{Gr}(H_+ \oplus H_-)$, where we can take as the reference polarization the splitting to positive and negative Fourier modes. Using this polarization, the bundle of fermionic Fock spaces over $\mathcal{A}$ can be trivialized as $\mathcal{F} = \mathcal{A} \times \mathcal{F}_0$. However, the action of the gauge group $\mathcal{G}$ on $\mathcal{F}$ acquires a central extension $\hat{\mathcal{G}} \subset \widehat{LK}$, where $LK$ is the free loop group of $K$. The Lie algebra cocycle determining the central extension is

$$c(X, Y) = \frac{1}{2\pi\mathrm{i}} \int_{S^1} \mathrm{tr}_\rho X\ \mathrm{d}Y \qquad [17]$$

where $\mathrm{tr}_\rho$ is the trace in the representation $\rho$ of $K$. Because of the central extension, the quotient $\mathcal{F}/\hat{\mathcal{G}}$ defines only a projective vector bundle over $\mathcal{A}/\mathcal{G}$, the Dixmier–Douady class being given by [16].

In the Example 1 (and Example 2) above, the complex line bundles can be constructed quite explicitly. Let us study the case $K = \mathrm{SU}(n)$. Define $U_\lambda \subset K$ as the set of matrices $g$ such that $\lambda$ is not an eigenvalue of $g$. Select $n$ different points $\lambda_j$ on the unit circle such that their product is not equal to 1. We assume that the points are ordered counterclockwise on the circle. Then the sets $U_j = U_{\lambda_j}$ form an open cover of $\mathrm{SU}(n)$. On each $U_j$ we can choose a continuous branch of the logarithmic function $\log: U_j \to \boldsymbol{su}(\boldsymbol{n})$. The spectrum of the Dirac operator $D_g$ with the holonomy $g$ consists of the infinite set of numbers $\mathbb{Z} + \mathrm{Spec}(-\mathrm{i}\log(g))$. In particular, the numbers $\mathbb{Z} - \mathrm{i}\log\lambda_j$ do not belong to the spectrum of $D_g$. Choosing $\mu_k = -\mathrm{i}\log\lambda_k$ as an increasing sequence in the interval $[0, 2\pi]$, we can as well define $U_j = \{x \in M | \mu_j \notin \mathrm{Spec}(D_x)\}$. In any case, the

top exterior power of the spectral subspace $E_{\mu_j,\mu_k}(x)$ is given by zero Fourier modes consisting of the spectral subspace of the holonomy $g$ in the segment $[\lambda_j, \lambda_k]$ of the unit circle.

## Index Theory and Gerbes

Gauge and gravitational anomalies in quantum field theory can be computed by Atiyah–Singer index theory. The basic setup is as follows. On a compact even-dimensional spin manifold $S$ (without boundary) the Dirac operators coupled to vector potentials and metrics form a family of Fredholm operators. The parameter space is the set $\mathcal{A}$ of smooth vector potentials (gauge connections) in a vector bundle over $S$ and the set of smooth Riemann metrics on $S$. The family of Dirac operators is covariant with respect to gauge transformations and diffeomorphisms of $S$; thus, we may view the Dirac operators parametrized by the moduli space $\mathcal{A}/\mathcal{G}$ of gauge connections and the moduli space $\mathcal{M}/\mathrm{Diff}_0(S)$ of Riemann metrics. Again, in order that the moduli spaces are smooth manifolds, one has to restrict to the based gauge transformations, that is, those which are equal to the neutral element in a fixed base point in each connected component of $S$. Similarly, the Jacobian of a diffeomorphism is required to be equal to the identity matrix at the base points. Passing to the quotient modulo gauge transformations and diffeomorphims, we obtain a vector bundle over the space

$$S \times \mathcal{A}/\mathcal{G} \times \mathcal{M}/\mathrm{Diff}_0(S) \qquad [18]$$

Actually, we could as well consider a generalization in which the base space is a fibering over the moduli space with model fiber equal to $S$, but for simplicity we stick to [18].

According to the Atiyah–Singer index formula for families, the K-theory class of the family of Dirac operators acting on the smooth sections of the tensor product of the spin bundle and the vector bundle $V$ over [18] is given through the differential forms

$$\hat{A}(R) \wedge \mathrm{ch}(V)$$

where $\hat{A}(R)$ is the A-roof genus, a function of the Riemann curvature tensor $R$ associated with the Riemann metric,

$$\hat{A}(R) = \det{}^{1/2}\left(\frac{R/4\pi \mathrm{i}}{\sinh(R/4\pi \mathrm{i})}\right)$$

and $\mathrm{ch}(V)$ is the Chern character

$$\mathrm{ch}(V) = \mathrm{tr}\, \mathrm{e}^{F/2\pi \mathrm{i}}$$

where $F$ is the curvature tensor of a gauge connection. Here both $R$ and $F$ are forms on the infinite-dimensional base space [18]. After integrating over the fiber $S$,

$$\mathrm{Ind} = \int_S \hat{A}(R) \wedge \mathrm{ch}(V) \qquad [19]$$

we obtain a family of differential forms $\phi_{2k}$, one in each even dimension, on the moduli space.

The (cohomology classes of) forms $\phi_{2k}$ contain important topological information for the quantized Yang–Mills theory and for quantum gravity. The form $\phi_2$ describes potential chiral anomalies. The chiral anomaly is a manifestation of gauge or reparametrization symmetry breaking. If the class $[\phi_2]$ is nonzero, the quantum effective action cannot be viewed as a function on the moduli space. Instead, it becomes a section of a complex line bundle DET over the moduli space.

Since the Dirac operators are Fredholm (on compact manifolds), at a given point in the moduli space we can define the complex line

$$\mathrm{DET}_x = \bigwedge^{\mathrm{top}}(\ker D_x^+) \otimes \bigwedge^{\mathrm{top}}(\mathrm{coker}\, D_x^+) \qquad [20]$$

for the chiral Dirac operators $D_x^+$. In the even-dimensional case, the spin bundle is $\mathbb{Z}_2$ graded such that the grading operator $\Gamma$ anticommutes with $D_x$. Then $D_x^+ = P_- D_x P_+$, where $P_\pm = (1/2)(1 \pm \Gamma)$ are the chiral projections. $\wedge^{\mathrm{top}}$ means the operation on finite-dimensional vector spaces $W$ taking the exterior power of $W$ to dim $W$.

When the dimensions of the kernel and cokernel of $D_x$ are constant, eqn [20] defines a smooth complex line bundle over the moduli space. In the case of varying dimensions, a little extra work is needed to define the smooth structure.

The form $\phi_2$ is the Chern class of DET. So if DET is nontrivial, gauge covariant quantization of the family of Dirac operators is not possible.

One can also give a geometric and topological meaning to the chiral symmetry breaking in Hamiltonian quantization, and this leads us back to gerbes on the moduli space. Here we have to use an odd version of the index formula [19]. Assuming that the physical spacetime is even dimensional, at a fixed time the space is an odd-dimensional manifold $S$. We still assume that $S$ is compact. In this case, the integration in [19] is over odd-dimensional fibers and, therefore, the formula produces a sequence of odd forms on the moduli space.

The first of the odd forms $\phi_1$ gives the spectral flow of a one-parameter family of operators $D_{x(s)}$. Its integral along the path $x(t)$, after a correction by the difference of the eta invariant at the end points

of the path, in the moduli space, gives twice the difference of positive eigenvalues crossing over to the negative side of the spectrum minus the flow of eigenvalues in the opposite direction. The second term $\phi_3$ is the Dixmier–Douady class of the projective bundle of Fock spaces over the moduli space. In Examples 1 and 2, the index theory calculation gives exactly the form [16] on $K$.

**Example** Consider Dirac operators on the three-dimensional sphere $S^3$ coupled to vector potentials. Any vector bundle on $S^3$ is trivial, so let $V = S^3 \times \mathbb{C}^N$. Take SU($N$) as the gauge group and let $\mathcal{A}$ be the space of 1-forms on $S^3$ taking values in the Lie algebra $\boldsymbol{su}(N)$ of SU($N$). Fix a point $x_s$ on $S^3$, the "south pole," and let $\mathcal{G}$ be the group of gauge transformations based at $x_s$. That is, $\mathcal{G}$ consists of smooth functions $g: S^3 \to \mathrm{SU}(N)$ with $g(x_s) = 1$. In this case $\mathcal{A}/\mathcal{G}$ can be identified as $\mathrm{Map}(S^2, \mathrm{SU}(N))$ times a contractible space. This is because any point $x$ on the equator of $S^3$ determines a unique semicircle from the south pole to the north pole through $x$. The parallel transport along this path with respect to a vector potential $A \in \mathcal{A}$ defines an element $g'_A(x) \in \mathrm{SU}(N)$, using the fixed trivialization of $V$. Set $g_A(x) = g'_A(x) g'_A(x_0)^{-1}$, where $x_0$ is a fixed point on the equator. The element $g_A(x)$ then depends only on the gauge equivalence class $[A] \in \mathcal{A}/\mathcal{G}$. It is not difficult to show that the map $A \mapsto g_A$ is a homotopy equivalence from the moduli space of gauge potentials to the group $\mathcal{G}_2 = \mathrm{Map}_{x_0}(S^2, \mathrm{SU}(N))$, based at $x_0$. When $N > 2$, the cohomology $H^5(\mathrm{SU}(N), \mathbb{Z}) = \mathbb{Z}$ transgresses to the cohomology $H^3(\mathcal{G}_2, \mathbb{Z}) = \mathbb{Z}$. In particular, the generator

$$\omega_5 = \left(\frac{\mathrm{i}}{2\pi}\right)^3 \frac{2}{5!} \mathrm{tr}(g^{-1}\,\mathrm{d}g)^5$$

of $H^5(\mathrm{SU}(N), \mathbb{Z})$ gives the generator of $H^3(\mathcal{G}_2, \mathbb{Z})$ by contraction and integration,

$$\Omega = \int_{S^2} \omega_5$$

## Gauge Group Extensions

The new feature for gerbes associated with Dirac operators in higher than one dimension is that the gauge group, acting on the bundle of Fock spaces parametrized by vector potentials, is represented through an abelian extension. On the Lie algebra level this means that the Lie algebra extension is not given by a scalar cocycle $c$ as in the one-dimensional case but by a cocycle taking values in an abelian Lie algebra. In the case of Dirac operators coupled to vector potentials, the abelian Lie algebra consists of a certain class of complex functions on $\mathcal{A}$. The extension is then defined by the commutators

$$[(X,\alpha),(Y,\beta)] = ([X,Y], \mathcal{L}_X\beta - \mathcal{L}_Y\alpha + c(X,Y)) \quad [21]$$

where $\alpha, \beta$ are functions on $\mathcal{A}$ and $\mathcal{L}_X\beta$ denotes the Lie derivative of $\beta$ in the direction of the infinitesimal gauge transformation $X$. The 2-cocycle property of $c$ is expressed as

$$c([X,Y],Z) + \mathcal{L}_X c(Y,Z) + \text{cyclic permutations of } X, Y, Z = 0$$

In the case of Dirac operators on a 3-manifold $S$ the form $c$ is the Mickelsson–Faddeev cocycle

$$c(X,Y) = \frac{i}{12\pi^2} \int_S \mathrm{tr}_\rho A \wedge (\mathrm{d}X \wedge \mathrm{d}Y - \mathrm{d}Y \wedge \mathrm{d}X) \quad [22]$$

The corresponding gauge group extension is an extension of $\mathrm{Map}(S, G)$ by the normal subgroup $\mathrm{Map}(\mathcal{A}, S^1)$. As a topological space, the extension is the product

$$\mathrm{Map}(\mathcal{A}, S^1) \times_{S^1} P$$

where $P$ is a principal $S^1$ bundle over $\mathrm{Map}(S, G)$.

The Chern class $c_1$ of the bundle $P$ is again computed by transgression from $\omega_5$; this time

$$c_1 = \int_S \omega_5$$

In fact, we can think of the cocycle $c$ as a 2-form on the space of flat vector potentials $A = g^{-1}\mathrm{d}g$ with $g \in \mathrm{Map}(S^3, G)$. Then one can show that the cohomology classes $[c]$ and $[c_1]$ are equal.

As we have seen, the central extension of a loop group is the key to understanding the quantum field theory gerbe. Here is a brief description of it starting from the 3-form [16] on a compact Lie group $G$. First define a central extension $\mathrm{Map}(D, G) \times S^1$ of the group of smooth maps from the unit disk $D$ to $G$, with pointwise multiplication. The group multiplication is given as

$$(g, \lambda) \cdot (g', \lambda') = (gg', \lambda\lambda' \cdot \mathrm{e}^{2\pi \mathrm{i}\gamma(g,g')})$$

where

$$\gamma(g, g') = \frac{1}{8\pi^2} \int_D \mathrm{tr}_\rho\, g^{-1}\mathrm{d}g \wedge \mathrm{d}g' g'^{-1} \quad [23]$$

where the trace is computed in a fixed unitary representation $\rho$ of $G$. This group contains as a normal subgroup the group $N$ consisting of pairs $(g, \mathrm{e}^{2\pi \mathrm{i} C(g)})$ with

$$C(g) = \frac{1}{24\pi^2} \int_B \mathrm{tr}_\rho\, (g^{-1}\mathrm{d}g)^3 \quad [24]$$

Here $g(x) = 1$ on the boundary circle $S^1 = \partial D$, and thus can be viewed as a function $S^2 \to G$. The three-dimensional unit ball $B$ has $S^2$ as a boundary and $g$ is extended in an arbitrary way from the boundary to the ball $B$. The extension is possible since $\pi_2(G) = 0$ for any finite-dimensional Lie group. The value of $C(g)$ depends on the extension only modulo an integer and therefore $e^{2\pi i C(g)}$ is well defined.

The central extension is then defined as

$$\widehat{LG} = (\mathrm{Map}(D, G) \times S^1)/N$$

One can show easily that the Lie algebra of $\widehat{LG}$ is indeed given through the cocycle [17]. When $G = \mathrm{SU}(n)$ in the defining representation, this central extension is the basic extension: The cohomology class is the generator of $H^2(LG, \mathbb{Z})$. In general, to obtain the basic extension one has to correct [23] and [24] by a normalization factor.

This construction generalizes to the higher loop groups $\mathrm{Map}(S, G)$ for compact odd-dimensional manifolds $S$. For example, in the case of a 3-manifold, one starts from an extension of $\mathrm{Map}(D, G)$, where $D$ is a 4-manifold with boundary $S$. The extension is defined by a 2-cocycle $\gamma$, but now for given $g, g'$ the cocycle $\gamma$ is a real-valued function of a point $g_0 \in \mathrm{Map}(S, G)$, which is a certain differential polynomial in the Maurer–Cartan 1-forms $g_0^{-1} dg_0, g^{-1} dg, g^{-1} dg$. The normal subgroup $N$ is defined in a similar way; now $C(g)$ is the integral of the 5-form $\omega_5$ over a 5-manifold $B$ with boundary $\partial B$ identified as $D/\sim$, the equivalence shrinking the boundary of $D$ to one point. This gives the extension only over the connected component of identity in $\mathrm{Map}(S, G)$, but it can be generalized to the whole group. For example, when $S = S^3$ and $G$ is simple, the connected components are labeled by elements of the third homotopy group $\pi_3 G = \mathbb{Z}$.

In some cases, the de Rham cohomology class of the extension vanishes but the extension still contains interesting torsion information. In quantum field theory this comes from Hamiltonian formulation of global anomalies. A typical example of this phenomenon is the Witten SU(2) anomaly in four spacetime dimensions. In the Hamiltonian formulation, we take $S^3$ as the physical space, the gauge group $G = \mathrm{SU}(2)$. In this case, the second cohomology of $\mathrm{Map}(S^3, G)$ becomes pure torsion, related to the fact that the 5-form $\omega_5$ on SU(2) vanishes for dimensional reasons. Here the homotopy group $\pi_4(G) = \mathbb{Z}_2$ leads the nontrivial fundamental group $\mathbb{Z}_2$ in each connected component of $\mathrm{Map}(S^3, G)$. Using this fact, one can show that there is a nontrivial $\mathbb{Z}_2$ extension of the group $\mathrm{Map}(S^3, G)$.

# Ginzburg–Landau Equation

**Y Morita**, Ryukoku University, Otsu, Japan

## Introduction

In the Ginzburg–Landau theory of superconductivity, a complex order parameter $\Psi$ characterizes a macroscopic/mesoscopic superconducting state in a bulk superconductor. The square of the magnitude $|\Psi|^2$ expresses the density of superconducting electrons and $\Psi$ is regarded as a macroscopic wave function. With a magnetic vector potential $\mathbb{A}$ and the order parameter $\Psi$, the Helmholtz free energy density in a superconducting material near the critical temperature is given by

$$F = F_n + \alpha|\Psi|^2 + \frac{\beta}{2}|\Psi|^4 + \frac{1}{2m_s}\left|\left(-i\hbar\nabla - \frac{e_s}{c}\mathbb{A}\right)\Psi\right|^2 + \frac{|\mathbb{H}|^2}{8\pi}$$

where $F_n$ denotes the energy density of the normal state, $c$ is the light speed, $\mathbb{H} = \mathrm{curl}\ \mathbb{A}$, and $m_s$ and $e_s$ are mass and charge of a superconducting electron, respectively. The parameters $\alpha$ and $\beta$ depend on temperature and are determined by the material. Moreover, below the critical temperature $T_c$, $\alpha = \alpha(T)$ and $\beta = \beta(T)$ take negative and positive values, respectively. In the presence of an applied magnetic field $\mathbb{H}_{ap}$, we have to consider the Gibbs free energy density, $G = F - \mathbb{H}\cdot\mathbb{H}_{ap}/4\pi$.

Introduce the following physical parameters:

$$\Psi_0 = \sqrt{-\alpha/\beta}, \qquad H_c = \sqrt{4\pi\alpha^2/\beta}$$
$$\lambda = \sqrt{-\beta m_s c^2/4\pi\alpha e_s^2}, \qquad \xi = \sqrt{-\hbar^2/2m_s\alpha} \qquad [1]$$
$$\kappa = \lambda/\xi$$

The value $\Psi_0^2$ implies the equilibrium density and $H_c$ is the thermodynamic critical field, which is obtained by equating $G = F_n - |\mathbb{H}_{ap}|^2/8\pi$ (for the normal state $\Psi = 0$, $\mathbb{H} = \mathbb{H}_{ap}$) with $G = F_n - \alpha^2/2\beta$ (for the perfect superconductivity $|\Psi|^2 = \Psi_0^2$, $\mathbb{A} = 0$). The parameters $\lambda$ and $\xi$ stand for penetration depth and coherence length, respectively. The ratio $\kappa$ of these characteristic lengths is called the Ginzburg–Landau parameter, which determines the type of superconducting material: type I for $\kappa < 1/\sqrt{2}$ and type II for $\kappa > 1/\sqrt{2}$.

We use the nondimensional variables $x', \Psi', \mathbb{A}'$, $\mathbb{H}_{ap}'$, and $\tilde{G}$:

$$x = \lambda x', \qquad \Psi = \Psi_0\Psi'$$
$$\mathbb{A} = \sqrt{2}H_c\xi\mathbb{A}' \ (\mathbb{H}' = \mathrm{curl}'\mathbb{A}'),$$
$$\mathbb{H}_{ap} = \sqrt{2}H_c\mathbb{H}_{ap}'/\kappa \qquad [2]$$
$$F = F_n + (\tilde{G}/\kappa^2 - 1/2 + 2\mathbb{H}'\cdot\mathbb{H}_{ap}'/\kappa^2 - |\mathbb{H}_{ap}'|^2/\kappa^2)H_c^2/4\pi$$

Dropping the primes after the change of variables and integrating $\tilde{G}$ over a domain $\Omega \subset \mathbb{R}^n (n = 2, 3)$, which is occupied by a superconducting sample, yields a functional of $\Psi$ and $\mathbb{A}$, called the Ginzburg–Landau energy in a nondimensional form,

$$E(\Psi, \mathbb{A}) = \int_\Omega \left\{ |(\nabla - i\mathbb{A})\Psi|^2 + \frac{\kappa^2}{2}(1 - |\Psi|^2)^2 + |\mathrm{curl}\ \mathbb{A} - \mathbb{H}_{ap}|^2 \right\} dx \qquad [3]$$

The Ginzburg–Landau equations are the Euler–Lagrange equations of this energy, which are given by

$$(\nabla - i\mathbb{A})^2\Psi = \kappa^2(|\Psi|^2 - 1) \quad \text{in } \Omega \qquad [4]$$

$$\mathrm{curl}^2\ \mathbb{A} = \mathbb{J} + \mathrm{curl}\ \mathbb{H}_{ap} \quad \text{in } \Omega \qquad [5]$$

where

$$\mathbb{J} := \frac{1}{2i}(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*) - |\Psi|^2\mathbb{A} \qquad [6]$$

$\Psi^*$ stands for the complex conjugate of $\Psi$. In a two-dimensional domain $\Omega$, the differential operator "curl" acts on $\mathbb{A} = (A_1, A_2) : \mathbb{R}^2 \to \mathbb{R}^2$ such that

$$\mathrm{curl}\ \mathbb{A} = \partial_{x_1}A_2 - \partial_{x_2}A_1$$
$$\mathrm{curl}\ H = (\partial_{x_2}H, -\partial_{x_1}H)$$
$$H := \mathrm{curl}\ \mathbb{A}$$

and $\mathbb{H}_{ap}$ is replaced by a scalar-valued function. Note that $\mathbb{J}$ represents a supercurrent in the material. Every critical point of the energy is obtained by solving the Ginzburg–Landau equations with appropriate boundary conditions and, thus, a physical state in the superconducting sample is realized by a solution of the equations. A minimizer of [3] is a solution of [4]–[5] that minimizes the energy [3] in an appropriate function space, whereas a local minimizer is a solution minimizing the energy locally in the space. A solution is called a stable solution if it is a local minimizer of the energy. A physically stable phenomenon could be realized by a minimizer or at least a local minimizer.

The Ginzburg–Landau energy and the equations are gauge invariant under the transformation

$$(\Psi, \mathbb{A}) \longmapsto (\Psi e^{i\chi}, \mathbb{A} + \nabla\chi) \quad [7]$$

for a smooth scalar function $\chi(x)$. Therefore, we can identify two solutions which have the correspondence through the transformation [7]. The following London (Coulomb) gauge is often chosen:

$$\operatorname{div} \mathbb{A} = 0 \quad \text{in } \Omega \quad [8]$$

(with a boundary condition if necessary).

Let $(\Psi, \mathbb{A})$ be a smooth solution of [4]–[5]. In a region for $|\Psi(x)| > 0$, the expression $\Psi = w(x) \exp(i\theta(x))$ $(w = |\Psi(x)|)$ leads to

$$\nabla^2 w = |\nabla\theta - \mathbb{A}|^2 w + \kappa^2(w^2 - 1)w \quad [9]$$

$$\operatorname{div}(w^2(\nabla\theta - \mathbb{A})) = 0 \quad [10]$$

$$\operatorname{curl}^2 \mathbb{A} = \mathbb{J} = w^2(\nabla\theta - \mathbb{A}) \quad [11]$$

where the gauge [8] is fixed and curl $\mathbb{H}_{ap} = 0$ is assumed. Let $S$ be a surface in $\Omega$ bounded by a closed curve $\partial S$. Suppose $w(x) > 0$ on $\partial S$. Then from [11],

$$\begin{aligned}\Phi &:= \int_{\partial S} (\mathbb{J}/w^2 + \mathbb{A}) \cdot d\mathbf{s} \\ &= \int_{\partial S} \frac{1}{w^2} \mathbb{J} \cdot d\mathbf{s} + \int_S \operatorname{curl} \mathbb{A} \cdot d\mathbf{S} \\ &= \int_{\partial S} \nabla\theta \cdot d\mathbf{s} = 2d\pi \end{aligned} \quad [12]$$

where $d$ is an integer; in fact, $d = \deg(\Psi, \partial S)$ is the winding number of $\Psi(\partial S)$ in the complex plane. Thus, the identity [12] relates the magnetic field to a topological degree of the order parameter. The quantity $\Phi$, multiplied by an appropriate constant, is called the fluxoid. A connected component of vanishing points of $\Psi$ generally has codimension 2 in the domain, and it is called a vortex.

From the expression [9], the asymptotic behavior $w \to 1$ as $\kappa \to \infty$ is expected under a suitable condition. Then, by [11], $\mathbb{H} = \operatorname{curl} \mathbb{A}$ enjoys the property $\operatorname{curl}^2 \mathbb{H} + \operatorname{curl} \mathbb{H} = 0$, which is known as the London equation. However, this is valid for $|\Psi| > 0$. Otherwise, a singularity appears around zeros of $\Psi$.

There are several characteristic phenomena observed in a bulk superconductor. Typical phenomena are: perfect conductivity (persistent current), perfect diamagnetism (Meissner effect), nucleation of superconductivity, and vortices (quantization of a penetrating magnetic field). These phenomena can be expressed by solutions of the Ginzburg–Landau equations in various settings.

## Ginzburg–Landau Equations in $\mathbb{R}^2$

A standard model of the Ginzburg–Landau energy is considered in the whole space $\mathbb{R}^2$. Let $\mathbb{A} = (A_1, A_2)$ and assume $\mathbb{H}_{ap} = 0$ in [3]. Consider then the energy functional

$$\begin{aligned}\mathcal{E}(\Psi, A) = \int_{\mathbb{R}^2} &|D_A\Psi|^2 + |\operatorname{curl} \mathbb{A}|^2 \\ &+ \frac{\kappa^2}{2}(1 - |\Psi|^2)^2 \, dx \end{aligned} \quad [13]$$

where $D_A := \nabla - i\mathbb{A}$. Then the Ginzburg–Landau equations are

$$D_A^2 \Psi = \kappa^2(|\Psi|^2 - 1)\Psi \quad \text{in } \mathbb{R}^2 \quad [14]$$

$$\operatorname{curl}^2 \mathbb{A} = \operatorname{Im}(\Psi^* D_A \Psi) \quad \text{in } \mathbb{R}^2 \quad [15]$$

In the gauge theory, this model can be regarded as a two-dimensional abelian (U(1)) Higgs model. In that context, $\Psi$ is a scalar (Higgs) field, $\mathbb{A}$ is a connection on the U(1) bundle $\mathbb{R}^2 \times U(1)$, and $D_A$ is the covariant derivative.

Equations [14]–[15] are useful in observing quantization of the magnetic field, although it is an ideal model for superconductivity. By the natural condition that the right-hand side of [13] is finite, we may assume that $|D_A\Psi|, |\operatorname{curl} \mathbb{A}| \to 0$ and $|\Psi| \to 1$ as $|x| \to \infty$. From [12], the flux quantization follows:

$$\int_{\mathbb{R}^2} \operatorname{curl} \mathbb{A} \, dx = 2d\pi \quad [16]$$

If $\Psi$ has a finite number of zeros $\{a_j\}_{j=1}^N$, [16] implies

$$\int_{\mathbb{R}^2} \operatorname{curl} \mathbb{A} \, dx = 2\pi \sum_{j=1}^N \deg(\Psi, \partial B(a_j, \rho))$$

for a small positive number $\rho$, where $B(a_j, \rho)$ stands for the disk with the center $a_j$ and the radius $\rho$. A zero of $\Psi$ represents a vortex, at which the magnetic field is quantized, and a supercurrent moves around the field.

To characterize the configuration analytically, we find a solution $(\Psi, \mathbb{A})$ expressed by the polar coordinate in the form

$$\Psi = f(r) \exp(id\theta), \qquad \mathbb{A}(r) = \alpha(r)(-\sin\theta, \cos\theta)$$

Substituting these into [14]–[15], one obtains

$$\frac{1}{r}(rf')' - \left(\frac{d}{r} - \alpha\right)^2 f = \kappa^2(f^2 - 1)f$$

$$\left(\frac{1}{r}(r\alpha)'\right)' = f^2\left(\alpha - \frac{d}{r}\right)$$

$(' = d/dr)$ with the boundary conditions

$$f(0) = 0, \quad f(\infty) = 1, \quad \alpha(\infty) = 0$$

This system of the equations has a solution for $\kappa > 0$. In addition to these types of solutions, when $\kappa = 1/\sqrt{2}$, a special transformation reduces the system of [14]–[15] to a scalar nonlinear equation with a singular term. Then, it is proved that for an arbitrary $d \in \mathbb{Z}$, under the constraint of [16] there exists a minimizer of [13] with zeros of prescribed points $\{a_j\}_{j=1}^{|d|}$ (Jaffe and Taubes 1980).

## Solutions for Persistent Current

A current flowing in a superconducting ring with no decay even in the absence of an applied magnetic field is called a persistent current. Assume that a superconducting sample $\Omega$ in $\mathbb{R}^3$ is surrounded by vacuum and adopt the energy functional as

$$\mathcal{E}(\Psi, \mathbb{A}) = \int_\Omega |D_A\Psi|^2 + \frac{\kappa^2}{2}(1 - |\Psi|^2)^2 \, dx + \int_{\mathbb{R}^3} |\text{curl}\, \mathbb{A}|^2 \quad [17]$$

Although the functional [17] is minimized by a trivial solution $(\Psi, \mathbb{A}) = (\exp(ic), 0)(c \in \mathbb{R})$, which is the case for perfect diamagnetism, this is not the solution describing a persistent current since $\mathbb{J} = 0$ everywhere. We have to look for a nontrivial solution that locally minimizes the energy, that is, a local minimizer of [17]. To characterize a solution representing the persistent current, we define a mapping from $\Omega$ to $S^1 \subset \mathbb{C}$ by $x \in \Omega \to \Psi(x)/|\Psi(x)|$ for a solution $(\Psi, \mathbb{A})$ of the corresponding Ginzburg–Landau equations to [17]. Consider a domain having infinitely many homotopy classes in the space of continuous functions $C^0(\bar{\Omega}, S^1)$ (e.g., a solid torus). If $(\Psi, \mathbb{A})$ is a local minimizer and $\Psi/|\Psi|$ is not homotopic to a constant map of $C^0(\bar{\Omega}, S^1)$, then it is a solution describing a persistent current. The existence of such a solution has been established mathematically for large $\kappa$ (Jimbo and Morita 1996, Rubinstein and Sternberg 1996).

## Configuration of Solutions under an Applied Magnetic Field

In the presence of an applied magnetic field, according to the magnitude of the field, a sample exhibits the transition from the superconducting state to the normal state and vice versa. This transition can be considered mathematically as a bifurcation of solutions to the Ginzburg–Landau equations with a parameter measuring the magnitude of the applied magnetic field. In fact, let $\mathbb{H}_{ap}$ be an applied magnetic field perpendicular to the horizontal plane and assume that it is constant along the vertical axis, that is, $\mathbb{H}_{ap} = (0, 0, H_a)$. Then a rich bifurcation structure is suggested by numerical and analytical studies in the parameter space of $(H_a, \kappa)$. Mathematical developments for variational methods and nonlinear analysis reveal the configuration of the solutions and provide rigorous estimates for critical fields in a parameter regime for a two-dimensional model, predicted by physicists.

Throughout this section, we consider the Ginzburg–Landau model in an infinite cylinder $\Omega = D \times \mathbb{R}$ $(D \subset \mathbb{R}^2)$ with a constant applied magnetic field $\mathbb{H}_{ap} = H_a \boldsymbol{e}_3 = (0, 0, H_a), H_a > 0$. Assuming the uniformity along the vertical axis, we may write $\mathbb{A} = (A_1, A_2)$ and $H = \text{curl}\,\mathbb{A} = \partial_{x_1}A_2 - \partial_{x_2}A_1$ as in the previous section. Then the Ginzburg–Landau energy on $D$ is

$$\mathcal{E}(\Psi, \mathbb{A}) = \int_D \left\{ |D_A\Psi|^2 + \frac{\kappa^2}{2}(1 - |\Psi|^2)^2 + |\text{curl}\,\mathbb{A} - H_a|^2 \right\} dx \quad [18]$$

With the London gauge

$$\text{div}\,\mathbb{A} = 0 \quad \text{in } D, \qquad \mathbb{A} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial D$$

the Ginzburg–Landau equations in the present setting are written as

$$D_A^2\Psi = (|\Psi|^2 - 1)\Psi \quad \text{in } D \quad [19]$$

$$-\nabla^2\mathbb{A} = \text{Im}(\Psi^* D_A\Psi) \quad \text{in } D \quad [20]$$

$$\boldsymbol{n} \cdot \nabla\Psi = 0 \quad \text{on } \partial D \quad [21]$$

$$\text{curl}\,\mathbb{A} = \text{H}_a \quad \text{on } \partial \text{D} \quad [22]$$

where $\boldsymbol{n}$ denotes the outer unit normal.

### Meissner Solutions

As seen in the case of no applied magnetic field, the trivial solution $(\Psi, \mathbb{A}) = (\exp(ic), 0)$ is a minimizer of [18]. This solution expresses no magnetic field in the sample. In a superconducting sample, the diamagnetism holds even in the presence of an applied magnetic field if the field is weak. Namely, the sample is shielded so that penetration of the field is only allowed near the surface of the sample. This phenomenon is called the Meissner effect. A solution expressing Meissner effect is called a Meissner solution. Mathematically, it is understood that as $H_a$ increases, such a Meissner solution continues from the trivial solution. Then the solution preserves the configuration $0 < |\Psi(x)| < 1$. A study of the asymptotic behavior of the Meissner solution as $\kappa$ tends to $\infty$ shows that the Meissner solution is a

minimizer up to $H_a = O(\log \kappa)$ for sufficiently large $\kappa$ (Serfaty 1999).

### Nucleation of Superconductivity

In an experiment, the Meissner state breaks down by a stronger applied magnetic field. Then the sample turns to be the normal state (in a type I conductor) or it allows a mixed state of superconductivity and normal state (in a type II conductor). In the former case, the critical magnitude of the field is denoted by $H_c$, which corresponds to the one of [1], while it is denoted by $H_{c_1}$ in the latter case. Moreover, the mixed state eventually breaks down to be normal state by further increasing the applied field up to another critical field $H_{c_2}$. To characterize these two types mathematically, we consider a transition from the normal state to the superconducting state by reducing the magnitude of the field.

Let $\mathbb{A}_{ap}$ satisfy curl $\mathbb{A}_{ap} = H_a (x \in D)$ and $\mathbb{A}_{ap} \cdot \boldsymbol{n} = 0 (x \in \partial D)$. Then eqns [19]–[22] have a trivial solution $(\Psi, \mathbb{A}) = (0, \mathbb{A}_{ap})$, which stands for the normal state. Consider the second variation of the energy functional [18] at this trivial solution

$$\frac{1}{2}\frac{d^2}{ds^2}E(s\psi, \mathbb{A}_{ap} + s\mathbb{B})\bigg|_{s=0} = \int_D |(\nabla - i\mathbb{A}_{ap})\psi|^2 - \kappa^2|\psi|^2 + |\text{curl}\,\mathbb{B}|^2 dx$$

If the minimum of this second variation for nonzero $(\psi, \mathbb{B})$ is positive (or negative), then the trivial solution is stable (or unstable). The minimum gives the least eigenvalue of the linearized problem of [19]–[20] around the trivial solution. Seeking such a least eigenvalue $\mu$ is reduced to studying an eigenvalue problem of the Schrödinger operator $L[\psi] := -(\nabla - i\mathbb{A}_{ap})^2\psi$.

If the domain $D$ is the whole space $\mathbb{R}^2$, it is proved that $\mu = H_a$. Back to the original variable of [2], we can define a critical field $H_{c_2} = \sqrt{2}H_c\kappa$; $\kappa = 1/\sqrt{2}$ separates a class of superconductors into type I by $\kappa < 1/\sqrt{2}$ $(H_{c_2} < H_c)$ and type II by $\kappa > 1/\sqrt{2}$ $(H_{c_2} > H_c)$.

In the bounded domain $D$, however, the critical field at which superconductivity nucleates in the interior of a sample is larger than $H_{c_2}$ (it is denoted by $H_{c_3}$), since the eigenvalue problem of $L$ is considered in the domain with the Neumann boundary condition. A study of the least eigenvalue $\mu$ shows that the critical field has the asymptotics as

$$H_{c_3}/\sqrt{2}H_c = \frac{\kappa}{\beta} + O(1), \quad \kappa \to \infty$$

where $0 < \beta < 1$. If the applied field is very close to $H_{c_3}$ and $\kappa$ is sufficiently large, the amplitude of the eigenfunction associated with the least eigenvalue of $L$ (with the Neumann boundary condition) is very small except for a $1/\kappa$ neighborhood of the boundary. This implies that the nucleation of superconductivity takes place at the boundary. This phenomenon is called surface nucleation (Del Pino *et al.* 2000, Lu and Pan 1999).

### Solutions of Vortices

In a type II superconductor, it is well known that there exists a mixed state of superconductivity and normal state in a parameter regime $H_{c_1} < H_a < H_{c_2}$. In the mixed state, the magnetic field penetrating in the sample is quantized such that it delivers a finite number of lines or curves in the sample. This configuration (called vortex) is characterized by zero sets of the order parameter of the Ginzburg–Landau equations. In a two-dimensional domain, isolating vanishing points of the order parameter are called vortices. Thus, it is quite an interesting problem how such a vortex configuration can be described mathematically by a minimizer of the energy functional. In the section "Ginzburg–Landau equations in $\mathbb{R}^2$," a specific configuration for vortex solutions is stated under very special conditions, $\kappa = 1/\sqrt{2}$, on the whole space and no applied magnetic field. However, this result is not generalized in the present setting.

A standard approach to a solution with the vortex configuration is using a bifurcation analysis near the critical field $H_{c_2}$ (or $H_{c_3}$) by expanding a solution and the difference $H_a - H_{c_2}$ in a small parameter. Then the leading term is given by an eigenfunction of the least eigenvalue of the Schrödinger operator coming from the linearization. Under the doubly periodic conditions in the whole space $\mathbb{R}^2$, the spatial pattern of vortices, called Abrikosov's vortex lattice, is studied by a local bifurcation theory.

However, this kind of bifurcation analysis only works near the critical field and the trivial solution $(\Psi, \mathbb{A}) = (0, \mathbb{A}_{ap})$, which implies that only a small-amplitude solution can be found. To realize a sharp configuration of vortices, we need to consider a parameter regime far from the bifurcation point. As a matter of fact, mathematical and numerical studies for sufficiently large $\kappa$ exhibit nice configurations of vortex solutions. In this case, in a neighborhood of each vortex, with radius $O(1/\kappa)$, a sharp layer arises, and there exists a solution with multivortices in an appropriate parameter region for $H_a$. In addition, as $H_a$ increases (up to $H_{c_2}$), the number of vortices also increases. This implies that the minimizer of the energy functional [18] admits a larger number of zeros for a higher magnitude of applied magnetic field. However, it is a puzzle since

a solution with a smaller number of vortices seems to have less energy. Thus, there is some balance mechanism between contributions of the vortices and the applied magnetic field to the total energy.

Mathematically, it is possible to estimate $\mathcal{E}(\Psi, \mathbb{A})$ for the vortex solution to [19]–[22] as follows: consider a family of square tiles $K_j$ with side-length $\rho$ which are periodically arranged over the whole space. Assume each square in the domain $D$ has a single vortex. For an appropriate test function, the energy over $K_j$ is estimated as $O(\log(\kappa\rho))$. Since the number of vortices in the domain is $O(|D|/\rho^2)$ ($|D|$: the measure of $D$), we obtain an upper bound $O((|D|/\rho^2)\log(\kappa\rho))$. This bound is less than $\mathcal{E}(0, \mathbb{A}_{\mathrm{ap}}) = |D|\kappa^2/2$ for $H_{\mathrm{a}}/\kappa^2 = o(1)$ and $\rho = 1/\sqrt{H_{\mathrm{a}}}$. Although in a general case it is difficult to estimate the energy of the minimizer from below, the leading order can be precisely determined in some range of the interval $(H_{c_1}, H_{c2})$ if $\kappa$ is sufficiently large (Sandier and Serfaty 2000).

## A Simplified Model

Since the Ginzburg–Landau equations [4]–[5] are coupled equations for $\Psi$ and $\mathbb{A}$, we often encounter mathematical difficulty in realizing a solution with the configuration shown by a numerical experiment. To look at a specific configuration, we may use a simpler model equation. A typical simplification is to neglect the magnetic field, which leads to the equation for the order parameter $\psi$:

$$\nabla^2\psi + \kappa^2(1 - |\psi|^2)\psi = 0 \quad \text{in } \Omega \qquad [23]$$

This equation is also called the Ginzburg–Landau equation and it is the Euler–Lagrange equation of the energy

$$G(\psi) = \int_\Omega |\nabla\psi|^2 + \frac{\kappa^2}{2}(1 - |\psi|^2)^2\, \mathrm{d}x \qquad [24]$$

in an appropriate function space. Under no constraint, a constant solution with $|\psi| = 1$ is a minimizer. If a domain is topologically nontrivial, eqn [23] also allows local minimizers of [24] for large $\kappa$ as seen in the section "Solutions for Persistent Current."

On the other hand, [23] in a simply connected domain $D \subset \mathbb{R}^2$ with a boundary condition $\psi = g(x)(x \in \partial D)$ is used for a study of a vortex solution for large $\kappa$. Let $\epsilon = 1/\kappa$. Under the constraint $\deg(g, \partial D) = d$, a minimizer $\psi_\epsilon$ must have at least $|d|$ zeros. The leading order of the energy around each vortex is estimated as $2\pi\log(1/\epsilon)$. The result of Bethuel *et al.* (1994) describes the energy for a minimizer

$$G(\psi_\epsilon) = 2\pi|d|\,\log(1/\epsilon) + \gamma + W(a_1^\epsilon, \ldots, a_{|d|}^\epsilon) + o(1)$$

where $\{a_j^\epsilon\}$ are zeros of $\psi_\epsilon$ and $\gamma$ is a universal constant. The function $W$ is explicitly given as

$$W(a_1, \ldots, a_{|d|}) = 2\pi \sum_{1 \le j,k \le |d|, j \ne k} \log|a_j - a_k| + R$$

where $R$ is derived from a Green function satisfying some boundary condition depending on $g$. Moreover, as $\epsilon \to 0$, the zeros converge to a minimizer of $W$, which implies that the asymptotic position of every zero (vortex) is determined by the explicit function $W$. The first term of $W$ shows that vortices with the same sign of the degree are repulsive to one another and the optimal arrangement of vortices never allows the superposition of multivortices. Although the boundary condition is rather artificial, their mathematical formulation promoted the development of variational methods applied to the Ginzburg–Landau equation.

## Time-Dependent Ginzburg–Landau Equations

The Ginzburg–Landau equations in the preceding sections are static models. We consider time evolution models called the time-dependent Ginzburg–Landau equations. The evolution equations serve various numerical simulations exhibiting dynamical properties of solutions. They also provide mathematical problems on global time behaviors of solutions, stability of stationary solutions, dynamical laws of vortices, etc. The Ginzburg–Landau energy is denoted by $\mathcal{E}(u), u = (\Psi, \mathbb{A})$. The simplest model for the time-dependent problem is the gradient flow for $\mathcal{E}(u)$

$$\partial_t u = -\frac{\delta\mathcal{E}}{\delta u}$$

where $\delta\mathcal{E}/\delta u$ is the first variation of the energy. A more standard evolution equation in a nondimensional form is given by

$$(\partial_t + \mathrm{i}\phi)\Psi - D_A^2\Psi = \kappa^2(1 - |\Psi|^2)\Psi \qquad [25]$$

$$\eta(\partial_t\mathbb{A} + \nabla\phi) + \mathrm{curl}^2\,\mathbb{A} = \mathrm{Im}(\Psi^* D_A\Psi) + \mathrm{curl}\,\mathbb{H}_{\mathrm{ap}} \qquad [26]$$

where $\phi(x, t)$ is the electric (scalar) potential and $\eta$ is a positive parameter with a physical quantity. In fact, this equation was derived by Gor'kov and Eliashberg from the Bardeen, Cooper, and Schrieffer (BCS) theory.

The system of the equations [25]–[26] is invariant under the following time-dependent gauge transformation:

$$(\Psi, \phi, \mathbb{A}) \longmapsto (\Psi\,\exp(\mathrm{i}\chi), \phi - \partial_t\chi, \mathbb{A} + \nabla\chi)$$

The equations in the bounded domain $D \subset \mathbb{R}^2$ are considered subject to boundary and initial conditions

$$\begin{aligned} D_A\Psi \cdot \boldsymbol{n} &= 0 && \text{on } \partial\Omega \times (0,T) \\ \operatorname{curl} \mathbb{A} &= H_{\mathrm{a}} && \text{on } \partial\Omega \times (0,T) \\ \Psi(x,0) &= \Psi_0 && \text{in } \Omega \\ \mathbb{A}(x,0) &= \mathbb{A}_0(x) && \text{in } \Omega \end{aligned} \qquad [27]$$

Then, besides the Coulomb gauge [8], we can choose the Lorentz gauge as follows:

$$\begin{aligned} \operatorname{div} \mathbb{A} + \phi &= 0 \quad \text{in } D, \qquad \int_D \phi \, \mathrm{d}x = 0 \\ \mathbb{A} \cdot \boldsymbol{n} &= 0 \quad \text{on } \partial D \end{aligned}$$

For a smooth solution $u(x,t)$ to [25]–[26] with [27],

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathcal{E}(u) = -2\int_\Omega |(\partial_t + \mathrm{i}\phi)\Psi|^2 + \eta|\partial_t\mathbb{A} + \nabla\phi|^2 \, \mathrm{d}x \le 0$$

holds if $\mathbb{H}_{\mathrm{ap}}$ is time independent. This is also true in the case of the whole space $\mathbb{R}^2$ with a condition for the asymptotic behavior as $|x| \to \infty$.

Suppose that a domain $\Omega \subset \mathbb{R}^3$ is occupied by a superconducting sample and it is surrounded by a medium (or vacuum). Then the electromagnetic behavior in the outside domain, caused by the induced magnetic field of a supercurrent in $\Omega$ and an applied magnetic field, should be expressed by the Maxwell equations. With the electric field $\mathbb{E} = -(\mu\partial_t\mathbb{A} + \nabla\phi)$, we obtain

$$-\nu\partial_t\mathbb{E} - \sigma\mathbb{E} + \operatorname{curl}^2 \mathbb{A} = \operatorname{curl} \mathbb{H}_{\mathrm{ap}} \quad \text{in } \mathbb{R}^3 \setminus \bar{\Omega}$$

where $\mu$, $\nu$, and $\sigma$ are physical parameters (e.g., $\sigma = 0$ in the vacuum). To match the inside and the outside of $\Omega$, appropriate boundary conditions are required.

From a point of the gauge theory as in the section "Ginzburg–Landau equations in $\mathbb{R}^2$," the following time-dependent equations in the whole space are also considered:

$$\begin{aligned} (\partial_t + \mathrm{i}\phi)^2\Psi - D_A^2\Psi &= \kappa^2(1 - |\Psi|^2)\Psi \\ -\partial_t\mathbb{E} + \operatorname{curl}^2 \mathbb{A} &= \operatorname{Im}(\Psi^* D_A\Psi) \\ -\nabla \cdot \mathbb{E} &= \operatorname{Im}(\Psi^*(\partial_t + \mathrm{i}\phi)\Psi) \end{aligned}$$

## Other Topics

In realistic problems, a superconducting sample contains impurities. This inhomogeneity is usually expressed by putting a variable coefficient into the Ginzburg–Landau energy and the equations. Such a model with a variable coefficient is useful in studies for pinning of vortices, Josephson effect through an inhomogeneous media, etc. A model in a thin film with variable thickness is also described by the Ginzburg–Landau equations with a variable coefficient. Since the Ginzburg–Landau equations (or a modified model) can be considered in various settings, more applications to realistic problems would be treated by the development of nonlinear analysis.

# Glassy Disordered Systems: Dynamical Evolution

**S Franz**, The Abdus Salam ICTP, Trieste, Italy

## Introduction

Many macroscopic systems if left to evolve in isolation or in contact with a bath, are able to relax, after a finite time, to history-independent equilibrium states characterized by time-independent values of the state variables and time-translation invariance correlations. In glassy systems, the relaxation time becomes so large that equilibrium behavior is never observed. On short timescales, the microscopic degrees of freedom appear to be frozen in far-from-equilibrium disordered states. On longer timescales slow, history-dependent, off-equilibrium relaxation phenomena become detectable.

The list of physical systems falling in disordered glassy states at low temperature is long, just to mention a few examples one can cite the canonical case of simple and complex liquid systems undergoing a glass transition, polymeric glasses, dipolar glasses, spin glasses, charge density wave systems, vortex systems in type II superconductors, and many other systems.

Experimental and theoretical research has pointed out the existence of dynamical scaling laws characterizing the off-equilibrium evolution of glassy systems. These laws, in turn, reflect the statistical properties of the regions of configuration space explored during relaxation.

The goal of a theory of glassy systems is the comprehension of the mechanisms that lead to the growth of relaxation time and the nature of the scaling laws in off-equilibrium relaxation. A well-developed description of glassy phenomena is provided by mean-field theory based on spin glass models, which gives a coherent framework that is able to describe the dynamics of glassy systems and provides a statistical interpretation of glassy relaxation. Despite important limitations of the mean-field description for finite-dimensional systems, it allows precise discussions of general concepts such as effective temperatures and configurational entropies that have been successfully applied to the description of glassy systems.

In the following, examples of two different ways of freezing will be discussed: spin glasses, where disorder is built in the random nature of the coupling between the dynamical variables, and structural glasses, where the disordered nature of the frozen state has a self-induced character. These systems are examples of two different ways of freezing.

## A Glimpse of Freezing Phenomenology

### Spin Glasses

The archetypical example of systems undergoing the complex dynamical phenomena described in this article is the case of spin glasses (Fischer and Hertz 1991, Young 1997). Spin glass materials are magnetic systems where the magnetic atoms occupy random position in lattices formed by nonmagnetic matrices fixed at the moment of the preparation of the material. The exchange interaction between the spin of the magnetic impurities in these materials is an oscillating function, taking positive and negative values according to the distance between the atoms.

Spin glass models (*see* Spin Glasses, Mean Field Spin Glasses and Neural Networks, and Short-Range Spin Glasses: The Metastate Approach) are defined by giving the form of the exchange Hamiltonian, describing the interaction between the spins $S_i$ of the magnetic atoms. In the presence of an external magnetic field $h$, the exchange Hamiltonian can be written as

$$H = -\sum_{i,j\in\Lambda} J_{ij} S_i \cdot S_j - h \sum_{i\in\Lambda} S_i \qquad [1]$$

The spin variable can have classical or quantum nature. This article will be limited to the physics of classical systems. The most common choice in models is to use Ising variables $S_i = \pm 1$. The couplings $J_{ij}$, which in real material depend on the distance, are most commonly chosen to be independent random variables with a distribution with support on both positive and negative values. Most commonly, one considers either a symmetric bimodal distribution on $\{-1, 1\}$ or a symmetric Gaussian. The sums are restricted to lattices $\Lambda$ of various types. The most common choices are $\Lambda = Z^d$ for the Edwards–Anderson model, the complete graph $\Lambda = \{(i,j) | i < j; i,j = 1, \ldots, N\}$ for the Sherrington–Kirkpatrick (SK) model, and the Erdos–Renyi random graph for the Viana–Bray (VB) model.

The presence of interactions of both signs induces frustration in the system: the impossibility of minimizing all the terms of the Hamiltonian at the same time. One then has a complex energy landscape, where relaxation to equilibrium is hampered by barriers of energetic and entropic nature.

Spin glass materials, which have a paramagnetic behavior at high temperature, show glassy behavior at low temperature, where magnetic degrees of freedom appear to be frozen for long times in apparently random directions. There is quite a

general consensus, based on the analysis of the experimental data and the numerical simulations, that in three dimensions and in the absence of a magnetic field, the two regimes are separated by a thermodynamic phase transition at a temperature $T_c$ where the magnetic response $\chi$ exhibits a cusp (see Figure 1). By linear response, $\chi$ is related to the equilibrium spin correlation function

$$\chi = \frac{1}{K_B TN} \sum_i \left( \langle S_i^2 \rangle - \langle S_i \rangle^2 \right)$$

having denoted by $\langle \cdot \rangle$ the Boltzmann–Gibbs average. A cusp in $\chi$ indicates a second-order transition where the so-called Edwards–Anderson parameter $q = (1/N) \sum_i \langle S_i \rangle^2$ becomes different from zero, indicating freezing of the spins in random directions. In the presence of a magnetic field, although the low-temperature phenomenology is similar to the one at zero field, the thermodynamic nature of the freezing transition is more controversial. Theoretically, mean-field theory, based on the SK model, predicts a phase transition with a cusp in the susceptibility both in the absence and in the presence of a magnetic field. Unfortunately, no firm theoretical result is available on the existence and the nature of phase transitions in finite-dimensional spin glass models which is a completely open problem.

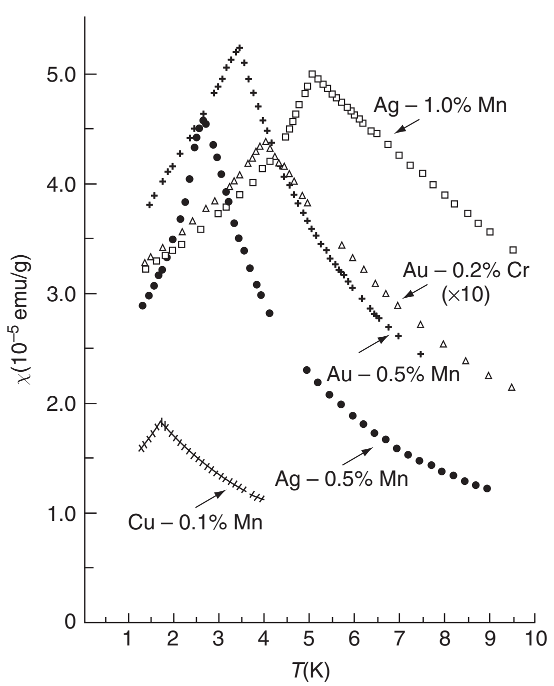

**Figure 1** Magnetic susceptibility as a function of temperature in spin glass materials. Reproduced from Fischer KH and Hertz JA (1991) *Spin Glasses*. Cambridge, UK: Cambridge University Press.

### Structural Glasses

Analogous freezing of dynamical variables is observed in a variety of systems. Some of them share with the spin glasses the presence of quenched disorder; in many others, this feature is absent. This is the case of structural glasses (Debenedetti 1996).

Many liquids under fast enough cooling, instead of crystallizing, as dictated by equilibrium thermodynamics, form glasses. Simple liquids can be modeled as classical systems of particles with pairwise interactions. In the simplest example of a monoatomic liquid, the potential energy of a configuration is then written as

$$V(r_1, \ldots, r_N) = \sum_{i<j} \phi(r_i - r_j) \qquad [2]$$

In the case of atomic mixtures, the potential $\phi$ acquires a dependence on the species of the interacting atoms.

Liquids can be characterized as good or bad glass formers depending on the facility by which they form glasses. In good glass formers, in order to avoid crystallization, it is in general sufficient to cross the region around the liquid–crystal transition point fast enough, so that the systems can set in a supercooled liquid metastable equilibrium. On lowering the temperature, the supercooled liquid becomes denser and more viscous while the relaxation time of the system, related to the viscosity through the Maxwell relation $\tau = \eta/G$ ($G$ is the instantaneous shear modulus of the liquid), undergoes a rapid growth. One defines a conventional glass transition temperature $T_g$ as the point where $\eta$ takes the solid-like value $\eta = 10^{13} Poise$, corresponding to a relaxation time $\tau \approx 100$ s. After that point, the system falls out of equilibrium; under usual experimental conditions, it does not have the time to adjust to external solicitations and behaves mechanically like a solid. The glass transition temperature is then characterized as the point where the liquid goes out of equilibrium, the relaxation time becomes larger than the external timescale and the positions of the atoms appear as frozen on that scale.

A great effort has been devoted to understand the behavior of the temperature dependence of the relaxation time and the nature of the dynamical processes in supercooled liquids. In deeply supercooled liquids, the empirical behavior of the relaxation time ranges from the Arrhenius form for "strong glasses" $\tau \sim \exp(\Delta/T)$ to the Vogel–Fulcher form $\tau(T) \sim \exp(D/(T - T_0))$ for "fragile glasses." The Vogel–Fulcher law predicts a finite-temperature divergence of the relaxation time at the temperature $T_0$. Unfortunately, in typical cases, the $T_0$ results are

estimated to be 10–15% lower then $T_g$ so that it is not possible to verify the law close enough to $T_0$ to support the divergent behavior.

As a consequence of freezing, one observes important qualitative changes in the behavior of thermodynamic quantities similar to those encountered in equilibrium phase transitions. In a narrow interval around $T_g$, specific heat and compressibility undergo jumps from liquid-like values to much lower solid-like values.

## Aging and Slow Dynamics

While the crudest picture of the glass transition describes freezing as complete structural arrest, both for the cases where the glass transition is a genuine off-equilibrium phenomenon, as in structural glasses, and in the case where it has a thermodynamical character as in spin glasses, the study of dynamical quantities reveals the existence of persisting, history-dependent, slow relaxation processes in the frozen phase (Norblad and Svendlidh 1997). This is the phenomenon of aging, which is a constitutive feature of the glassy state. Its theoretical analysis occupies a central theoretical role in the comprehension of the way glassy systems explore configuration space. A first characterization of relaxation is given by the behavior of "one-time quantities" like internal energy, density, etc., which slowly evolve in the course of time towards values corresponding to states of lower free energy. More interesting is the behavior of "two-time quantities," time-dependent correlation functions and responses, which reveal the deep off-equilibrium nature of glassy relaxation. In experimental, numerical, and theoretical studies, a special position is occupied by the linear response function. Using the language of magnetic systems, apt to the spin glasses, one considers the response of the magnetization to an applied magnetic field. To deal with other systems, different conjugated couples of variables are considered and simple changes of language are needed. Linear perturbations allow to reveal the dynamics of the systems without affecting its evolution. Denoting by $M(t)$ the magnetization at a time $t$ and by $h(t')$ the magnetic field at time $t'$, the instantaneous linear response function is defined as

$$R(t,t') = \left(\frac{\delta M(t)}{\delta h(t')}\right)_{h=0} \qquad [3]$$

Measures of the time integral of $R(t,t')$ are commonly performed to reveal the presence of aging in glassy systems. Aging is usually studied observing the dynamics that follows a rapid quench from high temperature, at an instant that marks the origin of time. One can reconstruct the response function measuring the zero-field-cooled (ZFC) magnetization as the response to a magnetic field acting from a waiting time $t_w$ to the measuring time $t$,

$$\chi_{ZFC}(t,t_w) = \int_{t_w}^{t} dt'\, R(t,t') \qquad [4]$$

or its complement, the thermoremanent magnetization (TRM) corresponding to the response to a magnetic field acting from the time of the quench up to $t_w$

$$\chi_{TRM}(t,t_w) = \int_{0}^{t_w} dt'\, R(t,t') \qquad [5]$$

In Figure 2, the behavior of the susceptibility $\chi_{ZFC}$ is shown as a function of $t - t_w$ in a typical example of aging experiment at low temperature. Out-of-equilibrium behavior is manifest in the dependence of the curves on the waiting time $t_w$. The relaxation appears slower and slower for larger waiting times, and the $t_w$ dependence does not disappear even for very large times. Two nontrivial dynamical regimes can be identified: a first regime for small $t - t_w$, that is, $t - t_w << t_w$ where the relaxation is independent of $t_w$ and a second regime roughly valid for $t - t_w \sim t_w$ where time-translation invariance is manifestly violated. The analysis of experimental and simulation data shows a scale-invariant behavior according to which curves corresponding to different waiting times can be superimposed rescaling the time difference $t - t_w$ with a suitable $t_w$-dependent relaxation time $\tau(t_w)$. This is a growing function of $t_w$ which seems to diverge for large $t_w$. Up to the waiting times where it has been possible to test the relation, $\tau(t_w)$ behaves as a power $\tau(t_w) \sim t_w^{\alpha}$ where in different materials and models, $\alpha = 0.8$–$0.9$.

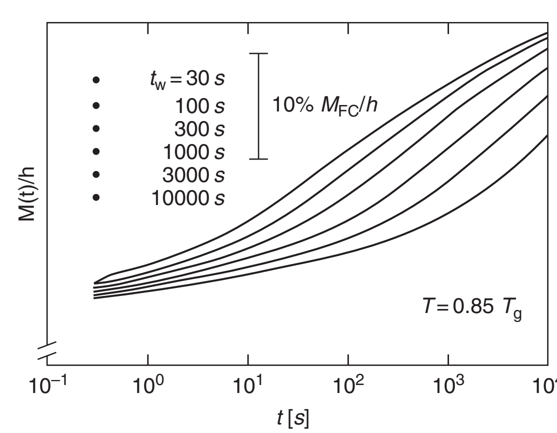

**Figure 2** ZFC magnetization in an aging experiment. The curves, from bottom to top, correspond to increasing waiting times. Reproduced from Norblad P and Svendlidh P (1997) Experiments in spin glasses. In: Young AP (ed.) *Spin Glasses and Random Fields*. Singapore: World Scientific, with permission from World Scientific Publishing Co. Pte Ltd.

Many efforts have been devoted to the comprehension of the scaling laws in aging (Bouchaud *et al.*). Among the theories and models of aging that have been proposed, one can cite the phenomenological model known as "trap model," developed by Bouchaud and collaborators that assimilates aging to a random walk between "traps" characterized by a broad distribution of trapping times. Suitable choices of the trapping-time distribution allow to derive scaling laws similar to the ones characteristic of aging systems. A different theory, the "droplet model" for spin glasses assimilates aging phenomena to the competition between slowly growing domains of equilibrium phases, in analogy with the dynamics of phase separation in first-order phase transitions. The approach that has led to the most detailed and spectacular predictions has been the study of microscopic mean-field models.

## Mean-Field Models of Disordered Systems

Mean-field theory starts from the analysis of the relaxation dynamics of disordered systems with weak long-range forces (Bouchaud *et al.*). The reference model of spin glass mean-field theory is the so called $p$-spin model, which considers $N$ spins $S_i$ with random $p$-body interactions with each other and is described by the Hamiltonian

$$H_p(\mathbf{S}) = \sum_{i_1<\cdots<i_p}^{1,N} J_{i_1,\ldots,i_p} S_{i_1}\cdots S_{i_p} \qquad [6]$$

where the quenched coupling constants $J_{i_1,\ldots,i_p}$ are assumed to be i.i.d. Gaussian variables with zero average and $N$ dependent variance $E(J^2_{i_1,\ldots,i_p}) = p!/2N^{p-1}$. The case $p=2$ coincides with the SK model defined in the introduction. The reason for considering the $p$-spin generalization is that the order of the transition passes from the second one for $p=2$ to the first one for $p \geq 3$ and that this last case has been suggested to provide a mean-field limit for the structural glass transition. It is also useful to define Hamiltonians

$$H[S] = \sum_{p\geq 1} a_p H_p[S] \qquad [7]$$

that mix $p$-spin Hamiltonians for different $p$. These are random Gaussian functions of the spin variables, with covariance induced by the coupling distribution

$$E[H(\mathbf{S})H(\mathbf{S}')] = Nf(q(\mathbf{S},\mathbf{S}')) = \frac{N}{2}\sum_{p\geq 1} a_p^2 q(\mathbf{S},\mathbf{S}')^p \qquad [8]$$

where the function

$$q(\mathbf{S},\mathbf{S}') = \frac{1}{N}\sum_{i=1}^{N} S_i S_i'$$

is the overlap between configurations. A crucial hypothesis in the study of relaxation in spin systems is that any local spin update rule verifying the detailed balance condition with respect to the Boltzmann–Gibbs measure gives rise to the same long-time properties. In this perspective, in Monte Carlo simulations, it is convenient to use Ising spins with Metropolis or Glauber dynamics. Much theoretical progress has been achieved considering spherical models where the spin variables are real numbers subject to a global spherical constraint $\sum_i S_i^2 = N$ and evolve according to the following Langevin dynamics:

$$\frac{\mathrm{d}S_i(t)}{\mathrm{d}t} = -\frac{\partial H(\mathbf{S}(t))}{\partial S_i} - \mu(t)S_i(t) + \eta_i(t) \qquad [9]$$

where $\mu(t)$ is a time-dependent multiplier that at each instant of time insures that the spherical constraint is respected, and $\eta_i(t)$ is a thermal white noise with variance

$$E(\eta_i(t)\eta_j(s)) = 2\,T\delta_{ij}\delta(t-s) \qquad [10]$$

In order to model the quench from high temperature performed in experiments, the initial conditions are randomly chosen with uniform probability. To describe long but finite-time dynamics, it is necessary to consider the limit of large volume $N\to\infty$ for finite time, which is the only case where one can have infinite relaxation times. Application of functional Martin–Siggia–Rose techniques has allowed the derivation of closed integro-differential equations for the spin autocorrelation function

$$C(t,t') = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\langle S_i(t)S_i(t')\rangle$$

and the response to an impulsive external field

$$h_i(t), R(t,t') = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\left\langle\frac{\delta S_i(t)}{\delta h_i(t')}\right\rangle$$

where the average has to be intended on quenched disordered couplings, initial conditions, and realization of thermal noise. Unfortunately, in the case $p=2$ relevant for spin glass phenomenology, the spherical constraints reduce the model to a linear system where different eigenmodes of the interaction matrix $J_{ij}$ evolve independently. This oversimplification renders the model similar to systems apt to describe phase separation rather then freezing phenomena. Many of the glassy features of the SK model however are captured by a mixture of $p=2$

with $p=4$ Hamiltonians and $f(q)=(1/2)(q^2+aq^4)$. For the general Hamiltonian [7] one gets the coupled equations

$$\frac{\partial C(t,t')}{\partial t} = -\mu(t)C(t,t') + \int_0^t dt'' f''(C(t,t''))R(t,t'')C(t',t'') + \int_{t'}^t dt'' f'(C(t,t''))R(t'',t')$$

$$\frac{\partial R(t,t')}{\partial t} = -\mu(t)R(t,t') + \int_{t'}^t dt'' f''(C(t,t''))R(t,t'')R(t'',t') \quad [11]$$

$\mu(t)$ is a multiplier that at each instant of time insures the spherical constraint $C(t,t)=1$, and is determined by

$$\mu(t) = \int_0^t dt'' C(t,t'')R(t,t'') + T \quad [12]$$

In the next sections, we will discuss how these equations describe dynamical freezing at low temperature. The gross features are determined by the form of the function $f(q)$. Two main behaviors can be identified:

1. Systems of type I. This behavior is found if $f'''(q)/(f''(q))^{3/2}$ is a monotonically decreasing function of $q$. To this family belongs the pure spherical $p$-spin model for $p \geq 3$, and one finds a dynamical transition not corresponding to a point of singularity in the free energy where the Edwards–Anderson parameter jumps discontinuously to a nonzero value. Models of this family have been proposed as appropriate mean-field limits for structural glass behavior.
2. Systems of type II. This behavior is found if $f'''(q)/(f''(q))^{3/2}$ is a monotonically increasing function of $q$. This family mimics the behavior of the SK model. An example of function $f$ verifying the condition for type II behavior is $f(q)=1/2(q^2+aq^4)$ for sufficiently small but positive values of $a$. In this case, the dynamical transition is found at a point of second-order singularity of the free energy and the Edwards–Anderson parameter is continuous at the transition. Models of this family provide a mean-field limit for spin glass type behavior.

### Equilibrium Dynamics at High Temperature

At high temperature, after a finite transient, eqn [11] describes equilibrium behavior. In these conditions, time-translation invariance holds $C(t,t')=C(t-t')$, $R(t,t')=R(t-t')$ while the Lagrange multiplier $\mu$ becomes time independent. In addition, correlation and response are related by the fluctuation–dissipation theorem (FDT) relation

$$R(t) = -\frac{1}{T}\frac{dC(t)}{dt} \quad [13]$$

Ergodic behavior is manifest in the fact that the dynamics decorrelate completely; $\lim_{t\to\infty} C(t)=0$. Then from [11] one gets the equilibrium equation:

$$\frac{dC(t)}{dt} = -TC(t) - \frac{1}{T}\int_0^t ds f'(C(t-s))\frac{dC(s)}{ds} \quad [14]$$

It is worth noticing that this equation, apart from an irrelevant inertial term, coincides for type I systems with the schematic mode-coupling theory (MCT) equation which has been successfully used to describe moderate supercooled liquids (Goetze 1989). In the context of liquid theory, mode-coupling equations stem from an approximate treatment for the dynamical evolution of the density–density space and time-dependent correlation function. The schematic MCT equations consider an equation for a single mode, neglecting any space dependence of the correlator.

Both in type I and in type II systems, eqn [14] displays a dynamical transition at a finite temperature $T_c$ where the relaxation time diverges as a power law $\tau \sim |T-T_c|^c$ and the asymptotic value of the correlation acquires a nonzero value.

This behavior in type I systems represents a failure of MCT to describe the temperature dependence of the relaxation time in supercooled liquids, which, as previously observed, empirically follows the Vogel–Fulcher law. The MCT temperature is interpreted as a singularity which is avoided in supercooled liquids, thanks to relaxation mechanisms specific of short-range systems. It has been noticed that this singularity at $T_c$ can be associated to the growth of spatial heterogeneities and dynamical correlations, as exemplified in the behavior of the four-point function

$$\chi_4(t) = \frac{1}{N}\sum_{i,j}\langle S_i(t)S_j(t)S_i(0)S_j(0)\rangle$$

and its associate correlation length (Franz and Parisi 2000, Biroli and Bouchaud 2004).

### Off-Equilibrium Dynamics Below $T_c$: Aging and Slow Dynamics

**Type I systems** Below the transition temperature $T_c$ slow dynamics and aging set in. In 1993, Cugliandolo and Kurchan found a long-time

solution to the equations of motion [11] for type I systems describing an asymptotic off-equilibrium state that follows from high-temperature quench. Soon after, type II systems were also analyzed (Bouchaud *et al.*).

The equations can be analyzed in the limit in which both times tend to infinity $t, t' \to \infty$. In this regime all "one-time quantities," that is, state functions like energy, magnetization, etc., reach asymptotic time-independent limit. Though the decay to the asymptotic value cannot read directly from the analysis of the equations in that limit, numerical and theoretical evidence suggests that the final values are approached as power laws in time.

The study of correlation and response functions displays an asymptotic scaling behavior similar to the one observed in glassy systems in laboratory and numerical experiments.

Two different interesting regimes are found, first of all there is a stationary regime: the limit $t, t_w \to \infty$ is performed keeping the difference $t - t_w = s$ finite. In this regime, equilibrium behavior is observed, with correlation and response related by the FDT relation $R_{st}(s) = -\beta \partial C_{st}(s)/\partial s$. The stationary regime is followed by an aging regime, where correlations decay below the value $q_{EA} = \lim_{s \to \infty} C_{st}(s)$ down to zero. One of the most striking features of aging evolution is that the system – though at a decreasing speed – constantly move far apart from any visited region of configuration space. The decay of correlations is nonstationary and takes place on a timescale $\tau(t_w)$ diverging for large $t_w$. While the theory can infer the existence of the timescale $\tau(t_w)$, its precise form remains undetermined. This is a consequence of an asymptotic invariance under monotonous time reparametrizations $t \to g(t)$ appearing for large times. Coherently with nonstationary behavior, other equilibrium properties break down in the aging regime. Correlation and response which do not verify the FDT are rather asymptotically related by a generalized form of the fluctuation–dissipation relation

$$R_{ag}(t, t_w) = \frac{X}{T} \frac{\partial C_{ag}((t - t_w)/\tau(t_w))}{\partial t_w} \qquad [15]$$

This relation, despite predicting the vanishing of the instantaneous response, implies a finite contribution of the aging dynamics to the value of the integrated ZFC and TRM responses. The constant $X$, called fluctuation–dissipation ratio (FDR), is a temperature-dependent factor monotonically varying between the values 1 and 0 as the temperature is decreased from $T_c$ down to zero. Violations of the FDT have to be expected in any off-equilibrium regime; however, a constant ratio between response and derivative of the correlation is very nongeneric. It is of great theoretical importance that the same constant that governs the FDR among spin autocorrelation and magnetic response, also appears in the relation of any other conceivable couple of correlation and conjugated response in the system. Slow dynamics can be interpreted as motion between finite-life metastable states with well-defined free energy $f$ and exponential multiplicity $\exp(N\Sigma(f))$. The FDR verifies the generalized thermodynamic relation

$$\frac{\partial \Sigma}{\partial f} = \frac{X}{T} \qquad [16]$$

This relation is in turn intimately related to the possibility of considering the ratio $T_{eff} = T/X$ as an effective temperature, that governs the heat exchanges among slow degrees of freedom (Cugliandolo *et al.* 1997). Slow degrees of freedom do not exchange heat with the fast ones, but they are in equilibrium between themselves at the temperature $T_{eff}$. The validity of relation [16] has been put at the basis of a detailed statistical description of the glassy state (Franz and Virasoro 2000, Biroli and Kurchan 2001, Nieuwenhuizen 2000) which assumes that metastable states with equal free energy are encountered with equal probability during the descent to equilibrium. Modified thermodynamic relations follow, that condensate all the dependence on the thermal history in the value of the effective temperature. Given the interest of a thermodynamic description of the glassy state, many numerical studies have addressed the problem of the identification and determination of effective temperatures from the fluctuation–dissipation relations, and its relation with configurational entropy. In **Figure 3** the result of a numerical study on a realistic system is presented, verifying relation [15]. Experimental verifications are at the moment starting and new results are waited in the future.

**Type II systems** In these systems the dynamic transition occurs at the point of thermodynamic singularity, where the Edwards–Anderson parameter becomes nonzero in a second-order fashion. The magnetic susceptibility exhibits a cusp singularity similar to the one found in spin glass materials. Differently from type I systems, one-time quantities tend to their equilibrium values for long times. The off-equilibrium nature of the relaxation shows up in the behavior of correlations and responses, which display aging behavior.

Their behavior generalizes the one found in type I systems, with a more complex pattern of violation

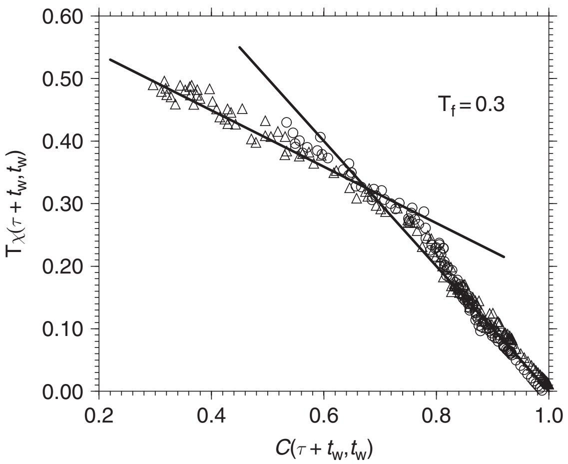

**Figure 3** Fluctuation–dissipation plot; $\chi_{ZFC}(t, t_w)$ vs. $C(t, t_w)$ in a model of Lennard-Jones glass for different values of the waiting time $t_w$. The slope of the curves is equal to the finite-time FDR divided by the temperature. One observes the characteristic shape of type-I systems with an FDR equal to 1 in the stationary regime for high correlations and equal to a constant smaller then 1 in the low-correlations aging regime. Reproduced from Kob W and Barrat J-L (1999) *Europhysics Letters* 46: 637, with permission from EDP Sciences.

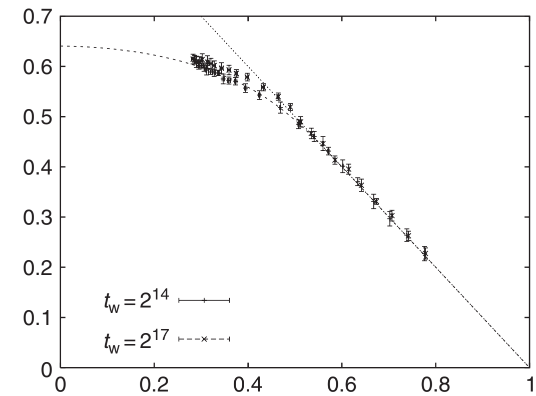

**Figure 4** Fluctuation–dissipation plot in a three-dimensional spin glass at low temperature. As predicted for type-II systems, the FDR is an increasing function of the correlation, constant only in the stationary part of the relaxation. Reproduced from Marinari E *et al.* (1998) Violation of the fluctuation dissipation theorem in finite dimensional spin glasses. *Journal of Physics A: Mathematical and General* 31: 2611, with permission from Institute of Physics Publishing Ltd.

of time-translation invariance and FDT. Also in this case a short-time equilibrium behavior can be identified where the correlation decreases from 1 to $q_{EA}$ and a long-time inhomogeneous aging behavior where correlations decrease to zero. Differently from type I system it is impossible to characterize aging through a unique timescale $\tau(t_w)$. One finds instead a continuum of timescales hierarchically organized. The analysis of the equations at the reparametrization-invariant level reveals the existence of a continuum of separate timescales $\tau(t_w, q)$ associated to each value of $C(t, t_w) = q < q_{EA}$ and that $\lim_{t_w \to \infty} \tau(t_w, q)/\tau(t_w, q') = 0$ for $q > q'$, meaning that for finite $t_w$ the time to decay to $q'$ is much larger than the time to decay to $q$. For large times, $1 << t_1 << t_2 << t_3$, the correlations verify the ultrametric property $C(t_3, t_1) = \min[C(t_3, t_2), C(t_2, t_1)]$. To each timescale corresponds in this case a different effective temperature, and correlation and response are related by the equation

$$\beta X(q) = \lim_{\substack{t, t_w \to \infty \\ C(t,t') = q}} \frac{R(t, t')}{\partial C(t, t')/\partial t'} \qquad [17]$$

where the function $X(q)$ is an increasing function of $q$ with the properties of a cumulative probability distribution. In fact it can be seen (Franz *et al.* 1999) that this is related to the Parisi overlap probability function describing the correlations among ergodic components at equilibrium, in a generalization of relation [14]. **Figure 4** shows the result of a numerical experiment in a three-dimensional spin glass, where $X(q)$ is not piecewise constant.

The ideas presented in this article, fruits of mean-field theory of disordered systems, are objects of intense debate in their application to the physics of short-range systems. Many of the relations derived have stimulated a lot of numerical, experimental, and theoretical work. Some of the predictions of the theory are very well verified in many short-range glassy systems, at least on the accessible timescales. Notably, the violations of FDR, and the possibility to associate the values of the FDR to effective temperatures is very well verified both in structural glass models, and in finite-range spin glasses. Since finite aging times imply finite length scales over which the dynamic variables can exhibit correlated behavior, this indicates that the mean-field theory is at least good at describing glassy phenomena on a local scale. The question if the mean-field theory also gives a good description on the infinite time limit and the anomalous response persists forever is at present an open theoretical problem. It relates to the possibility of having mean-field type of equilibrium ergodicity breaking, which is an open question, object of active research.

## Definitions

### Graded Vector Spaces

By a $\mathbb{Z}$-graded vector space (or simply, graded vector space) we mean a direct sum $A = \oplus_{i\in\mathbb{Z}} A_i$ of vector spaces over a field $k$ of characteristic zero. The $A_i$ are called the components of $A$ of degree $i$ and the degree of a homogeneous element $a \in A$ is denoted by $|a|$. We also denote by $A[n]$ the graded vector space with degree shifted by $n$, namely $A[n] = \oplus_{i\in\mathbb{Z}}(A[n])_i$ with $(A[n])_i = A_{i+n}$. The tensor product of two graded vector spaces $A$ and $B$ is again a graded vector space whose degree $r$ component is given by $(A\otimes B)_r = \oplus_{p+q=r} A_p \otimes B_q$.

The symmetric and exterior algebras of a graded vector space $A$ are defined, respectively, as $S(A) = T(A)/I_S$ and $\bigwedge(A) = T(A)/I_\wedge$, where $T(A) = \oplus_{n\geq 0} A^{\otimes n}$ is the tensor algebra of $A$ and $I_S$ (resp. $I_\wedge$) is the two-sided ideal generated by elements of the form $a\otimes b - (-1)^{|a|\,|b|} b\otimes a$ (resp. $a\otimes b + (-1)^{|a|\,|b|}\ b\otimes a$), with $a$ and $b$ homogeneous elements of $A$. The images of $A^{\otimes n}$ in $S(A)$ and $\bigwedge(A)$ are denoted by $S^n(A)$ and $\bigwedge^n(A)$, respectively. Notice that there is a canonical decalage isomorphism $S^n(A[1]) \simeq \bigwedge^n(A)[n]$.

### Graded Algebras and Graded Lie Algebras

We say that $A$ is a graded algebra (of degree zero) if $A$ is a graded vector space endowed with a degree zero bilinear associative product: $A\otimes A \to A$. A graded algebra is graded commutative if the product satisfies the condition

$$a\cdot b = (-1)^{|a|\,|b|} b\cdot a$$

for any two homogeneous elements $a, b\in A$ of degree $|a|$ and $|b|$, respectively.

A graded Lie algebra of degree $n$ is a graded vector space $A$ endowed with a graded Lie bracket on $A[n]$. Such a bracket can be seen as a degree $-n$ Lie bracket on $A$, that is, as a bilinear operation $\{\cdot,\cdot\}: A\otimes A\to A[-n]$ satisfying graded antisymmetry and graded Jacobi relations:

$$\{a,b\} = -(-1)^{(|a|+n)(|b|+n)}\{b,a\}$$

$$\{a,\{b,c\}\} = \{\{a,b\},c\} + (-1)^{(|a|+n)(|b|+n)}\{a\{b,c\}\}$$

### Graded Poisson Algebras

We can now define the main object of interest of this note:

**Definition 1** A graded Poisson algebra of degree $n$, or $n$-Poisson algebra, is a triple $(A,\cdot,\{,\})$ consisting of a graded vector space $A = \oplus_{i\in\mathbb{Z}} A_i$ endowed with a degree zero graded commutative product and with

a degree $-n$ Lie bracket. The bracket is required to be a biderivation of the product, namely:

$$\{a, b \cdot c\} = \{a, b\} \cdot c + (-1)^{|b|(|a|+n)} b \cdot \{a, c\}$$

*Notation*. Graded Poisson algebras of degree zero are called Poisson algebras, while for $n = 1$ one speaks of Gerstenhaber (1963) algebras or of Schouten algebras.

Sometimes a $\mathbb{Z}_2$-grading is used instead of a $\mathbb{Z}$-grading. In this case, one just speaks of even and odd Poisson algebras.

**Example 1** Any graded commutative algebra can be seen as a Poisson algebra with the trivial Lie structure, and any graded Lie algebra can be seen as a Poisson algebra with the trivial product.

**Example 2** The most classical example of a Poisson algebra (already considered by Poisson himself) is the algebra of smooth functions on $\mathbb{R}^{2n}$ endowed with usual multiplication and with the Poisson bracket $\{f, g\} = \partial_{q^i} f \partial_{p_i} g - \partial_{q^i} g \partial_{p_i} f$, where the $p_i$'s and the $q^i$'s, for $i = 1, \ldots, n$, are coordinates on $\mathbb{R}^{2n}$. The bivector field $\partial_{q^i} \wedge \partial_{p_i}$ is induced by the symplectic form $\omega = \mathrm{d}p_i \wedge \mathrm{d}q^i$. An immediate generalization of this example is the algebra of smooth functions on a symplectic manifold $(\mathbb{R}^{2n}, \omega)$ with the Poisson bracket $\{f, g\} = \omega^{ij} \partial_i f \partial_j g$, where $\omega^{ij} \partial_i \wedge \partial_j$ is the bivector field defined by the inverse of the symplectic form $\omega = \omega_{ij} \mathrm{d}x^i \wedge \mathrm{d}x^j$; viz. $\omega_{ij} \omega^{jk} = \delta_i^k$.

A further generalization is when the bracket on $C^\infty(\mathbb{R}^m)$ is defined by $\{f, g\} = \alpha^{ij} \partial_i f \partial_j g$, with the matrix function $\alpha$ not necessarily nondegenerate. The bracket is Poisson if and only if $\alpha$ is skewsymmetric and satisfies

$$\alpha^{ij} \partial_i \alpha^{kl} + \alpha^{il} \partial_i \alpha^{jk} + \alpha^{ik} \partial_i \alpha^{lj} = 0$$

An example of this, already considered by Lie (1894), is $\alpha^{ij}(x) = f_k^{ij} x^k$, where the $f_k^{ij}$'s are the structure constants of some Lie algebra.

**Example 3** Example 2 can be generalized to any symplectic manifold $(M, \omega)$. To every function $h \in C^\infty(M)$ one associates the Hamiltonian vector field $X_h$ which is the unique vector field satisfying $i_{X_h} \omega = \mathrm{d}h$. The Poisson bracket of two functions $f$ and $g$ is then defined by

$$\{f, g\} = i_{X_f} i_{X_g} \omega$$

In local coordinates, the corresponding Poisson bivector field is related to the symplectic form as in Example 2.

A generalization is the algebra of smooth functions on a manifold $M$ with bracket $\{f, g\} = \langle \alpha | \mathrm{d}f \wedge \mathrm{d}g \rangle$, where $\alpha$ is a bivector field (i.e., a section of $\bigwedge^2 TM$) such that $\{\alpha, \alpha\}_{SN} = 0$, where $\{\cdot, \cdot\}_{\mathrm{SN}}$ is the Schouten–Nijenhuis bracket (see the first subsection in the next section for details, and Example 2 for the local coordinate expression). Such a bivector field is called a Poisson bivector field and the manifold $M$ is called a Poisson manifold. Observe that a Poisson algebra structure on the algebra of smooth functions on a smooth manifold is necessarily defined this way. In the symplectic case, the bivector field corresponding to the Poisson bracket is the inverse of the symplectic form (regarded as a bundle map $TM \to T^*M$).

The linear case described at the end of Example 2 corresponds to $M = \mathfrak{g}^*$ where $\mathfrak{g}$ is a (finite-dimensional) Lie algebra. The Lie bracket $\bigwedge^2 \mathfrak{g} \to \mathfrak{g}$ is regarded as an element of $\mathfrak{g} \otimes \bigwedge^2 \mathfrak{g}^* \subset \Gamma(\bigwedge^2 T\mathfrak{g}^*)$ and reinterpreted as a Poisson bivector field on $\mathfrak{g}$. The Poisson algebra structure restricted to polynomial functions is described at the beginning of the next section.

## Batalin–Vilkovisky Algebras

When $n$ is odd, a generator for the bracket of an $n$-Poisson algebra $A$ is a degree $-n$ linear map from $A$ to itself,

$$\Delta : A \to A[-n]$$

such that

$$\Delta(a \cdot b) = \Delta(a) \cdot b + (-1)^{|a|} a \cdot \Delta(b) + (-1)^{|a|} \{a, b\}$$

A generator $\Delta$ is called exact if and only if it satisfies the condition $\Delta^2 = 0$, and in this case $\Delta$ becomes a derivation of the bracket:

$$\Delta(\{a, b\}) = \{\Delta(a), b\} + (-1)^{|a|+1} \{a, \Delta(b)\}$$

**Remark 1** Notice that not every odd Poisson algebra $A$ admits a generator. For instance, a nontrivial odd Lie algebra seen as an odd Poisson algebra with trivial multiplication admits no generator. Moreover, even if a generator $\Delta$ for an odd Poisson algebra exists, it is far from being unique. In fact, all different generators are obtained by adding to $\Delta$ a derivation of $A$ of degree $-n$.

**Definition 2** An $n$-Poisson algebra $A$ is called an $n$-Batalin–Vilkovisky algebra, if it is endowed with an exact generator.

*Notation*. When $n = 1$ it is customary to speak of Batalin–Vilkovisky algebras, or simply BV algebras (*see* Batalin–Vilkovisky Quantization; see also Batalin and Vilkovisky (1963), Getzler (1994), and Koszul (1985)).

There exists a characterization of $n$-Batalin–Vilkovisky algebras in terms of only the product and the generator (Getzler 1994, Koszul (1985). Suppose in fact that a graded vector space $A$ is endowed with a degree zero graded commutative product and a linear map $\Delta : A \to A[-n]$ such that $\Delta^2 = 0$, satisfying the following "seven-term" relation:

$$\begin{aligned}\Delta(a\cdot b\cdot c) + \Delta(a)\cdot b\cdot c + (-1)^{|a|}a\cdot\Delta(b)\cdot c\\ + (-1)^{|a|+|b|}a\cdot b\cdot\Delta(c)\\ = \Delta(a\cdot b)\cdot c + (-1)^{|a|}a\cdot\Delta(b\cdot c)\\ + (-1)^{(|a|+1)|b|}b\cdot\Delta(a\cdot c)\end{aligned}$$

In other words, $\Delta$ is a derivation of order 2.

Then, if we define the bilinear operation $\{,\} : A\otimes A \to A[-n]$ by

$$\{a,b\} = (-1)^{|a|}\Big(\Delta(a\cdot b) - \Delta(a)\cdot b - (-1)^{|a|}a\cdot\Delta(b)\Big)$$

we have that the quadruple $(A,\cdot,\{,\},\Delta)$ is an $n$-Batalin–Vilkovisky algebra. Conversely, one easily checks that the product and the generator of an $n$-Batalin–Vilkovisky algebra satisfy the above "seven-term" relation.

## Examples

### Schouten–Nijenhuis Bracket

Suppose $\mathfrak{g}$ is a graded Lie algebra of degree zero. Then $A = S(\mathfrak{g}[n])$ is a $(-n)$-Poisson algebra with its natural multiplication (the one induced from the tensor algebra $T(A)$) and a degree $-n$ bracket defined as follows (Koszul 1985, Krasil'shchik 1988): the bracket on $S^1(\mathfrak{g}[n]) = \mathfrak{g}[n]$ is defined as the suspension of the bracket on $\mathfrak{g}$, while on $S^k(\mathfrak{g}[n])$, for $k > 1$, the bracket, often called the Schouten–Nijenhuis bracket, is defined inductively by forcing the Leibniz rule

$$\{a, b\cdot c\} = \{a,b\}\cdot c + (-1)^{|b|(|a|+n)}b\cdot\{a,c\}$$

Moreover, when $n$ is odd, there exists a generator defined as

$$\Delta(a_1\cdot a_2\cdots a_k) = \sum_{i<j}(-1)^{\epsilon}\{a_i,a_j\}\cdot a_1\cdots\widehat{a_i}\cdots\widehat{a_j}\cdots a_k$$

where $a_1,\ldots,a_k \in \mathfrak{g}$ and $\epsilon = |a_i| + (|a_i|+1)(|a_1|+\cdots+|a_{i-1}|+i-1) + (|a_j|+1)(|a_1|+\cdots+\widehat{|a_i|}+\cdots+|a_{j-1}|+j-2)$. An easy check shows that $\Delta^2 = 0$, thus $S(\mathfrak{g}[n])$ is an $n$-Batalin–Vilkovisky algebra for every odd $n \in \mathbb{N}$. For $n = -1$ the $\Delta$-cohomology on $\bigwedge\mathfrak{g}$ is the usual Cartan–Chevalley–Eilenberg cohomology.

In particular, one can consider the Lie algebra $\mathfrak{g} = \mathrm{Der}(B) = \oplus_{j\in\mathbb{Z}}\mathrm{Der}^j(B)$ of derivations of a graded commutative algebra $B$. More explicitly, $\mathrm{Der}^j(B)$ consists of linear maps $\phi : B \to B$ of degree $j$ such that $\phi(ab) = \phi(a)b + (-1)^{j|a|}a\phi(b)$ and the bracket is $\{\phi,\psi\} = \phi\circ\psi - (-1)^{|\phi||\psi|}\psi\circ\phi$. The space of multiderivations $S(\mathrm{Der}(B)[-1])$, endowed with the Schouten–Nijenhuis bracket, is a Gerstenhaber algebra.

We can further specialize to the case when $B$ is the algebra $\mathcal{C}^\infty(M)$ of smooth functions on a smooth manifold $M$; then $\mathfrak{X}(M) = \mathrm{Der}(\mathcal{C}^\infty(M))$ is the space of vector fields on $M$ and $\mathcal{V}(M) = S(\mathfrak{X}(M)[-1])$ is the space of multivector fields on $M$. It is a classical result by Koszul (1985) that there is a bijective correspondence between generators for $\mathcal{V}(M)$ and connections on the highest exterior power $\bigwedge^{\dim M}TM$ of the tangent bundle of $M$. Moreover, flat connections correspond to generators which square to zero.

### Lie Algebroids

A Lie algebroid $E$ over a smooth manifold $M$ is a vector bundle $E$ over $M$ together with a Lie algebra structure (over $\mathbb{R}$) on the space $\Gamma(E)$ of smooth sections of $E$, and a bundle map $\rho : E \to TM$, called the anchor, extended to a map between sections of these bundles, such that

$$\{X, fY\} = f\{X,Y\} + (\rho(X)f)Y$$

for any smooth sections $X$ and $Y$ of $E$ and any smooth function $f$ on $M$. In particular, the anchor map induces a morphism of Lie algebras $\rho_* : \Gamma(E) \to \mathfrak{X}(M)$, namely $\rho_*(\{X,Y\}) = \{\rho_*(X), \rho_*(Y)\}$.

The link between Lie algebroids and Gerstenhaber algebras is given by the following Proposition (Kosmann-Schwarzbach and Monterde 2002, Xu 1999):

**Proposition 1** *Given a vector bundle $E$ over $M$, there exists a one-to-one correspondence between Gerstenhaber algebra structures on $A = \Gamma(\bigwedge(E))$ and Lie algebroid structures on $E$.*

The key of the proposition is that one can extend the Lie algebroid bracket to a unique graded antisymmetric bracket on $\Gamma(\bigwedge(E))$ such that $\{X,f\} = \rho(X)f$ for $X \in \Gamma(\bigwedge^1(E))$ and $f \in \Gamma(\bigwedge^0(E))$, and that for $Q \in \Gamma(\bigwedge^{q+1}(E))$, $\{Q,\cdot\}$ is a derivation of $\Gamma(\bigwedge(E))$ of degree $q$.

**Example 4** A finite-dimensional Lie algebra $\mathfrak{g}$ can be seen as a Lie algebroid over a trivial base manifold. The corresponding Gerstenhaber algebra is the one of last subsection.

**Example 5** The tangent bundle $TM$ of a smooth manifold $M$ is a Lie algebroid with anchor map given by the identity and algebroid Lie bracket given by the usual Lie bracket on vector fields. In this case, we recover the Gerstenhaber algebra of multivector fields on $M$ described in the last subsection.

**Example 6** If $M$ is a Poisson manifold with Poisson bivector field $\alpha$, then the cotangent bundle $T^*M$ inherits a natural Lie algebroid structure where the anchor map $\alpha^\# : T_p^*M \to T_pM$ at the point $p \in M$ is given by $\alpha^\#(\xi)(\eta) = \alpha(\xi, \eta)$, with $\xi, \eta \in T_p^*M$, and the Lie bracket of the 1-forms $\omega_1$ and $\omega_2$ is given by

$$\{\omega_1, \omega_2\} = L_{\alpha^\#(\omega_1)}\omega_2 - L_{\alpha^\#(\omega_2)}\omega_1 - \mathrm{d}\alpha(\omega_1, \omega_2)$$

The associated Gerstenhaber algebra is the de Rham algebra of differential forms endowed with the bracket defined by Koszul (1985). As shown in Kosmann-Schwarzbach (1995), $\Gamma(\bigwedge(T^*M))$ is indeed a BV algebra with an exact generator $\Delta = [\mathrm{d}, i_\alpha]$ given by the commutator of the contraction $i_\alpha$ with the Poisson bivector $\alpha$ and the de Rham differential d. Similar results hold if $M$ is a Jacobi manifold.

It is natural to ask what additional structure on a Lie algebroid $E$ makes the Gerstenhaber algebra $\Gamma(\bigwedge(E))$ into a BV algebra. The answer is given by the following result, which is proved in Xu (1999).

**Proposition 2** *Given a Lie algebroid E, there is a one-to-one correspondence between generators for the Gerstenhaber algebra $\Gamma(\bigwedge(E))$ and E-connections on $\bigwedge^{\mathrm{rk}\,E}E$ (where rk E denotes the rank of the vector bundle E). Exact generators correspond to flat E-connections , and in particular, since flat E-connections always exist, $\Gamma(\bigwedge(E))$ is always a BV algebra.*

### Lie Algebroid Cohomology

A Lie algebroid structure on $E \to M$ defines a differential $\delta$ on $\Gamma(\bigwedge E^*)$ by

$$\delta f := \rho^* \mathrm{d}f, \qquad f \in C^\infty(M) = \Gamma(\Lambda^0 E^*)$$

and

$$\langle \delta\alpha, X \wedge Y\rangle := \langle \delta\langle\alpha, X\rangle, Y\rangle - \langle \delta\langle\alpha, Y\rangle, X\rangle \\ - \langle \alpha, \{X, Y\}\rangle X, Y \in \Gamma(E), \alpha \in \Gamma(E^*)$$

where $\rho^* : \Omega^1(M) \to \Gamma(E^*)$ is the transpose of $\rho_* : \Gamma(E) \to \mathfrak{X}(M)$ and $\langle\,,\rangle$ is the canonical pairing of sections of $E^*$ and $E$. On $\Gamma(\bigwedge^n E^*)$, with $n \geq 2$, the differential $\delta$ is defined by forcing the Leibniz rule.

In Example 4 we get the Cartan–Chevalley–Eilenberg differential on $\bigwedge \mathfrak{g}^*$; in Example 5 we recover the de Rham differential on $\Omega^*(M) = \Gamma(\bigwedge T^*M)$, while in Example 6 the differential on $\mathcal{V}(M) = \Gamma(\bigwedge TM)$ is $\{\alpha, \}_{\mathrm{SN}}$.

### Lie–Rinehart Algebras

The algebraic generalization of a Lie algebroid is a Lie–Rinehart algebra. Recall that given a commutative associative algebra $B$ (over some ring $R$) and a $B$-module $\mathfrak{g}$, then a Lie–Rinehart algebra structure on $(B, \mathfrak{g})$ is a Lie algebra structure (over $R$) on $\mathfrak{g}$ and an action of $\mathfrak{g}$ on the left on $B$ by derivations, satisfying the following compatibility conditions:

$$\{\gamma, a\sigma\} = \gamma(a)\delta + a\{\gamma, \sigma\} \\ (a\gamma)(b) = a(\gamma(b))$$

for every $a, b \in B$ and $\gamma, \sigma \in \mathfrak{g}$.

The Lie–Rinehart structures on the pair $(B, \mathfrak{g})$ bijectively correspond to the Gerstenhaber algebra structures on the exterior algebra $\bigwedge_B(\mathfrak{g})$ of $\mathfrak{g}$ in the category of $B$-modules. When $\mathfrak{g}$ is of finite rank over $B$, generators for these structures are in turn in bijective correspondence with $(B, \mathfrak{g})$-connections on $\bigwedge_B^{\mathrm{rk}} B^{\mathfrak{g}}\mathfrak{g}$, and flat connections correspond to exact generators. For additional discussions, see Gerstenhaber and Schack (1992) and Huebschmann (1998).

Lie algebroids are Lie–Rinehart algebras in the smooth setting. Namely, if $E \to M$ is a Lie algebroid, then the pair $(\mathcal{C}^\infty(M), \Gamma(E))$ is a Lie–Rinehart algebra (with action induced by the anchor and the given Lie bracket).

### Lie–Rinehart Cohomology

Lie algebroid cohomology may be generalized to every Lie–Rinehart algebra $(B, \mathfrak{g})$. Namely, on the complex $\mathrm{Alt}_B(\mathfrak{g}, B)$ of alternating multilinear functions on $\mathfrak{g}$ with values in $B$, one can define a differential $\delta$ by the rules

$$\langle \delta a, \gamma\rangle = \gamma(a), \qquad a \in B = \mathrm{Alt}_B^0(\mathfrak{g}, B), \quad \gamma \in \mathfrak{g} \\ \langle \delta a, \gamma \wedge \sigma\rangle = \langle \delta\langle a, \gamma\rangle, \sigma\rangle - \langle \delta\langle a, \sigma\rangle, \gamma\rangle - \langle a, \{\gamma, \sigma\}\rangle \\ \gamma, \sigma \in \mathfrak{g}, \quad a \in \mathrm{Alt}_B^1(\mathfrak{g}, B)$$

and forcing the Leibniz rule on elements of $\mathrm{Alt}_B^n(\mathfrak{g}, B)$, $n \geq 2$.

### Hochschild Cohomology

Let $A$ be an associative algebra with product $\mu$, and consider the Hochschild cochain complex $\mathsf{Hoch}(A) = \prod_{n\geq 0} \mathrm{Hom}(A^{\otimes n}, A)[-n+1]$. There are two basic operations between two elements $f \in \mathrm{Hom}(A^{\otimes k}, A)[-k+1]$ and $g \in \mathrm{Hom}(A^{\otimes l}, A)[-l+1]$, namely a degree zero product

$$f \cup g(a_1 \otimes \cdots \otimes a_{k+l}) \\ = (-1)^{kl} f(a_1 \otimes \cdots \otimes a_l) \cdot g(a_{l+1} \otimes \cdots \otimes a_{k+l})$$

and a degree $-1$ bracket $\{f,g\}=f\circ g-(-1)^{(k-1)(l-1)}g\circ f$, where

$$f\circ g(a_1\otimes\cdots\otimes a_{k+l-1})\\=\sum_{i=1}^{k-1}(-1)^{i(l-1)}f(a_1\otimes\cdots\otimes a_i\otimes g(a_{i+1}\\\otimes\cdots\otimes a_{i_l})\otimes\cdots\otimes a_{k+l-1})$$

It is well known from Gerstenhaber (1963) that the cohomology $\mathsf{HHoch}(A)$ of the Hochschild complex with respect to the differential $d_{\mathsf{Hoch}}=\{\mu,\cdot\}$ has the structure of a Gerstenhaber algebra. More generally, there is a Gerstenhaber algebra structure on Hochschild cohomology of differential graded associative algebras (Loday 1998).

### Graded Symplectic Manifolds

The construction of Example 3 can be extended to graded symplectic manifolds (*see* Supermanifolds; see also Alexandrov *et al.* (1997), Getzler (1994), and Schwarz (1993)). Recall that a symplectic structure of degree $n$ on a graded manifold $N$ is a closed nondegenerate 2-form $\omega$ such that $L_E\omega=n\omega$ where $L_E$ is the Lie derivative with respect to the Euler field of $N$ (see Roytenberg (2002) for details). Let us denote by $X_h$ the vector field associated to the function $h\in\mathcal{C}^\infty(N)$ by the formula $i_{X_h}\omega=dh$. Then the bracket

$$\{f,g\}=i_{X_f}i_{X_g}\omega$$

gives $\mathcal{C}^\infty(N)$ the structure of a graded Poisson algebra of degree $n$.

If the symplectic form has odd degree and the graded manifold has a volume form, then it is possible to construct an exact generator defined by

$$\Delta(f)=\tfrac{1}{2}\mathrm{div}(X_f)$$

where div is the divergence operator associated to the given volume form (Getzler 1994, Kosmann-Schwazbach and Monterde 2002).

An explicit characterization of graded symplectic manifolds has been given in Roytenberg (2002). In particular, it is proved there that every symplectic form of degree $n$ with $n\geq 1$ is necessarily exact. More precisely, one has $\omega=d(i_E\omega/n)$.

### Shifted Cotangent Bundles

The main examples of graded symplectic manifolds are given by shifted cotangent bundles. If $N$ is a graded manifold then the shifted cotangent bundle $T^*[n]N$ is the graded manifold obtained by shifting by $n$ the degrees of the fibers of the cotangent bundle of $N$. This graded manifold possesses a nondegenerate closed 2-form of degree $n$, which can be expressed in local coordinates as

$$\omega=\sum_i dx^i\wedge dx_i^\dagger$$

where $\{x^i\}$ are local coordinates on $N$ and $\{x_i^\dagger\}$ are coordinate functions on the fibers of $T^*[n]N$. In local coordinates, the bracket between two homogeneous functions $f$ and $g$ is given by

$$\{f,g\}=-(-1)^{|x_i^\dagger||f|}\frac{\partial f}{\partial x_i^\dagger}\frac{\partial g}{\partial x^i}\\-(-1)^{(|f|+n)(|g|+n)+|x_i^\dagger||g|}\frac{\partial g}{\partial x_i^\dagger}\frac{\partial f}{\partial x^i}$$

If in addition the graded manifold $N$ is orientable, then $T^*[n]N$ has a volume form too; when $n$ is odd, the exact generator $\Delta(f)=(1/2)\mathrm{div}X_f$ is written in local coordinates as

$$\Delta=\frac{\partial}{\partial x_i^\dagger}\frac{\partial}{\partial x^i}$$

In the case $n=1$, we have a natural identification between functions on $T^*[1]N$ and multivector fields $\mathcal{V}(N)$ on $N$, and we recover again the Gerstenhaber algebra of the subsection "Schouten–Nijenhuis bracket." Moreover, it is easy to see that, under the above identification, $\Delta$ applied to a vector field of $N$ is the usual divergence operator.

### Examples from Algebraic Topology

For any $n>1$, the homology of the $n$-fold loop space $\Omega^n(M)$ of a topological space $M$ has the structure of an $(n-1)$-Poisson algebra (May 1972). In particular, the homology of the double loop space $\Omega^2(M)$ is a Gerstenhaber algebra, and has an exact generator defined using the natural circle action on this space (Getzler 1994). The homology of the free loop space $\mathcal{L}(M)$ of a closed oriented manifold $M$ is also a BV algebra when endowed with the "Chas–Sullivan intersection product" and with a generator defined again using the natural circle action on the free loop space (Cohen and Jones 2002).

## Applications

### BRST Quantization in the Hamiltonian Formalism

The BRST procedure is a method for quantizing classical mechanical systems or classical field theories in the presence of symmetries (*see* BRST Quantization). The starting point is a symplectic manifold $M$ (the "phase space"), a function $H$ (the "Hamiltonian" of the system) governing the evolution of the system, and the "constraints" given by

several functions $g_i$ which commute with $H$ and among each other up to a $\mathcal{C}^\infty(M)$-linear combination of the $g_i$'s.

Then the dynamics is constrained on the locus $V$ of common zeros of the $g_i$'s. When $V$ is a submanifold, the $g_i$'s are a set of generators for the ideal $I$ of functions vanishing on $V$. Observe that $I$ is closed under the Poisson bracket. Functions in $I$ are called "first class constraints." The Hamiltonian vector fields of first-class constraints, which by construction tangential to $V$, are the "symmetries" of the system.

When $V$ is smooth, then it is a coisotropic submanifold of $M$ and the Hamiltonian vector fields determined by the constraints give a foliation $\mathcal{F}$ of $V$. In the nicest case $V$ is a principal bundle with $\mathcal{F}$ its vertical foliation and the algebra of functions $\mathcal{C}^\infty(V/\mathcal{F})$ on the "reduced phase space" (*see* Poisson Reduction, and Symmetry and Symplectic Reduction) $V/\mathcal{F}$ is identified with the $I$-invariant subalgebra of $\mathcal{C}^\infty(M)/I$.

From a physical point of view, the points of $V/\mathcal{F}$ are the interesting states at a classical level, and a quantization of this system means a quantization of $\mathcal{C}^\infty(V/\mathcal{F})$. The BRST procedure gives a method of quantizing $\mathcal{C}^\infty(V/\mathcal{F})$ starting from the (known) quantization of $\mathcal{C}^\infty(M)$. Notice that these notions immediately generalize to graded symplectic manifolds.

From an algebraic point of view, one starts with a graded Poisson algebra $P$ and a multiplicative ideal $I$ which is closed under the Poisson bracket. The algebra of functions on the "reduced phase space" is replaced by $(P/I)^I$, the $I$-invariant subalgebra of $P/I$. This subalgebra inherits a Poisson bracket even if $P/I$ does not. Moreover, the pair $(B,\mathfrak{g})=(P/I,I/I^2)$ inherits a graded Lie–Rinehart structure. The "Rinehart complex" $\mathrm{Alt}_{P/I}(I/I^2,P/I)$ of alternating multilinear functions on $I/I^2$ with values in $P/I$, endowed with the differential described in the subsection "Lie-Rinehart cohomology," plays the role of the de Rham complex of vertical forms on $V$ with respect to the foliation $\mathcal{F}$ determined by the constraints.

In case $V$ is a smooth submanifold, we also have the following geometric interpretation: let $N^*V$ denote the conormal bundle of $V$ (i.e., the annihilator of $TV$ in $T_VP$). This is a Lie subalgebroid of $T^*P$ if and only if $V$ is coisotropic. Since we may identify $I/I^2$ with sections of $N^*C$ (by the de Rham differential), $(P/I,I/I^2)$ is the corresponding Lie–Rinehart pair. The Rinehart complex is then the corresponding Lie algebroid complex $\Gamma(\bigwedge(N^*V)^*)$ with differential described in the subsection "Lie algebroid cohomology." The image of the anchor map $N^*V\to TV$ is the distribution determining $\mathcal{F}$, so by duality we get an injective chain map from the vertical de Rham complex to the Rinehart complex.

The main point of the BRST procedure is to define a chain complex $C^\bullet=\bigwedge(\Psi^*\oplus\Psi)\otimes P$, where $\Psi$ is a graded vector space, with a coboundary operator $D$ (the "BRST operator"), and a quasi-isomorphism (i.e., a chain map that induces an isomorphism in cohomology)

$$\pi:(C^\bullet,D)\to\left(\mathrm{Alt}_{P/I}(I^2/I,P/I),\mathrm{d}\right)$$

This means in particular that the zeroth cohomology $H^0_D(C)$ gives the algebra $(P/I)^I$ of functions on the "reduced phase space." Observe that there is a natural symmetric inner product on $\Psi^*\oplus\Psi$ given by the evaluation of $\Psi^*$ on $\Psi$. This inner product, as an element of $S^2(\Psi\oplus\Psi^*)\simeq S^2(\Psi)\oplus(\Psi\otimes\Psi^*)\oplus S^2(\Psi^*)$, is concentrated in the component $\Psi\otimes\Psi^*$, and so it defines an element in $\bigwedge^2(\Psi[1]\oplus\Psi^*[-1])\simeq S^2(\Psi)[2]\oplus(\Psi\otimes\Psi^*)\oplus S^2(\Psi^*)[-2]$, that is, a degree zero bivector field on $\Psi[1]\oplus\Psi^*[-1]$. It is easy to see that this bivector field induces a degree zero Poisson structure on $S(\Psi^*[-1]\oplus\Psi[1])$. From another viewpoint this is the Poisson structure corresponding to the canonical symplectic structure on $T^*\Psi[1]$. Finally, we have that $S(\Psi^*[-1]\oplus\Psi[1])\otimes P$ is a degree zero Poisson algebra. Note that the superalgebra underlying the graded algebra $S(\Psi^*[-1]\oplus\Psi[1])\otimes P$ is canonically isomorphic to the complex $C^\bullet=\bigwedge(\Psi^*\oplus\Psi)\otimes P$. When $P=\mathcal{C}^\infty(M)$, we can think of $S(\Psi^*[-1]\oplus\Psi[1])\otimes\mathcal{C}^\infty(M)$ as the algebra of functions on the graded symplectic manifold $N=(\Psi[1]\oplus\Psi^*[-1])\times M$ (the "extended phase space"). In physical language, coordinate functions on $\Psi[1]$ are called "ghost fields" while coordinate functions on $\Psi^*[-1]$ are called "ghost momenta" or, by some authors, "antighost fields" (not to be confused with the antighosts of the Lagrangian functional-integral approach to quantization).

Suppose now that there exists an element $\Theta\in S(\Psi^*[-1]\oplus\Psi[1])\otimes P$ such that $\{\Theta,\cdot\}=D$, that one can extend the "known" quantization of $P$ to a quantization of $S(\Psi^*[-1]\oplus\Psi[1])\otimes P$ as operators on some (graded) Hilbert space $\mathcal{T}$ and that the operator $Q$ which quantizes $\Theta$ has square zero. Then one can consider the "true space of physical states" $H^0_Q(\mathcal{T})$ on which the $\mathrm{ad}_Q$-cohomology of operators will act. This provides one with a quantization of $(P/I)^I$.

For further details on this procedure, and in particular for the construction of $D$, we refer to Henneaux and Teitelboim (1992), Kostant and Sternberg (1987), and Stasheff (1997), and references therein. Observe that some authors refer to this method as BVF (Batalin–Vilkovisky–Fradkin) and reserve the name BRST for the case when the $g_i$'s are the components of an equivariant moment map.

For a generalization to graded manifolds different from $(\Psi[1] \oplus \Psi^*[-1]) \times M$ we refer to Roytenberg (2002). There it is proved that the element $\Theta$ exists if the graded symplectic form has degree different from –1.

#### BV Quantization in the Lagrangian Formalism

The BV formalism (*see* Batalin–Vilkovisky Quantization; see also Batalin and Vilkovisky (1983) and Henneaux and Teitelboim (1992)) is a procedure for the quantization of physical systems with symmetries in the Lagrangian formalism. As a first step, the "configuration space" $M$ of the system is augmented by the introduction of "ghosts." If $G$ is the group of symmetries, this means that one has to consider the graded manifold $W = \mathfrak{g}[1] \times M$. The second step is to double this space by introducing "antifields for fields and ghosts," namely one has to consider the "extended configuration space" $T^*[-1]W$, whose space of functions is a BV algebra (see the subsection "Shifted cotangent bundle." The algebra of "observables" is by definition the cohomology $H^*_\Delta(\mathcal{C}^\infty(T^*[-1]W))$ with respect to the exact generator $\Delta$.

## Related Topics

### AKSZ

The graded manifold $T^*[-1]W$ considered above is a particular example of a $QP$-manifold, that is, of a graded manifold $M$ endowed with an integrable (i.e., self-commuting) vector field $Q$ of degree 1 and a graded $Q$-invariant symplectic structure $P$. In quantization of classical mechanical theories, the graded symplectic manifold of interest is the space of fields and antifields with symplectic form of degree 1, while $Q$ is the Hamiltonian vector field defined by the action functional $S$; the integrability of $Q$ is equivalent to the classical master equation $\{S, S\} = 0$ for the action functional. Quantization of the theory is then reduced to the computation of the functional integral $\int_{\mathcal{L}} \exp(\mathrm{i}S/\hbar)$, where $\mathcal{L}$ is a Lagrangian submanifold of $M$. This functional integral actually depends only on the homology class of the Lagrangian. Locally, a $QP$ manifold is a shifted cotangent bundle $T^*[-1]N$ and a Lagrangian submanifold is the graph of an exact 1-form. In the notations of the subsection "Shifted cotangent bundle," a Lagrangian submanifold $\mathcal{L}$ is therefore locally defined by equations $x_i^\dagger = \partial\Phi/\partial x^i$, and the function $\Phi$ is called a gauge-fixing fermion. The action functional of interest is then the gauge-fixed action $S|_{\mathcal{L}} = S(x^i, \partial\Phi/\partial x^i)$.

The language of $QP$ manifolds has powerful applications to sigma models (*see* Topological Sigma Models): if $\Sigma$ is a finite-dimensional graded manifold equipped with a volume element, and $M$ is a $QP$ manifold, then the graded manifold $C^\infty(\Sigma, M)$ of smooth maps from $\Sigma$ to $M$ has a natural structure of $QP$ manifold which describes some field theory if one arranges for the symplectic structure to be of degree 1. As an illustrative example, if $\Sigma = T[1]X$, for a compact oriented three-dimensional smooth manifold $X$, and $M = \mathfrak{g}[1]$, where $\mathfrak{g}$ is the Lie algebra of a compact Lie group, the $QP$ manifold $C^\infty(\Sigma, M)$ is relevant to Chern–Simons theory on $X$. Similarly, if $\Sigma = T[1]X$, for a compact oriented two-dimensional smooth manifold $X$ and $M = T[1]N$ is the shifted tangent bundle of a symplectic manifold, then the $QP$ structure on $C^\infty(\Sigma, M)$ is related to the A-model with target $N$; if the symplectic manifold $N$ is of the form $N = T^*K$ for a complex manifold $K$, then one can endow $C^\infty(\Sigma, M)$ with a complex $QP$ manifold structure, which is related to the B-model with target $K$; this shows that, in some sense, the B-model can be obtained from the A-model by "analytic continuation" (Alexandrov *et al.* 1997). If $\Sigma = T[1]X$, for a compact oriented two-dimensional smooth manifold $X$ and $M = T^*[1]N$ with canonical symplectic structure, then the $QP$ structure on $C^\infty(\Sigma, M)$ is related to the Poisson sigma model ($QP$ structures on $T^*[1]N$ with canonical symplectic structure are in one-to-one correspondence with Poisson structures on $N$). The study of $QP$ manifolds is sometimes referred to as "the AKSZ formalism". In Roytenberg (2002) $QP$ manifolds with symplectic structure of degree 2 are studied and shown to be in one-to-one correspondence with Courant algebroids.

### Graded Poisson Algebras from Cohomology of $P_\infty$

The Poisson bracket on a Poisson manifold can be derived from the Poisson bivector field $\alpha$ using the Schouten–Nienhuis bracket as follows:

$$\{f, g\} = \{\{\alpha, f\}_{\mathrm{SN}}, g\}_{\mathrm{SN}}$$

This may be generalized to the case of a graded manifold $M$ endowed with a multivector field $\alpha$ of total degree 2 (i.e., $\alpha = \sum_{i=0}^\infty \alpha_i$, where $\alpha_i$ is an $i$-vector field of degree $2 - i$) satisfying the equation $\{\alpha, \alpha\}_{SN} = 0$. One then has the derived multibrackets

$$\begin{aligned} &\lambda_i : A^{\otimes i} \to A \\ &\lambda_i(a_1, \ldots, a_i) \\ &\quad := \{\{\ldots\{\{\alpha_i, a_1\}_{\mathrm{SN}}, a_2\}_{\mathrm{SN}} \ldots\}_{\mathrm{SN}}, a_i\}_{\mathrm{SN}} \end{aligned}$$

with $A = \mathcal{C}^\infty(M)$. Observe that $\lambda_i$ is a multiderivation of degree $2 - i$. The operations $\lambda_i$ define the structure of an $L_\infty$-algebra on $A$. Such a structure is called a $P_\infty$-algebra ($P$ for Poisson) since the $\lambda_i$'s are multiderivations. If $\lambda_0 = \alpha_0$ vanishes, then $\lambda_1$ is a differential, and the $\lambda_1$-cohomology inherits a graded Poisson algebra structure. This structure can be used

to describe the deformation quantization of coisotropic submanifolds and to describe their deformation theory.

# Gravitational Lensing

**J Wambsganss**, Universität Heidelberg, Heidelberg, Germany

## Introduction

Einstein's theory of general relativity states that gravity attracts light. The deflection angle of a light ray by an object with mass $m$ was predicted to be

$$\tilde{\alpha} = \frac{4Gm}{c^2 r} \qquad [1]$$

where $c$ and $G$ are the velocity of light and the gravitational constant, respectively, and $r$ is the impact parameter. The quantitative measurement of this light deflection at the solar limb during the solar eclipse in 1919 with

$$\tilde{\alpha} = \frac{4GM_\odot}{c^2 R_\odot} \approx 1.74 \text{ arcsec} \qquad [2]$$

(here $m$ is replaced by the solar mass $M_\odot$ and the impact parameter is the solar radius $R_\odot$) confirmed Einstein's theory.

In the decades following this measurement, various aspects of the gravitational lens effect were explored theoretically, which include (1) the possibility of multiple or ring-like images of background sources, (2) the use of lensing as a gravitational telescope on very faint and distant objects, and (3) the possibility of determining Hubble's constant with lensing. Only relatively recently – after the

discovery of the first doubly imaged quasar in 1979 – gravitational lensing became an observational science. Today gravitational lensing is a booming part of astrophysics.

Lensing has established itself as a very useful astrophysical tool with some remarkable successes: with the discovery of multiply-imaged quasars, giant luminous arcs, Einstein rings, quasar and galactic microlensing significant new results in areas as different as cosmology, physics of quasars, and galaxy structure could be reached. In this article, only the aspects of "strong lensing" can be treated. More detailed studies on strong and weak lensing can be found in the "Further reading" section.

## Basics of Gravitational Lensing

The path, the size, and the cross section of a light bundle propagating through spacetime in principle are affected by all the matter between the light source and the observer. For most practical purposes, we can assume that the lensing action is dominated by a single matter inhomogeneity at some location between source and observer. This is usually called the "thin-lens approximation": all the action of deflection is thought to take place at a single distance. This approach is valid only if the relative velocities of lens, source, and observer are small compared to the velocity of light ($v \ll c$) and if the Newtonian potential is small ($|\Phi| \ll c^2$). These two assumptions are justified in all astronomical cases of interest. The size of a galaxy, for example, is of order 50 kpc, even a cluster of galaxies is not much larger than 1 Mpc. This "lens thickness" is small compared to the typical distances of the order of few Gpc between observer and lens or lens and background quasar/galaxy, respectively. We assume that the underlying spacetime is well described by a perturbed Friedmann–Robertson–Walker metric:

$$ds^2 = \left(1 + \frac{2\Phi}{c^2}\right)c^2 dt^2 - a^2(t)\left(1 - \frac{2\Phi}{c^2}\right)d\sigma^2 \qquad [3]$$

A detailed description of optics in curved spacetimes and a derivation of the lens equation from Einstein's field equations can be found in Schneider *et al.* (1992, chapters 3 and 4).

### Lens Equation

The basic setup for such a simplified gravitational lens scenario involving a point source and a point lens is displayed in Figure 1. The three ingredients in such a lensing situation are the source S, the lens L, and the observer O. Light rays emitted from the source are deflected by the lens. For a point-like lens, there will always be (at least) two images $S_1$ and $S_2$ of the source. With external shear – due to the tidal field of objects outside but near the light bundles – there can be more images. The observer sees the images in directions corresponding to the tangents to the real incoming light paths.

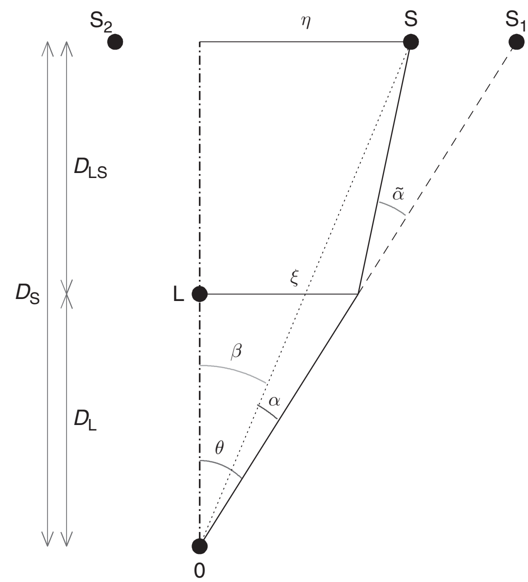

**Figure 1** The relation between the various angles and distances involved in the lensing setup can be derived for the case $\tilde{\alpha} \ll 1$ and formulated in the lens equation [6].

In Figure 1, the corresponding angles and angular diameter distances $D_L, D_S, D_{LS}$ are indicated. (In cosmology, the various methods to define distance diverge. The relevant distances for gravitational lensing are the angular diameter distances.) In the thin-lens approximation, the hyperbolic paths are approximated by their asymptotes. In the circular-symmetric case, the deflection angle is given as

$$\tilde{\alpha}(\xi) = \frac{4GM(\xi)}{c^2}\frac{1}{\xi} \qquad [4]$$

where $M(\xi)$ is the mass inside a radius $\xi$. In this depiction, the origin is chosen at the observer. From the diagram, it can be seen that the following relation holds:

$$\theta D_S = \beta D_S + \tilde{\alpha} D_{LS} \qquad [5]$$

(for $\theta, \beta, \tilde{\alpha} \ll 1$; this condition is fulfilled in practically all astrophysically relevant situations). With the definition of the reduced deflection angle as $\alpha(\theta) = (D_{LS}/D_S)\tilde{\alpha}(\theta)$, this can be expressed as

$$\beta = \theta - \alpha(\theta) \qquad [6]$$

This relation between the positions of images and source can easily be derived for a nonsymmetric mass distribution as well. In that case, all angles are

vector valued. The two-dimensional lens equation then reads

$$\boldsymbol{\beta} = \boldsymbol{\theta} - \boldsymbol{\alpha}(\boldsymbol{\theta}) \qquad [7]$$

### Einstein Radius

For a point lens of mass $M$, the deflection angle is given by eqn [4]. Plugging this deflection angle into eqn [6] and using the relation $\xi = D_L\theta$ (cf. Figure 1), one obtains

$$\beta(\theta) = \theta - \frac{D_{LS}}{D_L D_S}\frac{4GM}{c^2\theta} \qquad [8]$$

For the special case in which the source lies exactly behind the lens ($\beta = 0$), due to the symmetry, a ring-like image occurs whose angular radius is called Einstein radius $\theta_E$:

$$\theta_E = \sqrt{\frac{4GM}{c^2}\frac{D_{LS}}{D_L D_S}} \qquad [9]$$

The Einstein radius defines the angular scale for a lens situation. For a massive galaxy with a mass of $M = 10^{12}M_\odot$ at a redshift of $z_L = 0.5$ and a source at redshift $z_S = 2.0$ (we used here $H = 50\,\mathrm{km\ s^{-1}\ Mpc^{-1}}$ as the value of the Hubble constant and an Einstein–de Sitter universe), the Einstein radius is

$$\theta_E \approx 1.8\sqrt{\frac{M}{10^{12}M_\odot}}\,\mathrm{arcsec} \qquad [10]$$

(note that for cosmological distances, in general, $D_{LS} \neq D_S - D_L$!). For a galactic microlensing scenario in which stars in the disk of the Milky Way act as lenses for stars close to its center, the scale defined by the Einstein radius is

$$\theta_E \approx 0.5\sqrt{\frac{M}{M_\odot}}\,\mathrm{marcsec} \qquad [11]$$

An application and some illustrations of the point lens case can be found in the section on galactic microlensing.

### Critical Surface Mass Density

In the more general case of a three-dimensional mass distribution of an extended lens, the density $\rho(\boldsymbol{r})$ can be projected along the line of sight onto the lens plane to obtain the two-dimensional surface mass density distribution $\Sigma(\boldsymbol{\xi})$ as

$$\Sigma(\boldsymbol{\xi}) = \int_0^{D_S} \rho(\boldsymbol{r})\,\mathrm{d}z \qquad [12]$$

Here $\boldsymbol{r}$ is a three-dimensional vector in space, and $\boldsymbol{\xi}$ is a two-dimensional vector in the lens plane. The two-dimensional deflection angle $\tilde{\boldsymbol{\alpha}}$ is then given as the sum over all mass elements in the lens plane:

$$\tilde{\boldsymbol{\alpha}}(\boldsymbol{\xi}) = \frac{4G}{c^2}\int \frac{(\boldsymbol{\xi} - \boldsymbol{\xi}')\Sigma(\boldsymbol{\xi}')}{|\boldsymbol{\xi} - \boldsymbol{\xi}'|^2}\,\mathrm{d}^2\xi' \qquad [13]$$

For a finite circle with constant surface mass density $\Sigma$, the deflection angle can be written as

$$\alpha(\xi) = \frac{D_{LS}}{D_S}\frac{4G}{c^2}\frac{\Sigma\pi\xi^2}{\xi} \qquad [14]$$

With $\xi = D_L\theta$ this simplifies to

$$\alpha(\theta) = \frac{4\pi G\Sigma}{c^2}\frac{D_L D_{LS}}{D_S}\theta \qquad [15]$$

With the definition of the critical surface mass density $\Sigma_{crit}$ as

$$\Sigma_{crit} = \frac{c^2}{4\pi G}\frac{D_S}{D_L D_{LS}} \qquad [16]$$

the deflection angle for a such a mass distribution can be expressed as

$$\tilde{\alpha}(\theta) = \frac{\Sigma}{\Sigma_{crit}}\theta \qquad [17]$$

The critical surface mass density can be visualized as the lens mass $M$ "smeared out" over the area of the Einstein ring: $\Sigma_{crit} = M/(R_E^2\pi)$, where $R_E = \theta_E D_L$. The value of the critical surface mass density is roughly $\Sigma_{crit} \approx 0.8\,\mathrm{g\ cm^{-2}}$ for lens and source redshifts of $z_L = 0.5$ and $z_S = 2.0$, respectively. For an arbitrary mass distribution, the condition $\Sigma > \Sigma_{crit}$ at any point is sufficient to produce multiple images.

### Image Positions and Magnifications

The lens equation [6] can be re-formulated in the case of a single-point lens:

$$\beta = \theta - \frac{\theta_E^2}{\theta} \qquad [18]$$

Solving this for the image positions $\theta$, one finds that an isolated point source always produces two images of a background source. The positions of the images are given by the two solutions:

$$\theta_{1,2} = \frac{1}{2}\left(\beta \pm \sqrt{\beta^2 + 4\theta_E^2}\right) \qquad [19]$$

The magnification of an image is defined by the ratio between the solid angles of the image and the source, since the surface brightness is conserved. Hence, the magnification $\mu$ is given as

$$\mu = \frac{\theta}{\beta}\frac{\mathrm{d}\theta}{\mathrm{d}\beta} \qquad [20]$$

In the symmetric case above, the image magnification can be written as (by using the lens equation)

$$\mu_{1,2} = \left(1 - \left[\frac{\theta_E}{\theta_{1,2}}\right]^4\right)^{-1} = \frac{u^2+2}{2u\sqrt{u^2+4}} \pm \frac{1}{2} \qquad [21]$$

Here we defined $u$ as the "impact parameter," the angular separation between lens and source in units of the Einstein radius: $u = \beta/\theta_E$. The magnification of one image (the one inside the Einstein radius) is negative. This means it has negative parity: it is mirror-inverted. For $\beta \to 0$ the magnification diverges. In the limit of geometrical optics, the Einstein ring of a point source has infinite magnification! (Due to the fact that physical objects have a finite size, and also because at some limit wave optics has to be applied, in reality the magnification stays finite.) The sum of the absolute values of the two image magnifications is the measurable total magnification $\mu$:

$$\mu = |\mu_1| + |\mu_2| = \frac{u^2+2}{u\sqrt{u^2+4}} \qquad [22]$$

Note that this value is (always) larger than 1! (This does not violate energy conservation, since this is the magnification relative to an "empty" universe and not relative to a "smoothed out" universe. This issue is treated in detail in Schneider *et al.* (1992, chapter 4.5).) The "sum" of the two image magnifications is unity:

$$\mu_1 + \mu_2 = 1 \qquad [23]$$

### (Non)Singular Isothermal Sphere

A popular model for galaxy lenses is the singular isothermal sphere with a three-dimensional density distribution of

$$\rho(r) = \frac{\sigma_v^2}{2\pi G}\frac{1}{r^2} \qquad [24]$$

where $\sigma_v$ is the one-dimensional velocity dispersion. Projecting the matter on a plane, one obtains the circularly symmetric surface mass distribution

$$\Sigma(\xi) = \frac{\sigma_v^2}{2G}\frac{1}{\xi} \qquad [25]$$

With $M(\xi) = \int_0^\xi \Sigma(\xi')2\pi\xi' d\xi'$ plugged into eqn [4], one obtains the deflection angle for an isothermal sphere, which is a constant (i.e., independent of the impact parameter $\xi$):

$$\tilde{\alpha}(\xi) = 4\pi\frac{\sigma_v^2}{c^2} \qquad [26]$$

In practical units for the velocity dispersion of a galaxy, this can be expressed as

$$\tilde{\alpha}(\xi) = 1.15\left(\frac{\sigma_v}{200\,\mathrm{km\,s^{-1}}}\right)^2 \mathrm{arcsec} \qquad [27]$$

Two generalizations of this isothermal model are commonly used: models with finite cores are more realistic for (spiral) galaxies. In this case, the deflection angle is modified to (core radius $\xi_c$):

$$\tilde{\alpha}(\xi) = 4\pi\frac{\sigma_v^2}{c^2}\frac{\xi}{(\xi_c^2+\xi^2)^{1/2}} \qquad [28]$$

Furthermore, a realistic galaxy lens usually is not perfectly symmetric but is slightly elliptical. Depending on whether one wants an elliptical mass distribution or an elliptical potential, various formalisms are in use.

### Lens Mapping

In the vicinity of an arbitrary point, the lens mapping as shown in eqn [7] can be described by its Jacobian matrix $\mathcal{A}$:

$$\mathcal{A} = \frac{\partial\boldsymbol{\beta}}{\partial\boldsymbol{\theta}} = \left(\delta_{ij} - \frac{\partial\alpha_i(\boldsymbol{\theta})}{\partial\theta_j}\right) = \left(\delta_{ij} - \frac{\partial^2\psi(\boldsymbol{\theta})}{\partial\theta_i\partial\theta_j}\right) \qquad [29]$$

Here we made use of the fact that the deflection angle can be expressed as the gradient of an effective two-dimensional scalar potential $\psi$: $\boldsymbol{\nabla}_\theta\psi = \boldsymbol{\alpha}$, where

$$\psi(\boldsymbol{\theta}) = \frac{D_{LS}}{D_L D_S}\frac{2}{c^2}\int \Phi(\boldsymbol{r})\,dz \qquad [30]$$

and $\Phi(\boldsymbol{r})$ is the Newtonian potential of the lens. The determinant of the Jacobian $\mathcal{A}$ is the inverse of the magnification:

$$\mu = \frac{1}{\det \mathcal{A}} \qquad [31]$$

Defining

$$\psi_{ij} = \frac{\partial^2\psi}{\partial\theta_i\partial\theta_j} \qquad [32]$$

the Laplacian of the effective potential $\psi$ is twice the convergence:

$$\psi_{11} + \psi_{22} = 2\kappa = \mathrm{tr}\,\psi_{ij} \qquad [33]$$

With the definitions of the components of the external shear $\gamma$,

$$\gamma_1(\boldsymbol{\theta}) = \tfrac{1}{2}(\psi_{11} - \psi_{22}) = \gamma(\boldsymbol{\theta})\cos[2\varphi(\boldsymbol{\theta})] \qquad [34]$$

and

$$\gamma_2(\boldsymbol{\theta}) = \psi_{12} = \psi_{21} = \gamma(\boldsymbol{\theta})\sin[2\varphi(\boldsymbol{\theta})] \qquad [35]$$

(where the angle $\varphi$ reflects the direction of the shear-inducing tidal force relative to the coordinate system), the Jacobian matrix can be written as

$$\mathcal{A} = \begin{pmatrix} 1-\kappa-\gamma_1 & -\gamma_2 \\ -\gamma_2 & 1-\kappa+\gamma_1 \end{pmatrix} = (1-\kappa)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \gamma \begin{pmatrix} \cos 2\varphi & \sin 2\varphi \\ \sin 2\varphi & -\cos 2\varphi \end{pmatrix} \quad [36]$$

The magnification can now be expressed as a function of the local convergence $\kappa$ and the local shear $\gamma$:

$$\mu = (\det \mathcal{A})^{-1} = \frac{1}{(1-\kappa)^2 - \gamma^2} \quad [37]$$

Locations at which $\det A = 0$ have formally infinite magnification. They are called "critical curves" in the lens plane. The corresponding locations in the source plane are the "caustics." For spherically symmetric mass distributions, the critical curves are circles. For a point lens, the caustic degenerates into a point. For elliptical lenses or spherically symmetric lenses plus external shear, the caustics consist of cusps and folds.

### Time Delay and Fermat's Theorem

The deflection angle is the gradient of an effective lensing potential $\psi$. Hence, the lens equation can be rewritten as

$$(\boldsymbol{\theta} - \boldsymbol{\beta}) - \boldsymbol{\nabla}_\theta \psi = 0 \quad [38]$$

or

$$\boldsymbol{\nabla}_\theta \left( \frac{1}{2} (\boldsymbol{\theta} - \boldsymbol{\beta})^2 - \psi \right) = 0 \quad [39]$$

The term in brackets appears as well in the physical time delay function for gravitationally lensed images:

$$\tau(\boldsymbol{\theta}, \boldsymbol{\beta}) = \tau_{\text{geom}} + \tau_{\text{grav}} = \frac{1+z_L}{c} \frac{D_L D_S}{D_{LS}} \left( \frac{1}{2} (\boldsymbol{\theta} - \boldsymbol{\beta})^2 - \psi(\theta) \right) \quad [40]$$

This time delay surface is a function of the image geometry $(\boldsymbol{\theta}, \boldsymbol{\beta})$, the gravitational potential $\psi$, and the distances $D_L, D_S$, and $D_{LS}$. The first part – the geometrical time delay $\tau_{\text{geom}}$ – reflects the extra path length compared to the direct line between observer and source. The second part – the gravitational time delay $\tau_{\text{grav}}$ – is the retardation due to gravitational potential of the lensing mass (known and confirmed as Shapiro delay in the solar system). From eqns [39] and [40], it follows that the gravitationally lensed images appear at locations that correspond to extrema in the light travel time, which reflects Fermat's principle in gravitational-lensing optics.

The (angular-diameter) distances that appear in eqn [40] depend on the value of the Hubble constant. Therefore, it is possible to determine the latter by measuring the time delay between different images and using a good model for the effective gravitational potential $\psi$ of the lens.

## Lensing Phenomena

Strong lensing phenomena involve multiple images, caustics, critical lines, usually a significant magnification, and large distortions if extended sources are involved. Below we discuss the most frequent strong lensing phenomena.

### Galactic Microlensing

The conceptually simplest strong lensing scenario is a foreground star acting as a lens on a background star. Since stars in the Milky Way move relative to each other, this can be observed as a time-variable situation: due to the relative motion between observer, lensing star, and source star, the projected impact parameter between lens and source changes with time and produces a time-dependent magnification. If the impact parameter is smaller than an Einstein radius ($u < 1$), then the magnification is $\mu_{\text{min}} > 1.34$ (cf. eqn [22]).

For an extended source, a sequence image configurations with decreasing impact parameter is illustrated in Figure 2 for five instants of time. The separation of the two images is of order-2 Einstein radii when they are of comparable magnification, which corresponds to only about 1 marcsec in a realistic situation in the Milky Way. Hence, the two images cannot be resolved individually; we can only observe the combined brightness of the image pair. This is illustrated in Figures 3 and 4, which show the relative tracks and the respective light curves for five values of the minimum impact parameter $u_{\text{min}}$.

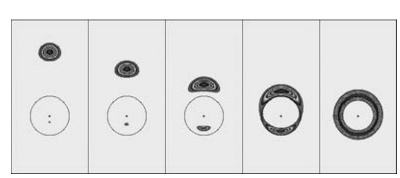

**Figure 2** Five snapshots of a gravitational lens situation with a point lens and an extended source: from left to right the alignment between lens and source gets better and better, until it is perfect in the rightmost panel. This results in the image of an "Einstein ring."

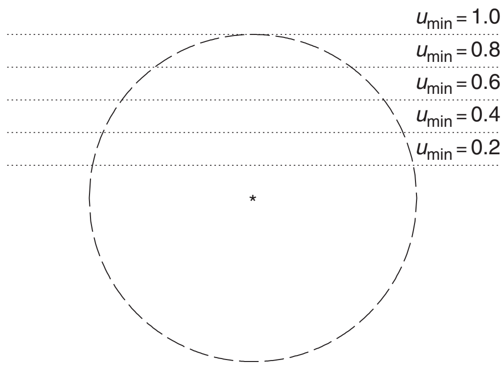

**Figure 3** Five relative tracks between background star and foreground lens (indicated as the central star) parametrized by the impact parameter $u_{min}$. The dashed line indicates the Einstein ring for the lens.

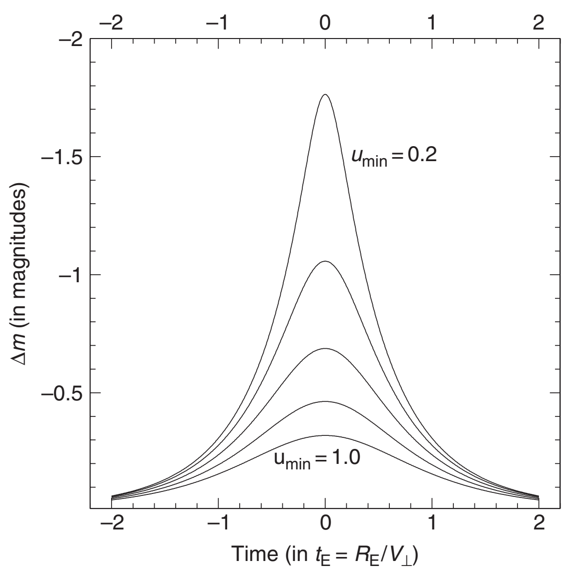

**Figure 4** Five microlensing light curves for the tracks indicated in **Figure 3**, parametrized by the impact parameter $u_{min}$. The vertical axis is the magnification in astronomical magnitudes relative to the unlensed case, the horizontal axis displays the time in "normalized" units.

Quantitatively, the total magnification $\mu = |\mu_1| + |\mu_2|$ of the two images (cf. eqn [22]) entirely depends on the impact parameter $u(t) = r(t)/R_E$ between the lensed star and the lensing object, measured in the lens plane (here $R_E$ is the Einstein radius of the lens, i.e., the radius at which a circular image appears for perfect alignment between source, lens, and observer, cf. Figure 2, rightmost panel):

$$\mu(u(t)) = \frac{u(t)^2 + 2}{u(t)\sqrt{(u(t)^2 + 4)}} \qquad [41]$$

The timescale of such a "microlensing event" is defined as the time it takes for the source to cross the Einstein radius. With realistic values for distances and relative velocity, this can be expressed as

$$t_0 = \frac{R_E}{v_\perp} \approx (0.214\,\mathrm{yr})\sqrt{\frac{M}{M_\odot}}\sqrt{\frac{D_L}{10\,\mathrm{kpc}}} \times \sqrt{1 - \frac{D_L}{D_S}}\left(\frac{v_\perp}{200\,\mathrm{km\,s^{-1}}}\right)^{-1} \qquad [42]$$

(here $v_\perp$ is the (relative) transverse velocity of the lens; we applied the simple relation $D_{LS} = D_S - D_L$, which is valid here).

Note that from eqn [42] it is obvious that it is not possible to determine the mass of the lens from one individual microlensing event. The duration of an event is determined by three unknown parameters: the mass of the lens $m$, the transverse velocity $v_\perp$, and the distance of the lens $D_L$ (assuming we know the distance to the source). It is impossible to disentangle these for individual events. Only with a model for the spatial and velocity distribution of the lensing stars in the Milky Way, one can obtain approximate information about the masses of the lensing objects.

In 1986, Bohdan Paczyński suggested to use this microlensing method as an observational test for potential dark matter candidates in the halo of the Milky Way. If the dark matter is in the form of astrophysical objects (such as brown dwarfs, neutron stars, black holes, sometimes called "MACHO" for MAssive Compact Halo Object), then they should occasionally act as lenses on stars in the neighboring galaxy Large Magellanic Cloud. It turned out that too few of such microlensing events were observed, in order to explain the dark matter this way.

However, this method produced more than 2000 microlensing events by ordinary stars in the direction to the center of the Milky Way. Two of these events provide convincing evidence for a planet accompanying the lensing star. It is likely that gravitational microlensing will provide a statistically very valuable sample of extrasolar planets, because in contrast to most other methods these planets are pre-selected by their host stars. Furthermore, microlensing is sensitive to masses as low as a few Earth masses.

### Multiply-Imaged Quasars

The first gravitationally lensed double quasar was discovered in 1979: two images of the same quasar, separated by about 6 arcsec. This led to the field of gravitational lensing as an observational science. By now, more than 120 multiply imaged quasars are known, mostly double and quadruple images. They

span image separations from 0.3 arcsec to almost 30 arcsec.

Gravitationally lensed quasar systems are studied individually in great detail to get a better understanding of both lens and source. The lens systems are analyzed statistically as well, in order to get information about the population of lenses (and quasars) in the universe, their distribution in distance (i.e., cosmic time) and mass, and hence about the cosmological model.

**Time delay and Hubble constant** As stated above, the signals from a gravitational lens system reach us with a certain "time delay" $\Delta t$, so that the measured fluxes as functions of time, $I_A(t)$ and $I_B(t)$, can be described as: $I_B(t) = \text{const.} \times I_A(t + \Delta t)$. Any intrinsic fluctuation of the quasar shows up in both images, in general with an overall offset in apparent magnitude and an offset in time.

Q0957 + 561 is the first lens system in which the time delay was firmly established:

$$\Delta t_{Q0957+561} = (417 \pm 3)\,\text{days} \qquad [43]$$

With a model of the lens system, the time delay can be used to determine the Hubble constant. (This can be seen very simply: imagine a certain lens situation like the one displayed in Figure 1. If now all length scales are reduced by a factor of 2 and at the same time all masses are reduced by a factor of 2, then for an observer, the angular configuration in the sky would appear exactly identical. But the total length of the light path is reduced by a factor of 2. Now, since the time delay between the two paths is the same fraction of the total lengths in either scenario, a measurement of this fractional length allows us to determine the total length, and hence the Hubble constant, the constant of proportionality between distance and redshift.) The resulting value of $H_0$ is

$$H_0 = (67 \pm 13)\,\text{km s}^{-1}\,\text{Mpc}^{-1} \qquad [44]$$

where the uncertainty comprises the 95% confidence level. To date, about a dozen quasar lens systems have measured time delays. The derived values of the Hubble constant are "lowish," if we assume the best astrophysical motivated lens models.

## Quasar Microlensing

Light bundles from "lensed" quasars are split by intervening galaxies. Usually the quasar light bundle passes through the galaxy and/or the galaxy halo. Galaxies consist at least partly of stars, and galaxy halos consist possibly of compact objects as well.

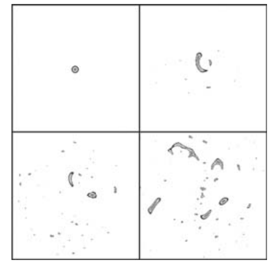

**Figure 5** "Microimages": the top left panel shows an assumed "unlensed" source profile of a quasar. The other three panels illustrate the microimage configuration as it would be produced by stellar objects in the foreground. The surface mass density of the lenses is 20% (top right), 50% (bottom left), and 80% (bottom right) of the critical density (cf. eqn [16]).

Each of these stars (or other compact objects like black holes, brown dwarfs, or planets) acts as a "compact lens" or "microlens" and produces at least one additional microimage of the source. This means the "macroimage" consists of many "microimages" (Figure 5). But because the image splitting is proportional to the square root of the lens mass, these microimages are only of order a microarcsecond apart and cannot be resolved. Various aspects of microlensing have been addressed after the first double quasar had been discovered.

The microlenses produce a complicated two-dimensional magnification distribution in the source plane. It consists of many caustics, locations that correspond to formally infinitely high magnification. An example for such a magnification pattern is shown in Figure 6. It is determined with the parameters of image A of the quadruple quasar Q2237 + 0305

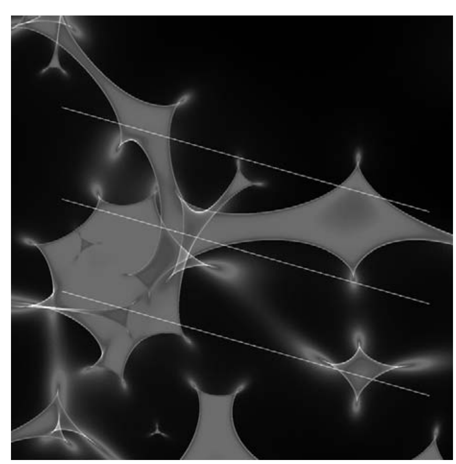

**Figure 6** Magnification pattern in the source plane, produced by a dense field of stars in the lensing galaxy. The gray scale reflects the magnification as a function of the quasar position. Light curves taken along the straight tracks are shown in Figure 7. The microlensing parameters were chosen according to a model for image A of the quadruple quasar *Q*2237 + 0305: $\kappa = 0.36$, $\gamma = 0.44$.

(surface mass density $\kappa = 0.36$; external shear $\gamma = 0.44$). Gray scale indicates the magnification.

Due to the relative motion between observer, lens, and source, the quasar changes its position relative to this arrangement of caustics, that is, the apparent brightness of the quasar changes with time. A one-dimensional cut through such a magnification pattern, convolved with a source profile of the quasar, results in a microlensed light curve. Examples for microlensed light curves taken along the straight lines in Figure 6 can be seen in Figure 7 for two different quasar sizes.

In particular when the quasar track crosses a caustic (the sharp lines in Figure 6 for which the magnification formally is infinite, because the determinant of the Jacobian disappears, cf. eqn [31]), a pair of highly magnified microimages appears newly or merges and disappears. Such a microlensing event can easily be detected as a strong peak in the light curve of the quasar image.

Microlens-induced fluctuations in the observed brightness of quasars contain information both about the light-emitting source (size of continuum region or broad line region of the quasar, brightness profile of quasar) and about the lensing objects (masses, density, transverse velocity). Hence, from a comparison between observed and simulated quasar microlensing, one can draw conclusions about the density and mass scale of the microlenses. So far the "best" example of a microlensed quasar is the quadruple quasar Q2237 + 0305.

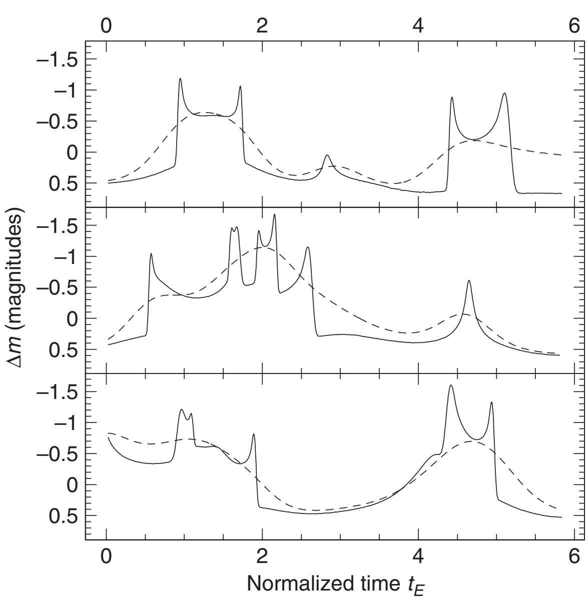

**Figure 7** Microlensing light curve for the straight lines in Figure 6. The solid and dashed lines indicate relatively small and large quasar sizes. The time axis is in units of Einstein radii divided by unit velocity.

### Einstein Rings

If a point source lies exactly behind a point lens, a ring-like image occurs. Theorists had recognized early on that such a symmetric lensing arrangement would result in a ring image, the so-called "Einstein ring." There are two necessary requirements for the observability of Einstein rings: the mass distribution of the lens needs to be approximately axially symmetric, as seen from the observer, and the source must lie exactly on top of the resulting degenerate pointlike caustic. Such a geometric arrangement is highly unlikely for pointlike sources. But astrophysical sources in the real universe have a finite extent, and it is enough if a part of the source covers the point caustic (or the complete astroid caustic in the case of a not quite axially symmetric mass distribution) in order to produce such an annular image.

In 1988, the first example of an "Einstein ring" was discovered. With high-resolution radio observations, the extended radio source MG1131 + 0456 turned out to be a ring with a diameter of about 1.75 arcsec. The source was identified as a radio lobe at a redshift of $z_S = 1.13$, whereas the lens is a galaxy at $z_L = 0.85$. By now more than a dozen cases have been found that qualify as Einstein rings. Their diameters vary between 0.33 and about 2 arcsec.

### Giant Luminous Arcs and Arclets

Fritz Zwicky had pointed out the potential use of galaxies and galaxy clusters as gravitational lenses in the 1930s. With background galaxies as sources, the apparent lensing consequences for them would be far more dramatic than for quasars: galaxies should be heavily deformed once they are strongly lensed. Rich clusters of galaxies at redshifts beyond $z \approx 0.2$ with masses of order $10^{14} M_\odot$ are very effective lenses if they are centrally concentrated. Their Einstein radii are of the order of 20 arcsec.

In 1986, the following gravitational lensing phenomenon was discovered: magnified, distorted, and strongly elongated images of background galaxies which happen to lie behind foreground clusters of galaxies, the so-called giant luminous arcs. The giant arcs can be exploited in two ways, as is typical for many lens phenomena. Firstly, they provide us with strongly magnified galaxies at (very) high redshifts. These galaxies would be too faint to be detected or analyzed in their unlensed state. Hence, with the lensing boost, we can study these galaxies in their early evolutionary stages, possibly as infant or protogalaxies, relatively shortly after the big bang. The other practical application of the arcs is to take them as tools to study the potential and mass distribution of the lensing galaxy cluster. In the simplest model of a spherically symmetric mass distribution for the cluster,

giant arcs form very close to the critical curve, which marks the Einstein ring. So with the redshifts of the cluster and the arc, it is easy to determine a rough estimate of the lensing mass by just determining the radius of curvature and interpreting it as the Einstein radius of the lens system.

#### Weak Lensing/Statistical Lensing/Cosmic Shear

In contrast to the phenomena that were mentioned here, "weak lensing" deals with effects of light deflection that cannot be measured individually, but rather in a statistical way only. No caustics, critical lines, or multiple images are involved. As was discussed above, "strong lensing" – usually defined as the regime that involves multiple images, high magnifications, and caustics in the source plane – is a rare phenomenon. Weak lensing on the other hand is much more common. In principle, weak lensing acts along each line of sight in the universe, since each light bundle's path is affected by matter inhomogeneities along or near its path. It is just a matter of how accurately we can measure. In recent years, many teams started impressive and ambitious observational programs to determine the slight distortion of tens of thousands of background galaxies by foreground galaxy clusters and/or by the large-scale structure in the universe, the so-called cosmic shear. It is beyond the scope of this article to discuss these applications of weak gravitational lensing. The interested reader is referred to the "Further reading" section, in particular to Bartelmann and Schneider (2001).

# Gravitational *N*-Body Problem (Classical)

**D C Heggie**, The University of Edinburgh, Edinburgh, UK

## Introduction

Let a number, $N$, of particles interact classically through Newton's laws of motion and Newton's inverse-square law of gravitation. Then the equations of motion are

$$\ddot{\boldsymbol{r}}_i = -G \sum_{j=1,\, j\neq i}^{j=N} m_j \frac{\boldsymbol{r}_i - \boldsymbol{r}_j}{|\boldsymbol{r}_i - \boldsymbol{r}_j|^3} \qquad [1]$$

where $\boldsymbol{r}_i$ is the position vector of the $i$th particle relative to some inertial frame, $G$ is the universal constant of gravitation, and $m_i$ is the mass of the $i$th particle. These equations provide an approximate mathematical model with numerous applications in astrophysics, including the motion of the Moon and other bodies in the solar system (planets, asteroids, comets, and meteor particles); stars in stellar systems ranging from binary and other multiple stars to star clusters and galaxies; and the motion of dark-matter particles in cosmology. For $N=1$ and $N=2$, the equations can be solved analytically. The case $N=3$ provides one of the richest of all unsolved dynamical problems – the general three-body problem. For problems dominated by one massive body, as in many planetary problems, approximate methods based on perturbation expansions have been developed. In stellar dynamics, astrophysicists have developed numerous numerical and theoretical approaches to the problem for larger values of $N$, including treatments based on the Boltzmann equation and the Fokker–Planck equation; such $N$-body systems can also be modeled as self-gravitating

gases, and thermodynamic insights underpin much of our qualitative understanding.

## Few-Body Problems

### The Two-Body Problem

For $N = 2$, the relative motion of the two bodies can be reduced to the force-free motion of the center of mass and the problem of the relative motion. If $\boldsymbol{r} = \boldsymbol{r}_1 - \boldsymbol{r}_2$, then

$$\ddot{\boldsymbol{r}} = -G(m_1 + m_2)\frac{\boldsymbol{r}}{|\boldsymbol{r}|^3} \qquad [2]$$

often called the Kepler problem. It represents motion of a particle of unit mass under a central inverse-square force of attraction. Energy and angular momentum are constant, and the motion takes place in a plane passing through the origin. Using plane polar coordinates $(r, \theta)$ in this plane, the equations for the energy and angular momentum reduce to

$$E = \frac{1}{2}\left(\dot{r}^2 + \frac{L^2}{r^2}\right) - \frac{G(m_1 + m_2)}{r} \qquad [3]$$

$$L = r^2\dot{\theta} \qquad [4]$$

(Note that these are not the energy and angular momentum of the two-body problem, even in the barycentric frame of the center of mass; $E$ and $L$ must be multiplied by the reduced mass $m_1 m_2/(m_1 + m_2)$.) Using eqns [3] and [4], the problem is reduced to quadratures. The solution shows that the motion is on a conic section (ellipse, circle, straight line, parabola, or hyperbola), with the origin at one focus.

This reduction depends on the existence of integrals of the equations of motion, and these in turn depend on symmetries of the underlying Lagrangian or Hamiltonian. Indeed, eqns [1] yield ten first integrals: six yield the rectilinear motion of the center of mass, three the total angular momentum, and one the energy. Furthermore, eqn [2] may be transformed, via the Kustaanheimo–Stiefel (KS) transformation, to a four-dimensional simple harmonic oscillator. This reveals further symmetries, corresponding to further invariants: the three components of the Lenz vector. Another manifestation of the abundance of symmetries of the Kepler problem is the fact that there exist action-angle variables in which the Hamiltonian depends only on one action, that is, $H = H(L)$. Another application of the KS transformation is one that has practical importance: it removes the singularity of (i.e., regularizes) the Kepler problem at $r = 0$, which is troublesome numerically.

To illustrate the character of the KS transformation, we consider briefly the planar case, which can be handled with a complex variable obeying the equation of motion $\ddot{z} = -z/|z|^3$ (after scaling eqn (2)). By introducing the Levi-Civita transformation $z = Z^2$ and Sundman's transformation of the time, that is, $\mathrm{d}t/\mathrm{d}\tau = |z|$, the equation of motion transforms to $Z'' = hZ/2$, where $h = |\dot{z}|^2/2 - 1/|z|$ is the constant of energy. The KS transformation is a very similar exercise using quaternions.

### The Restricted Three-Body Problem

The simplest three-body problem is given by the motion of a test particle in the gravitational field of two particles, of positive mass $m_1$, $m_2$, in circular Keplerian motion. This is called the circular restricted three-body problem, and the two massive particles are referred to as primaries. In a rotating frame of reference, with origin at the center of mass of these two particles, which are at rest at positions $\boldsymbol{r}_1$, $\boldsymbol{r}_2$, the equation of motion is

$$\ddot{\boldsymbol{r}} + 2\Omega \times \dot{\boldsymbol{r}} + \Omega \times (\Omega \times \boldsymbol{r}) = G\nabla\left(\frac{m_1}{|\boldsymbol{r} - \boldsymbol{r}_1|} + \frac{m_2}{|\boldsymbol{r} - \boldsymbol{r}_2|}\right) \qquad [5]$$

where $\boldsymbol{r}$ is the position of the massless particle and $\Omega$ is the angular velocity of the frame.

This problem has three degrees of freedom but only one known integral: it is the Hamiltonian in the rotating frame, and equivalent to the Jacobi integral, $J$. One consequence is that Liouville's theorem is not applicable, and more elaborate arguments are required to decide its integrability. Certainly, no general analytical solution is known.

There are five equilibrium solutions, discovered by Euler and Lagrange (see **Figure 1**). They lie at critical points of the effective potential in the

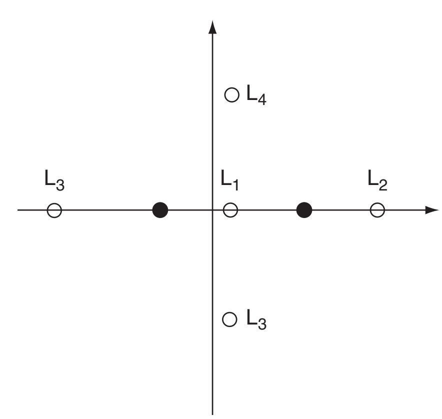

**Figure 1** The equilibrium solutions of the circular restricted three-body problem. A rotating frame of reference is chosen in which two particles are at rest on the *x*-axis. The massless particle is at equilibrium at each of the five points shown. Five similar configurations exist for the general three-body problem; these are the "central" configurations.

rotating frame, and demarcate possible regions of motion.

Throughout the twentieth century, much numerical effort was used in finding and classifying periodic orbits, and in determining their stability and bifurcations. For example, there are families of periodic orbits close to each primary; these are perturbed Kepler orbits, and are referred to as satellite motions. Other important families are the series of Liapounov orbits starting at the equilibrium points.

Some variants of the restricted three-body problem include the following:

1. The elliptic restricted three-body problem, in which the primaries move on an elliptic Keplerian orbit; in suitable coordinates the equation of motion closely resembles eqn [5], except for a factor on the right side which depends explicitly on the independent variable (transformed time); this system has no first integral.
2. Sitnikov's problem, which is a special case of the elliptic problem, in which $m_1 = m_2$, and the motion of the massless particle is confined to the axis of symmetry of the Keplerian motion; this is still nonintegrable, but simple enough to allow extensive analysis of such fundamental issues as integrability and stochasticity.
3. Hill's problem, which is a scaled version suitable for examining motions close to one primary; its importance in applications began with studies of the motion of the moon, and it remains vital for understanding the motion of asteroids.

## The General Three-Body Problem

**Exact solutions** When all three particles have nonzero masses, the equations of motion become

$$m_i \ddot{\boldsymbol{r}}_i = -\nabla_i W$$

where the potential energy is

$$W = -G \sum_{1 \le i < j \le 3} \frac{m_i m_j}{|\boldsymbol{r}_i - \boldsymbol{r}_j|}$$

Then the exact solutions of Euler and Lagrange survive in the form of homographic solutions. In these solutions, the configuration remains geometrically similar, but may rotate and/or pulsate in the same way as in the two-body problem.

Let us represent the position vector $\boldsymbol{r}_i$ in the planar three-body problem by the complex number $z_i$. Then, it is easy to see that we have a solution of the form $z_i(t) = z(t) z_{0i}$, provided that

$$\ddot{z} = -C \frac{z}{|z|^3}$$

and

$$m_i C z_{0i} = \nabla_i W(z_{01}, z_{02}, z_{03})$$

for some constant $C$. Thus, $z(t)$ may take the form of any solution of the Kepler problem, while the complex numbers $z_{0i}$ must correspond to what is called a central configuration. These are in fact critical points of the scale-free function $W\sqrt{I}$, where $I$ (the "moment of inertia of the system") is given by $I = \sum_1^3 m_i r_i^2$; and $C = -W/I$.

The existence of other important classes of periodic solutions can be proved analytically, even though it is not possible to express the solution in closed form. Examples include hierarchical three-body systems, in which two masses $m_1$, $m_2$ exhibit nearly elliptic relative motion, while a third mass orbits the barycenter of $m_1$ and $m_2$ in another nearly elliptic orbit. In the mathematical literature, this is referred to as motion of elliptic–elliptic type. More surprisingly, the existence of a periodic solution in which the three bodies travel in succession along the same path, shaped like a figure 8 (cf. **Figure 2**), was established by Chenciner and Montgomery (2000), following its independent discovery by Moore using numerical methods. Another interesting periodic motion that was discovered numerically, by Schubart, is a solution of the collinear three-body problem, and so collisions are inevitable. In this motion, the body in the middle alternately encounters the other two bodies.

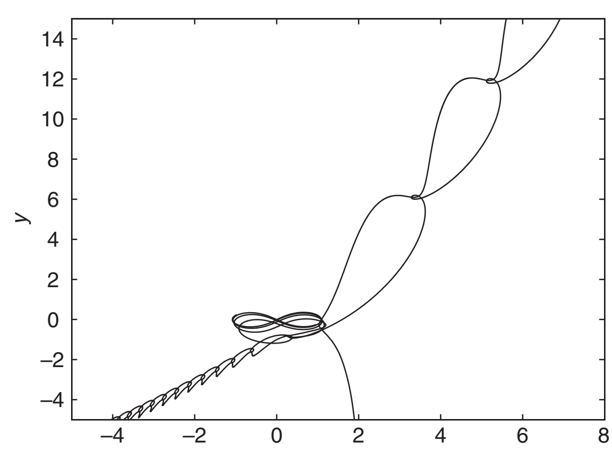

**Figure 2** A rare example of a scattering encounter between two binaries (which approach from upper right and lower left) which leads to a permanently bound triple system describing the "figure-8" periodic orbit. A fourth body escapes at the bottom. Note the differing scales on the two axes. (Reproduced with permission from Heggie DC (2000) A new outcome of binary-binary scattering. *Monthly Notices of the Royal Astronomical Society* 318(4): L61–L63; © Blackwell Publishing Ltd.)

**Singularities** As Schubart's solution illustrates, two-body encounters can occur in the three-body problem. Such singularities can be regularized just as in the pure two-body problem. Triple collisions cannot be regularized in general, and this singularity has been studied by the technique of "blowup." This has been worked out most thoroughly in the collinear three-body problem, which has only two degrees of freedom. The general idea is to transform to two variables, of which one (denoted by $r$, say) determines the scale of the system, while the other ($s$) determines the configuration (e.g., the ratio of separations of the three masses). By scaling the corresponding velocities and the time, one obtains a system of three equations of motion for $s$ and the two velocities which are perfectly regular in the limit $r \to 0$. In this limit, the energy integral restricts the solutions of the system to a manifold (called the collision manifold). Exactly the same manifold results for zero-energy solutions, which permits a simple visualization. Equilibria on the collision manifold correspond to the Lagrangian collinear solutions in which the system either expands to infinity or contracts to a three-body collision.

**Qualitative ideas** Reference has already been made to motion of elliptic–elliptic type. In a motion of elliptic–hyperbolic type, there is again an "inner" pair of bodies describing nearly Keplerian motion, while the relative motion of the third body is nearly hyperbolic. In applications, this is referred to as a kind of scattering encounter between a binary and a third body. When the encounter is sufficiently close, it is possible for one member of the binary to be exchanged with the third body. One of the major historical themes of the general three-body problem is the classification of connections between these different types of asymptotic motion. It is possible to show, for instance, that the measure of initial conditions of hyperbolic–elliptic type leading asymptotically to elliptic–elliptic motion (or any other type of permanently bound motion) is zero. Much of the study of such problems has been carried out numerically.

There are many ways in which the stability of three-body motions may be approached. One example is furnished by the central configurations already referred to. They can be used to establish sufficient conditions for ensuring that exchange is impossible, and similar conclusions.

A powerful tool for qualitative study of three-body motions is Lagrange's identity, which is now thought of as the reduction to three bodies of the virial theorem. Let the size of the system be characterized by the "moment of inertia" $I$. Then it is easy to show that

$$\frac{\mathrm{d}^2 I}{\mathrm{d}t^2} = 4T + 2W$$

where $T$, $W$ are, respectively, the kinetic and potential energies of the system. Usually, the barycentric frame is adopted. Since $E = T + V$ is constant and $T \geq 0$, it follows that the system is not bounded for all $t > 0$ unless $E < 0$.

**Perturbation theory** The question of the integrability of the general three-body problem has stimulated much research, including the famous study by Poincaré which established the nonexistence of integrals beyond the ten classical ones. Poincaré's work was an important landmark in the application to the three-body problem of perturbation methods. If one mass dominates, that is, $m_1 \gg m_2$ and $m_1 \gg m_3$, then the motion of $m_2$ and $m_3$ relative to $m_1$ is a mildly perturbed two-body motion, unless $m_2$ and $m_3$ are close together. Then it is beneficial to describe the motion of $m_2$ relative to $m_1$ by the parameters of Keplerian motion. These would be constant in the absence of $m_3$, and vary slowly because of the perturbation by $m_3$. This was the idea behind Lagrange's very general method of variation of parameters for solving systems of differential equations. Numerous methods were developed for the iterative solution of the resulting equations. In this way, the solution of such a three-body problem could be represented as a type of trigonometric series in which the arguments are the angle variables describing the two approximate Keplerian motions. These were of immense value in solving problems of celestial mechanics, that is, the study of the motions of planets, their satellites, comets, and asteroids.

A major step forward was the introduction of Hamiltonian methods. A three-body problem of the type considered here has a Hamiltonian of the form

$$H = H_1(L_1) + H_2(L_2) + R$$

where $H_i$, $i = 1, 2$, are the Hamiltonians describing the interaction between $m_i$ and $m_1$, and $R$ is the "disturbing function." It depends on all the variables, but is small compared with the $H_i$. Now perturbation theory reduces to the task of performing canonical transformations which simplify $R$ as much as possible.

Poincaré's major contribution in this area was to show that the series solutions produced by perturbation methods are not, in general, convergent, but

asymptotic. Thus, they were of practical rather than theoretical value. For example, nothing could be proved about the stability of the solar system using perturbation methods. It took the further analytic development of KAM theory to rescue this aspect of perturbation theory. This theory can be used to show that, provided that two of the three masses are sufficiently small, then for almost all initial conditions the motions remain close to Keplerian for all time. Unfortunately, now it is the practical aspect of the theory which is missing; though we have introduced this topic in the context of the three-body problem, it is extensible to any $N$-body system with $N-1$ small masses in nearly Keplerian motion about $m_1$, but to be applicable to the solar system the masses of the planets would have to be ridiculously small.

**Numerical methods** Numerical integrations of the three-body problem were first carried out near the beginning of the twentieth century, and are now commonplace. For typical scattering events, or other short-lived solutions, there is usually little need to go beyond common Runge–Kutta methods, provided that automatic step-size control is adopted. When close two-body approaches occur, some regularization based on the KS transformation is often exploited. In cases of prolonged elliptic–elliptic motion, an analytic approximation based on Keplerian motion may be adequate. Otherwise (as in problems of planetary motion, where the evolution takes place on an extremely long timescale), methods of very high order are often used. Symplectic methods, which have been developed in the context of Hamiltonian problems, are increasingly adopted for problems of this kind, as their long-term error behavior is generally much superior to that of methods which ignore the geometrical properties of the equations of motion.

### Four- and Five-Body Problems

Many of the foregoing remarks, on central configurations, numerical methods, KAM theory, etc., apply equally to few-body problems with $N > 3$. Of special interest from a theoretical point of view is the occurrence of a new kind of singularity, in which motions become unbounded in finite time. For $N = 4$, the known examples also require two-body collisions, but noncollision orbits exhibiting finite-time blowup are known for $N = 5$.

One of the practical (or, at least, astronomical) applications is again to scattering encounters, this time involving the approach of two binaries on a hyperbolic relative orbit. Numerical results show that a wide variety of outcomes is possible, including even the creation of the figure-8 periodic orbit of the three-body problem, while a fourth body escapes (**Figure 2**).

## Many-Body Problems

Many of the concepts already introduced, such as the virial theorem, apply equally well to the many-body classical gravitational problem. This section refers mainly to the new features which arise when $N$ is not small. In particular, statistical descriptions become central. The applications also have a different emphasis, moving from problems of planetary dynamics (celestial mechanics) to those of stellar dynamics. Typically, $N$ lies in the range $10^2$–$10^{12}$.

### Evolution of the Distribution Function

The most useful statistical description is obtained if the correlations we neglect and focus on the one-particle distribution function $f(\boldsymbol{r}, \boldsymbol{v}, t)$, which can be interpreted as the number density at time $t$ at the point in phase space corresponding to position $\boldsymbol{r}$ and velocity $\boldsymbol{v}$. Several processes contribute to the evolution of $f$.

**Collective effects** When the effects of near neighbors are neglected, the dynamics is described by the Vlasov–Poisson system

$$\frac{\partial f}{\partial t} + \boldsymbol{v} \cdot \frac{\partial f}{\partial \boldsymbol{r}} - \frac{\partial \phi(\boldsymbol{r}, t)}{\partial \boldsymbol{r}} \cdot \frac{\partial f}{\partial \boldsymbol{v}} = 0 \qquad [6]$$

$$\nabla^2 \phi = 4\pi G m \int f(\boldsymbol{r}, \boldsymbol{v}, t) \mathrm{d}^3 \boldsymbol{v} \qquad [7]$$

where $\phi$ is the gravitational potential and $m$ is the mass of each body. Obvious extensions are necessary if not all bodies have the same mass.

Solutions of eqn [6] may be found by the method of characteristics, which is most useful in cases where the equation of motion $\ddot{\boldsymbol{r}} = -\nabla\phi$ is integrable, for example, in stationary, spherical potentials. An example is the solution

$$f = |E|^{7/2} \qquad [8]$$

where $E$ is the specific energy of a body, that is, $E = v^2/2 + \phi$. This satisfies eqn [6] provided that $\phi$ is static. Equation [7] is satisfied provided that $\phi$ satisfies a case of the Lane–Emden equation, which is easy to solve in this case.

The solution just referred to is an example of an equilibrium solution. In an equilibrium solution, the virial theorem takes the form $4T + 2W = 0$, where

$T$, $W$ are appropriate mean-field approximations for the kinetic and potential energy, respectively. It follows that $E = -T$, where $E = T + V$ is the total energy. An increase in $E$ causes a decrease in $T$, which implies that a self-gravitating $N$-body system exhibits a negative specific heat.

There is little to choose between one equilibrium solution and another, except for their stability. In such an equilibrium, the bodies orbit within the potential on a timescale of the crossing time, which is conventionally defined to be

$$t_{\mathrm{cr}} = \frac{GM^{5/2}}{(2|E|)^{3/2}}$$

The most important evolutionary phenomenon of collisionless dynamics is violent relaxation. If $f$ is not time independent then $\phi$ is time dependent in general. Also, from the equation of motion of one body, $E$ varies according to $\mathrm{d}E/\mathrm{d}t = \partial\phi/\partial t$, and so energy is exchanged between bodies, which leads to an evolution of the distribution of energies. This process is known as violent relaxation.

Two other relaxation processes are of importance:

1. Relaxation is possible on each energy hypersurface, even in a static potential, if the potential is nonintegrable.
2. The range of collective phenomena becomes remarkably rich if the system exhibits ordered motions, as in rotating systems. Then an important role is played by resonant motions, especially resonances of low order. The corresponding theory lies at the basis of the theory of spiral structure in galaxies, for instance.

**Collisional effects** The approximations of collisionless stellar dynamics suppress two important processes:

1. The exponential divergence of stellar orbits, which takes place on a timescale of order $t_{\mathrm{cr}}$. Even in an integrable potential, therefore, $f$ evolves on each energy hypersurface.
2. Two-body relaxation. It operates on a timescale of order $(N/\ln N)t_{\mathrm{cr}}$, where $N$ is the number of particles. Although this two-body relaxation timescale, $t_{\mathrm{r}}$, is much longer than any other timescale we have considered, this process leads to evolution of $f(E)$, and it dominates the long-term evolution of large $N$-body systems. It is usually modeled by adding a collision term of Fokker–Planck type on the right-hand side of eqn [6].

In this case, the only equilibrium solutions in a steady potential are those in which $f(E) \propto \exp(-\beta E)$, where $\beta$ is a constant. Then eqn [7] becomes Liouville's equation, and for the case of spherical symmetry the relevant solutions are those corresponding to the isothermal sphere.

### Collisional Equilibrium

We consider the collisional evolution of an $N$-body system further in a later subsection and here develop fundamental ideas about the isothermal model. The isothermal model has infinite mass, and much has been learned by considering a model confined within an adiabatic boundary or enclosure. There is a series of such models, characterized by a single dimensionless parameter, which can be taken to be the ratio between the central density and the density at the boundary, $\rho_0/\rho_{\mathrm{e}}$ (**Figure 3**).

These models are extrema of the Boltzmann entropy $S = -k \int f \ln f \mathrm{d}^6\tau$, where $k$ is the Boltzmann constant, and the integration is taken over all available phase space. Their stability may be determined by evaluating the second variation of $S$. It is found that it is negative definite, so that $S$ is a local maximum and the configuration is stable, only if $\rho_0/\rho_{\mathrm{e}} < 709$ approximately. A physical explanation for this is the following. In the limit when $\rho_0/\rho_{\mathrm{e}} \simeq 1$, the self-gravity (which causes the spatial inhomogeneity) is weak, and the system behaves like an ordinary perfect gas. When $\rho_0/\rho_{\mathrm{e}} \gg 1$, however, the system is highly inhomogeneous, consisting of a core of low mass and high density surrounded by an extensive halo of high mass and low density. Consider a transfer of energy from the deep interior to the envelope. In the envelope, which is restrained by the enclosure, the additional energy causes a rise in temperature, but this is small, because of the very large mass of the halo. Extraction of energy from around the core, however, causes the bodies there to sink and accelerate, and, because of the negative

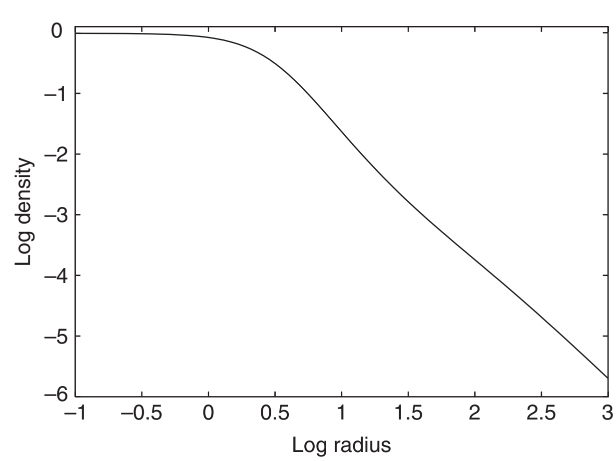

**Figure 3** The density profile of the nonsingular isothermal model, with conventional scalings.

specific heat of a self-gravitating system, they gain more kinetic energy than they lost in the original transfer. Now the system is hotter in the core than in the halo, and the transfer of energy from the interior to the exterior is self-sustaining, in a gravothermal runaway. The isothermal model with large density contrast is therefore unstable.

The negative specific heat, and the lack of an equilibrium which maximizes the entropy, are two examples of the anomalous thermodynamic behavior of the self-gravitating *N*-body problem. They are related to the long-range nature of the gravitational interaction, the importance of boundary terms, and the nonextensivity of the energy. Another consequence is the inequivalence of canonical and microcanonical ensembles.

### Numerical Methods

The foregoing considerations are difficult to extend to systems without a boundary, although they are a vital guide to the behavior even in this case. Our knowledge of such systems is due largely to numerical experiments, which fall into several classes:

1. Direct *N*-body calculations. These minimize the number of simplifying assumptions, but are expensive. Special-purpose hardware is readily available, which greatly accelerates the necessary calculations. Great care has to be taken in the treatment of few-body configurations, which otherwise consume almost all resources.
2. Hierarchical methods, including tree methods, which shorten the calculation of forces by grouping distant masses. They are mostly used for collisionless problems.
3. Grid-based methods, which are used for collisionless problems.
4. Fokker–Planck methods, which usually require a theoretical knowledge of the statistical effects of two-, three- and four-body interactions. Otherwise they can be very flexible, especially in the form of Monte Carlo codes.
5. Gas codes. The behavior of a self-gravitating system is simulated surprisingly well by modeling it as a self-gravitating perfect gas, rather like a star.

### Collisional Evolution

Consider an isolated *N*-body system, which is supposed initially to be given by a spherically symmetric equilibrium solution of eqns [6] and [7], such as eqn [8]. The temperature decreases with increasing radius, and a gravothermal runaway causes the "collapse" of the core, which reaches

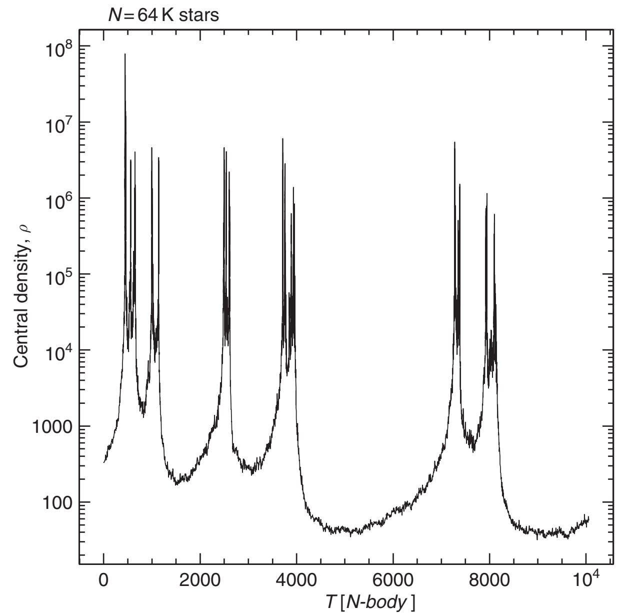

**Figure 4** Gravothermal oscillations in an *N*-body system with $N = 65\,536$. The central density is plotted as a function of time in units such that $t_{cr} = 2\sqrt{2}$. (Source: Baumgardt H, Hut P, and Makino J, with permission.)

extremely high density in finite time. (This collapse takes place on the long two-body relaxation timescale, and so it is not the rapid collapse, on a free-fall timescale, which the name rather suggests.)

At sufficiently high densities, the timescale of three-body reactions becomes competitive. These create bound pairs, the excess energy being removed by a third body. From the point of view of the one-particle distribution function, *f*, these reactions are exothermic, causing an expansion and cooling of the high-density central regions. This temperature inversion drives the gravothermal runaway in reverse, and the core expands, until contact with the cool envelope of the system restores a normal temperature profile. Core collapse resumes once more, and leads to a chaotic sequence of expansions and contractions, called gravothermal oscillations (Figure 4).

The monotonic addition of energy during the collapsed phases causes a secular expansion of the system, and a general increase in all timescales. In each relaxation time, a small fraction of the masses escape, and eventually (it is thought) the system consists of a dispersing collection of mutually unbound single masses, binaries, and (presumably) stable higher-order systems.

It is very remarkable that the long-term fate of the largest self-gravitating *N*-body system appears to be intimately linked with the three-body problem.

# Gravitational Waves

**G González and J Pullin**, Louisiana State University, Baton Rouge, LA, USA

In elementary physics presentations, one learns about electricity and magnetism, and also about gravity. There appear striking similarities between Newton's law of gravitational attraction and Coulomb's law of attraction between charges. There are also obvious differences, the most immediate one being that in gravitation all masses are positive and always attract each other, whereas in electromagnetism charges may attract or repel, depending on their signs. We also know today that Newton's theory of gravity is not considered an entirely correct description of the gravitational field, particularly when fields are time dependent and intense. The currently accepted theory of gravity is Einstein's theory of general relativity.

The similarity between electromagnetism and gravitation also holds to a certain extent when the fields depend on time. This is usually not discussed in elementary treatments since a full description of time-dependent gravitational fields requires the use of general relativity. It is true, however, that if the fields are weak, there exist several similarities between gravitation and electromagnetism. In particular, one can have waves in the gravitational field that are able to carry energy from a source to a receptor.

If one assumes that the metric of spacetime is close to the flat Minkowski metric $\eta_{\mu\nu}$, that is, $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ with $|h_{\mu\nu}| << 1$ in Cartesian coordinates, the Einstein equations of general relativity, expanding to linear order in $h_{\mu\nu}$, become

$$\begin{aligned} 0 =& R_{\mu\nu} - \tfrac{1}{2}\eta_{\mu\nu}R \\ =& \tfrac{1}{2}\left(\partial_\sigma\partial_\nu h^\sigma_{\mu\nu} + \partial_\sigma\partial_\mu h^\sigma_\nu - \partial_\mu\partial_\nu h \right. \\ & \left. - \Box h_{\mu\nu} - \eta_{\mu\nu}\partial_\mu\partial_\nu h^{\mu\nu} + \eta_{\mu\nu}\Box h\right) \end{aligned} \qquad [1]$$

These do not look like wave equations. However, if one chooses "harmonic coordinates," $\Box x^\mu = 0$, where $\Box$ is the d'Alembertian constructed with the full metric and then linearized, the vacuum Einstein equations become

$$\Box h_{\mu\nu} = 0 \qquad [2]$$

where $\Box$ is the d'Alembertian computed in the flat Minkowski metric.

Just as in electromagnetism the motion of charges produces waves, the motion of masses produces waves in the gravitational field. In the above wave equations, one would have nonzero right-hand sides if masses were present. In electromagnetism, the conservation of charge implies that the lowest order of "structure" a source must have to produce electromagnetic waves is that of a time-dependent dipole. In the gravitational field, the conservation of momentum implies that the lowest multipolar order of a source of gravitational waves must be a quadrupole. Moreover, gravity is a weaker force than electromagnetism when one considers usually available situations. One can exert forces of the orders of fractions of Newton with electromagnetic

charges easily collected in tabletop experiments. To produce similar amounts of gravitational force, one needs large quantities of mass. This last fact, coupled with the quadrupolar nature of the sources of gravitational waves, makes their production quite challenging in experimental terms. The luminosity of a gravitational wave source is given by the celebrated Einstein quadrupole formula,

$$L = \left(\frac{G}{5c^5}\right) \sum_{j=1,k=1}^{3} \left(\dddot{I}_{jk}\right)^2 \qquad [3]$$

where $G$ is Newton's gravitational constant, $c$ is the speed of light, and $\dddot{I}_{ij}$ is the third-order time derivative of the traceless part of the quadrupole mass moment of the source.

Gravity is, however, a dominant force if one considers the universe at large (say, at least planetary) scales. There one would expect gravitational waves to play some role in the dynamics of the systems. In such systems, the presence of gravitational waves has indeed been experimentally confirmed. We know of a system of two pulsars in mutual orbit, PSR1913 + 16, whose orbit has been tracked with enough accuracy via radioastronomy to make the influence of gravitational waves observable. The motion of the pulsars makes the system an emitter of gravitational waves. Since the waves carry away energy, the orbit of the system decreases in radius and the period of oscillation increases. The system has now been tracked for over 20 years, and the prediction of the emitted amount of energy in gravitational waves due to general relativity has been confirmed with a very significant degree of accuracy. Penrose was the first to notice that if one considers how accurately Newton's theory plus the corrections due to general relativity predict the positions of the pulsars in their orbit, this is in fact the most accurately verified physical prediction ever.

Technically, even the existence of gravitational waves at a conceptual mathematical level, was an open problem for many years. Since the correct description of the waves is through the general theory of relativity, a "gravitational wave" should really be viewed as a "ripple in spacetime." Disentangling if such ripples are a true physical effect or a time-dependent coordinate transformation that propagates – to use the words of Eddington – "with the speed of thought" took quite a bit of technical development within the general theory of relativity. It was only in the 1960s that a clear enough conceptual picture was developed to determine that gravitational waves were indeed a true physical phenomenon akin to electromagnetic waves. And in particular that one can unambiguously characterize them as transporting energy, momentum, and angular momentum from a source to an observer.

Gravitational waves are as difficult to detect as they are to produce. Since all masses fall in the same way in a gravitational field, one needs to couple to the gradients of the field to detect gravitational waves, which diminishes the efficiency. Attempting to produce gravitational waves via mechanical means in the lab (e.g., by rotating a bar of metal) produces too little luminosity, and in addition, the relatively low frequency implies that the wave zone is far away, which further decreases the chances for detection. Up to date, no one has succeeded in producing a Hertz-like experiment for gravitational waves and the jury is still out on the issue if future technologies (e.g., the use of superconductors to produce waves of gigahertz frequency) will ever allow such an experiment.

Efforts to attempt to detect gravitational waves produced by astrophysical phenomena started in the 1960s with pioneering work by Weber. The initially proposed technology for detection was the construction of large ($\sim 1$ ton) resonant bars. The idea was to use sensitive technology to measure the resonance of the bar as gravitational waves of astrophysical origin impact on it. Gravitational waves manifest themselves as a stretching and contraction of lengths. The contraction or stretching is proportional to the length of the object considered and is therefore characterized by a dimensionless number, the "strain" $\Delta L/L$ usually called "$h$." Conservative current estimates of possible astrophysical sources state that on Earth one should not expect strains larger than $10^{-22}$ for events that repeat more frequently than a few times every year. Detectors with bar technology are approaching their fundamental quantum limits with strains that appear to be too large for detection to be ensured. This led to the proposal of a new technology, the use of Michelson-type interferometers to detect the waves. Currently, several interferometric detectors are being built in the US, Europe, Japan, and Australia that expect to achieve enough sensitivity for detection within a few years. Contrary to the bars, which are quintessentially narrow-band detectors (most bars operate $\sim 900$ Hz with a bandwidth of $\sim 10$ Hz), interferometric detectors are broadband. Current detectors have a sensitivity curve limited by various sources of noise that make them suitable for detection within the 10 Hz–1 kHz band. The broadband nature of the detectors opens several opportunities for the use of data analysis techniques that can allow the detection of gravitational waves that have strains even lower than the noise of the detectors. Moreover, several of

the candidate events "evolve" in frequency as they emit gravitational waves (in the case of the binary pulsar, for instance, the frequency "sweeps up" as the system loses energy), and such evolution could be monitored with interferometric detectors. This would allow several insights into the physics of the observed systems.

An important limitation of any type of detector based on Earth is that the seismic noise increases quite significantly below 10 Hz. Even if seismic isolation allowed sensitivities below 10 Hz, gravity gradients due to Earth's seismic motion and due to clouds would limit ground-based detectors to 1 Hz and above. The frequency at which a system emits gravitational waves is inversely proportional to the system's mass (a simple way to see this is to realize that larger systems move proportionally slower to their size). However, larger systems generically have more mass and therefore consequently emit larger amounts of energy in gravitational waves. This suggests that setting up detectors in space, free of the constraints of seismic noise, would offer significant promise in detecting gravitational waves. Currently, there is a proposal for a space-borne gravitational wave detector consisting of three satellites in a solar orbit that trails that of Earth. Lasers would be sent between the satellites to track their relative positions, which will be separated by 5 million kilometers. Such a detector would be sensitive in frequencies of $10^{-4}$–$10^{-2}$ Hz. In such a frequency band, one expects that compact objects plunging into supermassive black holes and other sources will be readily available. Detection of gravitational waves on Earth is considered marginal, in the sense that conservative current estimates cannot guarantee that there will be enough events to make the detection successful at significant event rates. Conversely, for the detectors in space, detection should be guaranteed at high event rates.

Possible sources of gravitational waves to be detected by the Earth-based interferometric detectors are:

1. Binary systems of compact objects. As the system orbits, it emits gravitational waves, which makes the orbit shrink in size and the orbiting period shorter with the objects eventually merging together. Potential systems include black hole binaries, neutron star binaries and mixed black hole/neutron star binaries. As the system sweeps up in orbital speed towards the merger, so does the frequency of the gravitational waves emitted. For binaries of neutron stars, which usually have masses slightly larger than the mass of the Sun, the last few minutes of the binary inspiral will be detectable by the current generation of gravitational wave detectors, up to a distance of several mega-parsecs for the initial detectors, increasing to a few hundreds of mega-parsecs for improvements planned for the next few years. For black hole binaries, since the masses can be larger, one expects larger signal-to-noise ratio for the same distance or to be able to detect at larger distances.
2. Spinning neutron stars that develop "mountains" or other irregularities in the surface would produce gravitational waves of small amplitude but of a very regular periodic nature. This makes them prime candidates for data analysis techniques that could exhibit the presence of the wave even though it is weaker than the background noise of the interferometers. Integration periods of several months may be needed for detection, depending on the size of the asymmetries in the neutron stars.
3. Supernovas or other violent events are obviously possible sources of gravitational waves. However, the quadrupole nature of the waves requires the events to be asymmetric in order to produce gravitational waves. Current numerical models of supernovas are not accurate enough to predict in a clear way the level of asymmetry to make reliable predictions of how frequently and at what intensity could these types of sources be detected.
4. The primordial background of gravitational waves produced in the big bang is not expected to be detectable by the Earth-based detectors. The precise amplitude of the background is unknown, depending on details of cosmological models. The detectors are likely to be able to constrain some of the models that predict large amplitudes for the gravitational wave background.

For the space-based detectors, the situation is more favorable, since there exist sources of gravitational waves that are guaranteed to be detected. Potential sources of gravitational waves are:

1. *Merger of the supermassive black holes at the centers of two galaxies*. Given the large amounts of mass involved, they would be easily detected and very precise measurements of the system's parameters and of various general relativistic behaviors could be possible. Such systems should be detectable all across the universe, although it is not expected that such systems form for redshifts larger than 30.
2. *Inspiral of compact objects into the supermassive black holes at the centers of galaxies* (neutron

stars, white dwarfs, solar-sized black holes). These processes will allow the usage of gravitational waves to map precisely the gravitational field of the supermassive object.

3. *White-dwarf binaries and low-mass X-ray binaries*. There exist about a dozen such systems optically observable with gravitational wave frequencies above 0.1 mHz that the space-based detectors should be able to detect. There is likely to be a large population of other systems that are also detectable and are not optically visible. In fact, there may be so many of these sources that time resolution would be impossible, and they would form a random background.
4. *Collapse of supermassive stars*. The formation mechanism for the supermassive black holes in the centers of galaxies is still uncertain. One possibility is that they stem from the collapse of supermassive stars, and in that case a potentially significant emission of gravitational waves could take place.
5. *Primordial background of gravitational waves*. Unfortunately, the abundance of white-dwarf binaries as a source is expected to cloud the ability of the space detectors to observe primordial gravitational waves in an important portion of the spectrum of the instrument, although it appears possible at low frequencies, where it could compete with the bounds set by pulsar timing.

The current Earth-based gravitational wave projects include the LIGO project in the US, funded by the National Science Foundation and jointly operated by Caltech and MIT and a consortium of institutions known as the LIGO Science Collaboration. LIGO consists of two 4 km long Fabry–Perot recycled Michelson interferometers, one in Hanford, WA, and one in Livingston, LA. In Europe, the GEO600 project is a 600 m dual-recycled interferometer near Hanover in Germany and the Virgo project is a 3 km interferometer near Pisa in Italy operated by a French–Italian consortium with a similar optical configuration as LIGO. TAMA300 is a 300 m interferometer in Japan also with the same configuration as LIGO. When all these detectors are in operation, sources seen in coincidence could be localized by triangulation. TAMA is now operating close to design sensitivity, GEO600 and LIGO are likely to operate at design sensitivity in 2006, with VIRGO following close behind. The space-based interferometer project is called the LISA project and is planned as a joint NASA/ESA project. ESA has approved a launching date for 2015, but it is plausible that the mission could be launched at an earlier date.

A direct detection of gravitational waves would be a breakthrough in experimental science, as well as a confirmation of the dynamic nature of gravity in general relativity. Once the detection of gravitational waves becomes a routine matter, one can imagine a revolution in astronomy as one uses gravitational waves to "see" the universe. Since they are so hard to produce and interfere with, gravitational waves become an excellent type of "light" to look at the universe with. Gravitational waves will be produced by important concentrations of mass, correlating well with "interesting" astronomical processes, and is not expected to be affected by the presence of dust or other interfering objects that could easily obscure electromagnetic waves. In addition to this, one has several "standard candles" for gravitational waves (e.g., most neutron stars have masses that differ by a few percent from 1.4 solar masses). This could allow, for instance, to determine with a high degree of accuracy the Hubble constant. Gravitational waves will also provide insight into the nuclear equation of state that holds in the interior of compact objects like neutron stars. Contrary to ordinary electromagnetic radiation, which "decoupled" from matter only when the universe became cool enough after the big bang, gravitational waves could be used to probe the universe further into the past. The detection could also prove that gravitational waves travel at the speed of light, a prediction of general relativity and other theories.

An interesting observation is that most astrophysical objects that are quite visible in the electromagnetic spectrum are unlikely to be visible in terms of gravitational waves, and vice versa. This makes the information we will gather from gravitational wave astronomy complementary to what we learn from optical (electromagnetic) astronomy. Moreover, it should be noted that wavelengths of electromagnetic waves are typically very small compared to the size of the astronomical objects they depict. This is due to the fact that the waves are really not produced by the objects themselves but by atoms on the surface of the objects or in regions nearby, usually very hot and in gaseous form. In contrast, gravitational waves are produced by the bulk matter of astronomical objects and their wavelengths are expected to be long as compared to the objects that produce them. They are more akin to a sound than to light in this respect, another reason to suspect that the information we will get from them is unlike any information obtained electromagnetically.

Gravitational waves are likely to bring great surprises. Every time a new window has been opened on the universe – for instance, the use of radio waves – our view of the universe has been revolutionized. Given how differently they operate

at a detailed level with respect to radio waves, the surprises from gravitational waves used as tools to view the universe are potentially even greater.

# Growth Processes in Random Matrix Theory

**K Johansson**, Kungl Tekniska Högskolan, Stockholm, Sweden

## Introduction

Probability distributions coming from random matrix theory (RMT), RMT laws, occur in different contexts, notably in quantum physics and in number theory. RMT laws are also seen in certain local random growth models and related problems in discrete probability, random permutations, exclusion processes, and random tilings (dimer models). In these models limit laws for height/shape fluctuations are given by limit laws from RMT, in particular the largest eigenvalue or Tracy–Widom distributions. These models belong to the Kardar–Parisi–Zhang (KPZ) universality class. Models in this class have two universal exponents, 1/3 describing the interface fluctuations and 2/3 describing the correlations in the transversal direction. By a local random growth model, we mean a model where the random growth mechanism is local in that it does not depend on the global geometry as in diffusion limited aggregation (DLA). Typically there is also some smoothing mechanism. The connection with RMT can only be established for special exactly solvable models. Below we discuss a basic model based on a last-passage percolation problem, which translates into a polynuclear growth (PNG) process. Other models that can be treated are in a sense variations of this model. Point processes with determinantal correlation functions play a central role in RMT and in the analysis of the basic model and we start by discussing these. The basic model has several different interpretations that will be outlined. Another basic tool, which can be formulated in different ways, is the Robinson–Schensted–Knuth (RSK) correspondence well known in combinatorics. One approach is in terms of nonintersecting paths which translates into a multilayer PNG process. Limit theorems can be formulated for the height above a fixed location, and also for the whole height function in terms of the Airy process which extends the Hermitian Tracy–Widom distribution $F_2$. It is expected that several results should generalize to a broader class of models. There is a natural universality problem of extending the validity of the RMT laws.

### Determinantal Processes

Point processes with determinantal correlation functions play an important role in the exactly solvable models. We consider probability measures on $\Lambda^n, \Lambda \subseteq \mathbb{R}$, of the form

$$\frac{1}{Z_n}\det(\phi_i(x_j))_{i,j=1}^n \det(\psi_i(x_j))_{i,j=1}^n \, d^n\mu(x) \qquad [1]$$

which can be thought of as describing random points in $\Lambda$ at positions $x_1, \ldots, x_n$. Here, $\mu$ is a reference measure on $\Lambda$, for example, Lebesgue or counting measure, $Z_n$ a normalization constant, and $\phi_i, \psi_i$ given functions. A measure of this form has determinantal correlation functions in the sense that the density, with respect to $d^m\mu(y)$, of particles at $y_1, \ldots, y_m$ is

$$\rho(y_1, \ldots, y_m) = \det(K_n(y_i, y_j))_{i,j=1}^m \qquad [2]$$

There is an explicit formula for the correlation kernel $K_n$ in terms of the functions $\phi_i, \psi_i$.

The eigenvalue measures in the basic random matrix ensembles have the form

$$\frac{1}{Z_n}|\Delta_n(x)|^\beta \prod_{j=1}^n w(x_j)\, \mathrm{d}^n\mu(x) \qquad [3]$$

where $\Delta_n(x) = \det(x_j^{i-1})_{i,j=1}^n$ is Vandermonde's determinant, $x \in \Lambda^n$ and $x_1, \ldots, x_n$ are the eigenvalues. For the Gaussian unitary ensemble (GUE$_n$), $Z_n^{-1}\exp(-\operatorname{tr} M^2)\mathrm{d}M$ of $n \times n$ Hermitian matrices $M$, we have $\beta = 2, \Lambda = \mathbb{R}, w(x) = \exp(-x^2)$ and $\mu$ the Lebesgue measure. For the Laguerre unitary ensemble (LUE$_{n,\nu}$) of complex covariance matrices, $M^*M$, where $M$ is an $(n+\nu) \times n$-matrix with standard complex Gaussian elements, we have $w(x) = x^\nu \mathrm{e}^{-x}, \nu \geq 0, \beta = 2, \Lambda = [0, \infty)$ and $\mu$ the Lebesgue measure. The $\beta = 2$ case of [3] can be put into the form [1] and hence has determinantal correlation functions. In this case the correlation kernel can be expressed in terms of the normalized orthogonal polynomials $p_k(x)$ with respect to $w(x)\,\mathrm{d}\mu(x)$ on $\Lambda$. Because of this when $\beta = 2$ the ensemble [3] is referred to as an orthogonal polynomial ensemble (OPE). The kernel is given by

$$K_n(x,y) = \sum_{k=0}^{n-1} p_k(x)p_k(y)(w(x)w(y))^{1/2} \qquad [4]$$

A consequence of [2] is that the probability of finding no particle in a set $J \subseteq \Lambda$ is given by a Fredholm determinant,

$$\mathbb{P}[\text{no particle in } J] = \det(I - K_n)_{L^2(J,\mu)} \qquad [5]$$

In particular the distribution function $F(\xi)$ of the largest eigenvalue or rightmost particle $x_{\max} = \max_{1 \leq j \leq n} x_j$ in an OPE is given by [5] with $K_n$ as in [4] and $J = (\xi, \infty)$.

## A Basic Model

Let $(w(i,j))_{(i,j)\in\mathbb{Z}_+^2}$ be independent geometric random variables with parameter $a_ib_j$,

$$\mathbb{P}[w(i,j) = k] = (1 - a_ib_j)(a_ib_j)^k \qquad [6]$$

$k \geq 0$ and $0 \leq a_ib_j < 1$. As a limiting case we can obtain exponential random variables. Consider the last-passage time

$$G(M,N) = \max_\pi \sum_{(i,j)\in\pi} w(i,j) \qquad [7]$$

where the maximum is over all up/right paths $\pi$ from $(1,1)$ to $(M,N)$, that is, $\pi = \{(i_1,j_1), \ldots, (i_m,j_m)\}$ with $(i_{k+1},j_{k+1}) - (i_k,j_k) = (1,0)$ or $(0,1), (i_1,j_1) = (1,1)$ and $(i_m,j_m) = (M,N), m = M+N-1$. We can also think of this as a zero-temperature directed polymer, by thinking of the $w(i,j)$:s as (minus) energies and $\pi$ as random walk paths.

As will be explained in some more detail below, if the $w(i,j)$:s are exponential with mean 1 and $M \geq N$, then $G(M,N) = \lambda_{\max}$ in distribution, $M \geq N$, where $\lambda_{\max}$ is the largest eigenvalue in LUE$_{N,M-N}$. Hence, in this case $G(M,N)$ behaves exactly like a largest eigenvalue. If the $w(i,j)$:s are geometric with parameter $q$, then $G(M,N)$ has the same distribution as the rightmost particle in an OPE, namely [3], with $\beta = 2, w(x) = \binom{M-N+x}{x}q^x$ and $\mu$ the counting measure on $\Lambda = \mathbb{N}$, called the Meixner ensemble. Since in this case the relevant orthogonal polynomials are discrete the ensemble is referred to as a discrete OPE.

The random variables $\{G(M,N)\}_{(M,N)\in\mathbb{Z}_+^2}$ have two interpretations related to random growth. It follows from [7] that

$$G(M,N) = \max(G(M-1,N), G(M,N-1)) + w(M,N) \qquad [8]$$

This can be thought of as a growth rule. We change variables by letting $G(M,N) = h(M-N, M+N-1)$ and $w(M,N) = \omega(M-N, M+N-1)$ with $w(M,N) = 0$ if $(M,N) \notin \mathbb{Z}_+^2$. Then

$$h(x,t+1) = \max(h(x-1,t), h(x,t), h(x+1,t)) + \omega(x,t) \qquad [9]$$

$x \in \mathbb{Z}, t \in \mathbb{N}, h(x,0) \equiv 0$, and $\omega(x,t) = 0$ if $|x| \geq t$ or if $x - t$ is even. We can extend it to the whole real line by letting $h(x,t) = h([x],t)$. The growth rule [9] is a discrete polynuclear growth (PNG) model. Up-steps in the interface, $x \to h(x,t)$ (see the top curve in Figure 1), move at unit speed to the left and down-steps move at unit speed to the right and they merge at collision. On top of this smoothing mechanism, we have random deposition given by $\omega(x,t)$. Looking at the definition of $\omega$, we see that all deposition up to time $t$ is on top of a basic layer $(-t,t)$. The asymptotic shape will look like a droplet and this setting of PNG is called the droplet geometry. We see that height fluctuations are directly related to fluctuations of $G(M,N)$.

We get another growth model, the corner growth model, somewhat similar to the classical Eden growth model, by considering the random shape (see Figure 2),

$$\Omega(n) = \{(M,N) \in \mathbb{Z}_+^2; G(M,N) + M + N - 1 \leq n\} + [-1,0]^2 \qquad [10]$$

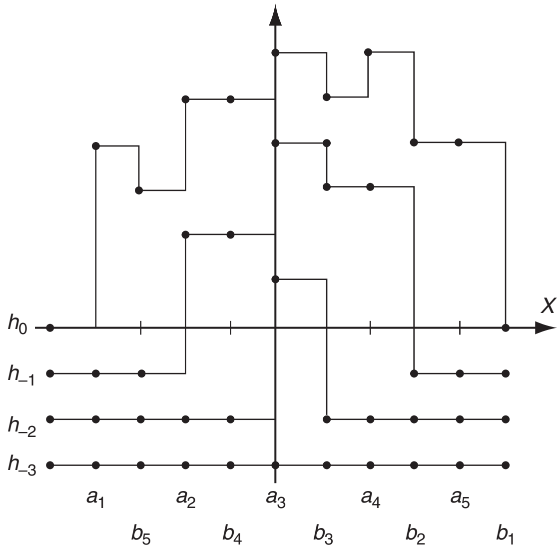

**Figure 1** Multilayer PNG model.

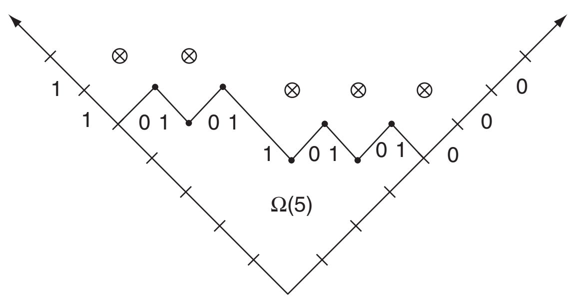

**Figure 2** Corner growth model at time $n=5$. The crosses are the possible growth sites.

The complement of this set in $\mathbb{Z}_+^2$ has a boundary $B(n)$ which we can think of as an interface. By [8] and the lack of memory property of the geometric/exponential distribution, the region $\Omega(n)$ grows by adding new squares independently at each corner of $B(n)$ with geometric/exponential waiting times (see Figure 2). If we look at $B(n)$ in a coordinate system with $M=N$ as vertical axis and write a 1 for every unit down-step on $B(n)$ and a 0 for every unit up-step (see Figure 2), the corner growth dynamics translates into the totally asymmetric simple exclusion process (TASEP), in discrete or continuous time, with initial configuration $\dots 1111000 \dots$ . As shown by Jockush, Propp, and Shor, $\Omega(n)$ also occurs in a uniform random domino tiling of a region called the Aztec diamond (see Figure 3). The shape $\Omega(n)$, when $q=1/2$, has the same law as the completely regular (frozen) North Polar Region (NPR) in the tiling and hence the boundary fluctuations of the NPR are related to the fluctuations of $G(M,N)$. The NPR in Figure 3 has the same shape as $\Omega(5)$ in Figure 2. This connects the models considered here with dimer or tiling problems in two-dimensional equilibrium statistical mechanics.

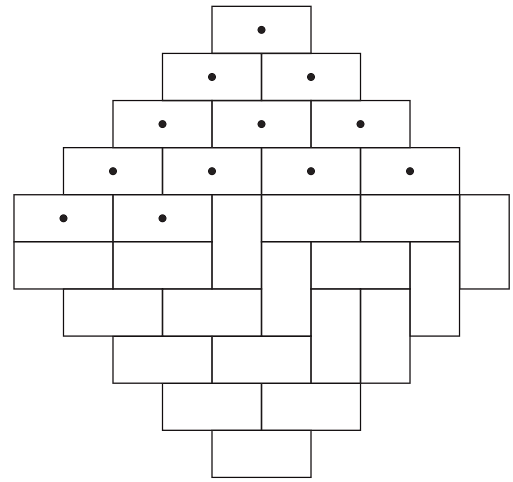

**Figure 3** Domino tiling of an Aztec diamond of size $n=5$. Dominos marked by dots form the NPR.

Consider a (Poissonized) random permutation $\sigma$ from $S_N$, where $N$ is a Poisson($\alpha$) random variable. Let $L(\alpha)$ denote the length of the longest increasing subsequence in $\sigma$, for example, $\sigma=316452$ has $L=3$. By thinking of the representation of a permutation by its permutation matrix, we see that $G(N,N)$ with $w(i,j)$ geometric with parameter $q=\alpha/N^2$ converges to $L(\alpha)$ in distribution as $N\to\infty$. We call this limit the Poisson limit. Taking this limit in the PNG process yields the Prähofer–Spohn continuous time PNG (cont-PNG) model, which is similar to the discrete PNG defined above but where all steps have unit size and we have continuous time dynamics with deposition events according to a two-dimensional spacetime Poisson process. The study of $L(\alpha)$, and its de-Poissonization when $N$ is nonrandom, is known as Ulam's problem in combinatorial probability.

## The RSK Correspondence

The mapping of the last-passage problem [7] into a determinantal process is based on the RSK correspondence. This correspondence maps the integer matrix $(w(i,j))_{1\le i,j\le M}$ bijectively to a pair of semi-standard Young tableaux $(P,Q)$ with common shape $\lambda$, which is a partition $\lambda=(\lambda_1,\lambda_2,\dots)$ of $\sum_{1\le i,j\le M} w(i,j)$. This map has the property that $G(M,N)=\lambda_1$, the length of the first row in the Young diagram. From the combinatorial definition of the Schur polynomials $s_\lambda$ it follows that the measure [6] on the integer matrix is mapped to a

probability measure on partitions, the Schur measure, given by

$$\mathbb{P}_{\text{Schur}}[\lambda] = \frac{1}{Z} s_\lambda(a_1, \ldots, a_M) s_\lambda(b_1, \ldots, b_M) \qquad [11]$$

This measure has determinantal correlation functions if we think of $x_i = \lambda_i - i$ as the positions of particles in $\mathbb{Z}$. If we use $x_i = \lambda_i + N - i$ as variables and specialize to $a_1 = \cdots = a_M = \sqrt{q}, b_1 = \cdots = b_N = \sqrt{q}$ and $b_j = 0$ for $j > N$ we get the Meixner ensemble. The case of exponential random variables, for example the relation to LUE discussed above, is obtained from the Meixner ensemble by taking an appropriate limit. In the Poisson limit we get the Poissonized Plancherel measure,

$$\mathbb{P}^{\alpha}_{\text{Plan}}[\lambda] = \sum_{N=0}^{\infty} \frac{e^{-\alpha/\alpha^n}}{N!} \qquad [12]$$

where $\mathbb{P}_{\text{Plan},N}[\lambda] = (\dim \lambda)^2/N!$ if $\lambda$ is a partition of $N$ and 0 otherwise. Here $\dim \lambda$ is the dimension of the irreducible representation of $S_N$ labeled by $\lambda$. In the work of Borodin and Olshanski in representation theory various measures on partitions with determinantal correlation functions occur naturally. Also Okounkov and co-workers have used the Plancherel and Schur measures in Gromov–Witten theory. The correlation kernel for the Plancherel measure represented as the point process $(x_i)_{i\geq 1}$ in $\mathbb{Z}$ with $x_i = \lambda_i - i$ has the correlation kernel, called the discrete Bessel kernel,

$$\begin{aligned} B^{\alpha}(x,y) = {} & \sqrt{\alpha}(x-y)^{-1} \\ & \times (J_x(2\sqrt{\alpha}) J_{y+1}(2\sqrt{\alpha}) \\ & - J_{x+1}(2\sqrt{\alpha}) J_y(2\sqrt{\alpha}) \end{aligned} \qquad [13]$$

where $J_n$ is the ordinary Bessel function. The random variable $L(\alpha)$ has the same distribution as $\max x_j + 1$. Hence, by [5],

$$\mathbb{P}[L(\alpha) \leq n] = \det(I - B^{\alpha})_{\ell^2(\{n, n+1, \ldots\})} \qquad [14]$$

The random variable $L(\alpha)$ also gives the height above the origin in cont-PNG.

There is a geometric interpretation of RSK going back to Viennot. The pair $(P, Q)$ is represented as a family of nonintersecting paths in a directed graph. These paths can be obtained by running a multilayer version of the PNG process where the size of collisions are deposited as growth in lower layers which evolve according to the same PNG dynamics. The information lost in the collisions is recorded in the lower layers. This can be done also for $\{w(i,j)\}_{i+j-1\leq t}$ and leads to a multilayer version of [9], $\{h_{-j}(x,t)\}_{j=1}^{\infty}$, where $h_{-j}(x,0) \equiv -j, h_{-j}(\pm t, t) = -j$, and $h(x,t) = h_0(x,t)$ is the top path (see Figure 1).

The Karlin–McGregor theorem or the Gessel–Viennot method say that the weight (probability) of a family of nonintersecting paths with fixed initial and final positions on a weighted directed acyclic graph is given by a determinant. It follows that the probability of a certain configuration $\{h_{-j}(0,t)\}_{j\geq 1}$ is given by a product of two determinants and hence has the form [1]. In Figure 1, the weights of the horizontal line segments will be 1, whereas each unit vertical step has weight $a_i$ or $b_j$ as indicated in the figure. This leads to [9] using the Jacobi–Trudi formula for the Schur polynomial.

## Limit Theorems

The existence of a limit shape in a model like [6] with $w(i,j)$ independent random variables, and in related problems follows by a subadditivity argument, although explicit shapes are only known in a few cases. The formalism described above makes it possible to get more detailed results about the fluctuations around the limit shape, like a central-limit theorem, but with a non-normal limit law. We know that $G(M,N)$ has the same distribution as $x_{\max} - N + 1$, where $x_{\max}$ is the rightmost particle in the Meixner ensemble. This, together with [4], [5], and an asymptotic analysis of the Meixner polynomials, gives

$$\mathbb{P}\left[G(M,N) \leq \omega(\gamma,q)N + \xi\sigma(\gamma,q)N^{1/3}\right] \to F_2(\xi) \qquad [15]$$

as $N \to \infty, M \to \infty, M/N \to \gamma \geq 1$, where

$$\omega(\gamma,q) = \frac{(1+\sqrt{q\gamma})^2}{1-q} - 1 \qquad [16]$$

and

$$\sigma(\gamma,q) = \frac{(q/\gamma)^{1/6}}{1-q} (\sqrt{\gamma} + \sqrt{q})^{2/3} (1+\sqrt{q\gamma})^{2/3} \qquad [17]$$

The limiting distribution function $F_2$ is the Tracy–Widom distribution given by

$$F_2(\xi) = \det(I - A)_{L^2(\xi,\infty)} \qquad [18]$$

where

$$A(x,y) = \frac{\mathrm{Ai}(x)\mathrm{Ai}'(y) - \mathrm{Ai}'(x)\mathrm{Ai}(y)}{x-y} \qquad [19]$$

is the Airy kernel. It is also the limiting largest eigenvalue distribution for GUE$_n$,

$$\lim_{N\to\infty} \mathbb{P}\left[\frac{\sqrt{2n}\lambda^{(n)}_{\max} - 2n}{n^{1/3}} \leq \xi\right] = F_2(\xi) \qquad [20]$$

The function $F_2$ can also be expressed in terms of a Painlevé II function. The limit theorem [15]

translates into a fluctuation result for the height function in the corner growth and the PNG models, saying that the height fluctuations above a fixed location at time $t$ are of order $t^{1/3}$ and given by the $F_2$-distribution. Here we see the KPZ exponent 1/3.

For the length $L(\alpha)$ of the length of a longest increasing subsequence in a random permutation or the height above the origin in the cont-PNG, [14] and asymptotics for Bessel functions yield

$$\mathbb{P}[(L(\alpha) - 2\sqrt{\alpha})/\alpha^{1/6} \le \xi] \to F_2(\xi) \qquad [21]$$

as $\alpha \to \infty$. This result was first proved by Baik, Deift, and Johansson using a Toeplitz determinant formula (Gessel's formula) for the left-hand side of [14] and the Deift–Zhou nonlinear steepest descent method for oscillatory Riemann–Hilbert problems. The above limit theorems can be extended to limit theorems for the whole point process rescaled around the rightmost point. This results in a limiting determinantal point process given by the Airy kernel [19].

## The Airy Process

From the point of view of the growth processes, for example, the PNG process [7], it is natural to consider a scaling limit of the whole height function $x \to h(x,t)$ as $t \to \infty$. Looking at the height configuration in the multilayer growth process $x \to \{h_{-j}(x,t)\}_{j\ge 1}$ at different locations $x_1, \dots, x_r, x_{r+1}, \dots, x_{M-1}$ leads, via the Karlin–McGregor or Gessel–Viennot method, to probability measures of the form

$$\frac{1}{Z}\prod_{r=0}^{M-1} \det\left(\phi_{r,r+1}\left(y_i^r, y_j^{r+1}\right)\right)_{i,j=1}^{n} \qquad [22]$$

with $y^0$ and $y^M$ fixed configurations. Here, in the discrete PNG model, $\phi_{r,r+1}(x,y)$ is the transition probability (weight) to go from height $x$ to height $y$ between positions $x_r$ and $x_{r+1}$. This measure generalizes [1] and it also has determinantal correlation functions. Measures of this form also arise in multimatrix models and in Dyson's Brownian motion model, $t \to M(t), t \in \mathbb{R}$, for Hermitian matrices, which is a Gaussian multimatrix model. The elements of the time-dependent Hermitian matrix $M(t)$ evolve according to independent Ornstein–Uhlenbeck processes and we have the transition kernel

$$Z^{-1} \exp[-\mathrm{tr}(M(t) - qM(0))^2/(1-q^2)] \qquad [23]$$

where $q = \exp(-t)$. This process has GUE as its stationary distribution. The Harish–Chandra/Itzykson–Zuber integral can be used to show that the joint eigenvalue measure for $M(t_1), \dots, M(t_{M-1})$ has the form [22] and hence has determinantal correlation functions. The correlation kernel is the extended Hermite kernel,

$$K_n(\tau, x; \sigma, y) = \begin{cases} \displaystyle\sum_{k=1}^{\infty} \mathrm{e}^{-k(\tau-\sigma)} p_{n-k}(x) p_{n-k}(y)\, \mathrm{e}^{-\frac{1}{2}(x^2+y^2)} & \text{if } \tau \ge \sigma \\ \displaystyle -\sum_{k=-\infty}^{0} \mathrm{e}^{-k(\tau-\sigma)} p_{n-k}(x) p_{n-k}(y) \mathrm{e}^{-\frac{1}{2}(x^2+y^2)} & \text{if } \tau < \sigma \end{cases} \qquad [24]$$

with $p_k$ the normalized Hermite polynomials, $p_k \equiv 0$ if $k < 0$. Notice that this reduces to the Hermite kernel [4] when $\tau = \sigma$. This machinery can be used to show that the largest eigenvalue process $t \to \lambda_{\max}^{(n)}(t)$ induced by $M(t)$ converges in the sense of finite-dimensional distributions to a limiting process, the Airy process,

$$\left(\sqrt{2n}\lambda_{\max}^{n}(n^{-1/3}t) - 2n\right)/n^{1/3} \to \mathcal{A}(t) \qquad [25]$$

as $n \to \infty$. The Airy process $\mathcal{A}(t)$, which is a stationary process, can be viewed as the top curve of a multilayer process $t \to (\mathcal{A}_{-j}(t))_{j\ge 1}, \mathcal{A}(t) = \mathcal{A}_0(t)$ such that the point process $\{\mathcal{A}_{-j}(t_k)\}_{1\le k\le M, j\ge 0}$ has determinantal correlation functions with correlation kernel

$$A(\tau, \xi; \tau', \xi') = \begin{cases} \displaystyle\int_0^{\infty} \mathrm{e}^{-\lambda(\tau-\tau')} \mathrm{Ai}\,(\xi+\lambda) \mathrm{Ai}\,(\xi'+\lambda) \mathrm{d}\lambda & \text{if } \tau \ge \tau' \\ \displaystyle -\int_{-\infty}^{0} \mathrm{e}^{-\lambda(\tau-\tau')} \mathrm{Ai}\,(\xi+\lambda) \mathrm{Ai}\,(\xi'+\lambda)\, \mathrm{d}\lambda & \text{if } \tau < \tau' \end{cases} \qquad [26]$$

the extended Airy kernel, which reduces to the ordinary Airy kernel [19] when $\tau = \tau'$. The Airy process can be viewed as an extension of the Tracy–Widom distribution $F_2$. For the PNG model above, the multilayer process is described by an extended kernel, which in the cont-PNG is an extended version of the discrete Bessel kernel [13]. In a suitable scaling limit, this extended kernel converges to the extended Airy kernel. For the PNG process [7], this leads to the limit law

$$(dN^{1/3})^{-1}\left[h\left(2d^{-1}\frac{1+\sqrt{q}}{1-\sqrt{q}}N^{2/3}\tau, 2N-1\right) - \frac{2\sqrt{q}}{1-q}N\right] \to \mathcal{A}(\tau) \qquad [27]$$

as $N \to \infty$, where $d = (1-q)^{-1}(\sqrt{q})^{1/3}(1+\sqrt{q})^{1/3}$. Notice the exponent 2/3 which is the second KPZ exponent. This exponent can also be seen in the transversal fluctuations of the maximal paths in [6] for $G(N, N)$. These are superdiffusive, they have fluctuations of order $N^{2/3}$ around the diagonal, compared to $N^{1/2}$ for random walk paths between the same points. A fluctuation result like [27] can also be proved for the corner growth model and hence also for the Aztec diamond. The boundary of the NPR suitably rescaled converges to the Airy process.

## Variations

Above we discussed one possible geometry, the droplet, for the PNG process. If we start with $h(x, 0) \equiv 0$ and allow random depositions along the whole line, we get an interface that is macroscopically flat, and not curved as in the droplet case. In this case, the height fluctuations above a fixed location at time $t$ are again of size $t^{1/3}$ and described by the Gaussian Orthogonal Ensemble largest eigenvalue distribution. This law comes from the scaling limit of the rightmost particle in [3] with $\beta = 1, w(x) = \exp(-x^2), \Lambda = \mathbb{R}$, and $\mu$ the Lebesgue measure. In this case, the correlation functions are not determinants but rather pfaffians. The result for flat PNG follows from the Baik–Rains analysis of symmetrized last-passage or permutation problems. In the PNG model we can also consider an interface in equilibrium. This can be put into the last-passage percolation picture by suitable boundary conditions, different parameters for $w(i, j)$ when $i$ or $j$ equals 1 or extra Poisson points on the axes in the Poisson limit. Results by Baik and Rains show that in the cont-PNG in equilibrium the height fluctuations are given by a relative of the Tracy–Widom distribution, $F_0$. In these last two cases, the scaling limit of the whole height profile is not known.

The types of results discussed above can only be obtained for very special models. However, it is expected that many of the results (in particular the KPZ exponents 1/3 and 2/3, and also the fluctuation laws, including the Airy process) should generalize to many other models. The different interpretations of [6] mentioned above suggest different generalizations, various local growth models, directed polymers, asymmetric exclusion processes, and dimer/tiling problems. RMT laws are natural limit laws for which the domain of attraction is not understood.

## Hamiltonian Fluid Dynamics

**P J Morrison**, University of Texas at Austin, Austin, TX, USA

### Introduction

The ideal fluid description is one in which viscosity or other phenomenological terms are neglected. Thus, as is the case for systems governed by Newton's second law without dissipation, such fluid descriptions possess Lagrangian and Hamiltonian descriptions. In fact, in the eighteenth century, Lagrange himself discussed what is in essence the action principle for the incompressible fluid. The subsequent history of action functional and Hamiltonian formulations of the ideal fluid is long and convoluted with contributions from Clebsch in the nineteenth century, and the likes of L Landau and V Arnol'd in the mid-twentieth century. In the early 1980s, there was a flurry of activity on the noncanonical Poisson bracket formulation, and this formulation is the focus of the present treatment, which is motivated by the work of the author, D Holm, J Marsden, T Ratiu, A Weinstein, and others.

### Noncanonical Hamiltonian Structure

The traditional arena for Hamiltonian dynamics is the cotangent bundle $\mathcal{M} := T^*\mathcal{Q}$, the phase space, which is naturally a symplectic manifold with a closed nondegenerate 2-form. In coordinates, the 2-form is given by $\omega_c = dq \wedge dp$, where $q$ denotes the configuration coordinate for the base space manifold $\mathcal{Q}$ and $p$ denotes the corresponding canonical momenta that arise from Legendre (convex) transformation. The 2-form $\omega_c$ provides a natural identification at a point $z = (q, p) \in \mathcal{M}$ of $T_z\mathcal{M}$ with $T_z^*\mathcal{M}$, and because of nondegeneracy its inverse, the cosymplectic form, provides the map $J_c : T_z^*\mathcal{M} \to T_z\mathcal{M}$. Thus, for a Hamiltonian $H : \mathcal{M} \to \mathbb{R}$ we have the Hamiltonian system of ordinary differential equations $\dot{z} = J_c\, dH$, which in canonical coordinates has the familiar form

$$\dot{q}^i = \partial H/\partial p_i, \qquad \dot{p}_i = -\partial H/\partial q^i \qquad [1]$$

with $i = 1, 2, \ldots, N$, where $N$ is the number of degrees of freedom.

Hamilton's equations can also be written in terms of the Poisson bracket $[f, g] := \omega_c(J_c\, df, J_c\, dg)$, where $f, g : \mathcal{M} \to \mathbb{R}$ are smooth phase-space functions. In terms of $z = (q, p)$, Hamilton's equations are

$$\dot{z}^\alpha = J_c^{\alpha\beta} \frac{\partial H}{\partial z^\beta} = [z^\alpha, H] \qquad [2]$$

where the Poisson bracket is

$$[f, g] = \frac{\partial f}{\partial z^\alpha} J_c^{\alpha\beta} \frac{\partial g}{\partial z^\beta} \qquad [3]$$

with

$$(J_c^{\alpha\beta}) = \begin{pmatrix} 0_N & I_N \\ -I_N & 0_N \end{pmatrix} \qquad [4]$$

Note, repeated indices are to be summed with $\alpha, \beta = 1, 2, \ldots, 2N$. In [4], $0_N$ is an $N \times N$ matrix of zeros and $I_N$ is the $N \times N$ unit matrix.

#### Noncanonical Poisson Brackets

The canonical Poisson bracket description of [2]–[4] suggests a generalization, with antecedents to S Lie and others, that was termed noncanonical Hamiltonian form in the fluid mechanics context by P Morrison and J Greene (1980):

*A system has noncanonical Hamiltonian form if it can be written as $\dot{z} = [z, H]$, where the noncanonical Poisson bracket $[\,,]$ is a Lie product for a realization of a Lie enveloping algebra on phase-space functions.*

Recall a Lie enveloping algebra $\mathfrak{a}$ is a Lie algebra, with the usual product $[\,,]$ that is bilinear, antisymmetric, and satisfies the Jacobi identity, which in addition has a product $\mathfrak{a} \times \mathfrak{a} \to \mathfrak{a}$ that satisfies the Leibniz identity $[fg, h] = f[g, h] + [f, h]g$ for all $f, g, h \in \mathfrak{a}$.

The geometric description of noncanonical Hamiltonian form has evolved into a structure called the Poisson manifold, a differential manifold $\mathcal{Z}$ endowed with the binary bracket operation $[\,,]$ defined on smooth functions, say, $f, g : \mathcal{Z} \to \mathbb{R}$. Poisson manifolds differ from symplectic manifolds

because the nondegeneracy condition is removed. In coordinates, [ , ] is given by

$$[f, g] = \frac{\partial f}{\partial z^\alpha} J^{\alpha\beta} \frac{\partial g}{\partial z^\beta}, \quad \alpha, \beta = 1, 2, \ldots, M \qquad [5]$$

where $M = \dim \mathcal{Z}$. Note that $J$ need not have the form of [3], may depend upon the coordinate $z$, and may have vanishing determinant. Bilinearity, $[f, g] = -[g, f]$ for all $f, g$, and the Jacobi identity, $[f, [g, h]] + [g, [h, f]] + [h, [f, g]] \equiv 0$, for all $f, g, h$, imply that the cosymplectic matrix satisfies $J^{\alpha\beta} = -J^{\beta\alpha}$ and

$$J^{\alpha\delta} \frac{\partial J^{\beta\gamma}}{\partial z^\delta} + J^{\beta\delta} \frac{\partial J^{\gamma\alpha}}{\partial z^\delta} + J^{\gamma\delta} \frac{\partial J^{\alpha\beta}}{\partial z^\delta} \equiv 0 \qquad [6]$$

respectively, for $\alpha, \beta, \gamma, \delta = 1, 2, \ldots, M$.

The local structure of $\mathcal{Z}$ is elucidated by the Darboux–Lie theorem, which states that in a neighborhood of a point $z \in \mathcal{Z}$, for which rank $J = M$, there exist coordinates in which $J$ has the following form:

$$(J) = \begin{pmatrix} 0_N & I_N & 0 \\ -I_N & 0_N & 0 \\ 0 & 0 & 0_{M-2N} \end{pmatrix} \qquad [7]$$

From [7] it is clear that in the right coordinates, the system looks like a canonical $N$-degree-of-freedom Hamiltonian system with some extraneous coordinates, $M - 2N$ in fact. Through any point of the $M$-dimensional phase space $\mathcal{Z}$, there exists a local foliation by symplectic leaves of dimension $2N$.

A consequence of the degeneracy is that there exists a special class of invariants called Casimir invariants that is built into the phase space. Since the rank of $J$ is $2N$, there exist possibly $M - 2N$ independent null eigenvectors. A consequence of the Darboux–Lie theorem is that the independent null eigenvectors exist and, moreover, the null space can in fact be spanned by the gradients of the Casimir invariants, which satisfy $J^{\alpha\beta} \partial C^{(a)} / \partial z^\beta = 0$, where $a = 1, 2, 3, \ldots, M - 2N$. That the Casimir invariants are constants of motion follows from

$$\dot{C}^{(a)} = \frac{\partial C^{(a)}}{\partial z^\alpha} J^{\alpha\beta} \frac{\partial H}{\partial z^\beta} = 0 \qquad [8]$$

Thus, Casimir invariants are constants of motion for any Hamiltonian. The symplectic leaves of dimension $2N$ are the intersections of the $M - 2N$ surfaces defined by $C^{(a)} = \text{constant}$. Dynamics generated by any $H$ that begins on a particular symplectic leaf remains there. The structure of Poisson manifolds has now been widely studied, but we will not pursue this further here.

Let us turn to infinite-dimensional systems, field theories such as those that govern ideal fluids, where the governing equations are partial differential equations. Although the level of rigor does not match that achieved for the finite systems described above, formally one can parody most of the steps and, consequently, the finite theory provides cogent imagery and serves as a beacon for shedding light. In infinite dimensions, an analog of [5] is given by

$$\{F, G\} = \int_\Omega \mathrm{d}\mu \, \frac{\delta F}{\delta \psi^i} \mathcal{J}^{ij} \frac{\delta G}{\delta \psi^j} =: \left\langle \frac{\delta F}{\delta \psi}, \mathcal{J} \frac{\delta G}{\delta \psi} \right\rangle \qquad [9]$$

where $F$ and $G$ are functionals of the functions $\psi^i(\mu, t)$, which are functions of $\mu = (\mu_1, \ldots, \mu_n)$, independent variables of some kind, $\delta F / \delta \psi^i$ denotes the functional (variational) derivative, and $\langle \, , \rangle$ is a pairing between a vector (function) space and its dual. The $\psi^i, i = 1, \ldots, n$, are $n$ field components, and now $\mathcal{J}$ is a cosymplectic operator. To be noncanonically Hamiltonian requires antisymmetry, $\{F, G\} = -\{G, F\}$, and the Jacobi identity, $\{F, \{G, H\}\} + \{G, \{H, F\}\} + \{H, \{F, G\}\} \equiv 0$, for all functionals $F$, $G$, and $H$. Antisymmetry requires $\mathcal{J}$ to be skew-symmetric, that is, $\langle f, \mathcal{J} g \rangle = \langle \mathcal{J}^\dagger f, g \rangle = -\langle g, \mathcal{J} f \rangle$. The Jacobi identity for infinite-dimensional systems has a condition analogous to [6]; it can be shown that one need only consider variations of $\mathcal{J}$ when calculating, for example, $\{F, \{G, H\}\}$.

## Lie–Poisson Brackets

As noted in the Introduction, the usual variables of fluid mechanics are not a set of canonical variables, and, consequently, the Hamiltonian description in terms of these variables is noncanonical. There is a special general form that the Poisson bracket takes for equations that describe media in terms of Eulerian-like variables, the so-called Lie–Poisson brackets, a special form of noncanonical Poisson bracket. Lie–Poisson brackets describe essentially every fundamental equation that describes classical media. In addition to the equations for the ideal fluid, they describe Liouville's equation for the dynamics of the phase-space density of a collection of particles, the various hierarchy of kinetic theory, the Vlasov equation of plasma physics, and various approximations thereof, and magnetized and other more complicated fluids.

Both finite- and infinite-dimensional Lie–Poisson brackets are intimately associated with a Lie group $\mathfrak{G}$. We use the pairing between a vector space and its dual, $\langle \, , \rangle$, where the second slot is reserved for elements of the Lie algebra $\mathfrak{g}$ of $\mathfrak{G}$ and the first slot for elements of its dual $\mathfrak{g}^*$. Thus, $\langle \, , \rangle : \mathfrak{g}^* \times \mathfrak{g} \to \mathbb{R}$. In terms of the pairing, noncanonical Lie–Poisson brackets have the following compact form:

$$\{F, G\} = \langle \chi, [F_\chi, G_\chi] \rangle \qquad [10]$$

where we suppose the dynamical variable $\chi \in \mathfrak{g}^*$, $[\,,\,]$ is the Lie algebra product, which takes $\mathfrak{g} \times \mathfrak{g} \to \mathfrak{g}$, and we have introduced the shorthand $F_\chi := \delta F/\delta\chi$. The quantities $F_\chi$ and $G_\chi$ are, of course, in $\mathfrak{g}$. We refer to $\{\,,\,\}$ as the "outer" bracket of the realization enveloping algebra and $[\,,\,]$ as the "inner" bracket of the Lie algebra $\mathfrak{g}$. The binary operator $[\,,\,]^\dagger$ is defined as follows:

$$\langle \chi, [f, g] \rangle =: \left\langle [\chi, g]^\dagger, f \right\rangle \qquad [11]$$

where evidently $\chi \in \mathfrak{g}^*, g, f \in \mathfrak{g}$, and $[\,,\,]^\dagger : \mathfrak{g}^* \times \mathfrak{g} \to \mathfrak{g}^*$. The operator $[\,,\,]^\dagger$, which defines the coadjoint orbit, is necessary for obtaining the equations of motion from a Lie–Poisson bracket.

For finite-dimensional systems, the group $\mathfrak{G}$ must be a finite-parameter Lie group, the variable $\psi$ corresponds to $w$, and the cosymplectic form in coordinates is given by $J_{ab} = c^c_{ab} w_c$, where the $c^c_{ab}$ are the structure constants for the Lie algebra $\mathfrak{g}$, which satisfy

$$\begin{aligned} c^c_{ab} &= -c^c_{ba} \\ c^e_{ab} c^d_{ec} + c^e_{bc} c^d_{ea} &+ c^e_{ca} c^d_{eb} = 0 \end{aligned} \qquad [12]$$

relations that imply [10] satisfies the antisymmetry condition and the Jacobi identity.

For infinite-dimensional systems, the group $\mathfrak{G}$ must be an infinite-parameter Lie group and the cosymplectic operator has the form $\mathcal{J}_{ij} = \mathcal{C}^k_{ij} \chi_k$, where $\mathcal{C}^k_{ij}$ are structure operators. The meaning of these structure operators will be clarified when we consider brackets for fluid mechanics.

## The Fluid State

Fluid mechanics has a long history, and thus it comes as no surprise that the fluid state has been described in many ways. Because the Hamiltonian structure depends on the state variables, some of these ways are described below, beginning with Lagrangian variable description.

### Lagrangian Variables

The description of a fluid that is most like that of particle mechanics occurs in terms of variables usually referred to as Lagrangian variables. This description dates to the eighteenth century. The idea behind the use of these variables is a simple one: if a fluid is described as a continuum collection of fluid particles, also called fluid parcels or elements, then its motion is governed by an equation that is an infinite-dimensional version of Newton's second law and, consequently, as we will see, both the Hamiltonian and the Lagrangian descriptions are infinite degree-of-freedom generalizations of those of ordinary particle mechanics.

The position of a fluid element, referred to a fixed rectangular coordinate systems, is given by $q = q(a, t)$, where $q = (q_1, q_2, q_3)$ and $a = (a_1, a_2, a_3)$ is a continuum label that replaces the index $i$ of [1]. In practice, the label can be any quantity that identifies a fluid particle, but it is often taken to be the position of the fluid particle at time $t = 0$ in rectangular coordinates. The quantities $q^i(a, t)$ are coordinates for the configuration space $\mathcal{Q}$, which is in fact a function space because in addition to the three indices "$i$" there is the continuum label $a$. We assume that $a$ varies over a fixed domain, $\Omega \subset \mathbb{R}^3$, which is completely filled with fluid, and that the function $q : \Omega \to \Omega$ is one-to-one and onto. We will assume that as many derivatives of $q$ with respect to $a$ as needed exist, but we will not say more about $\mathcal{Q}$; in fact, not much is known about the solution function space for the 3D fluid equations in Lagrangian variables. Often in the Hamiltonian context the functions $q = q(a, t)$ are assumed to be diffeomorphisms and their collection is referred to as the diffeomorphism group.

In the sequel several manipulations are needed and so we record here some identities for later use. Viewing the map $a \mapsto q$ at fixed $t$ as a coordinate change, the Jacobian matrix $\partial q^k/\partial a^i =: q^k_{,i}$ has an inverse given by

$$\frac{\partial q^k}{\partial a^j} \frac{A^i_k}{\mathfrak{J}} = \delta^i_j \qquad [13]$$

where $A^i_k$ is the cofactor of $q^k_{,i}$ and $\mathfrak{J}$ is its determinant. A convenient expression for $A^i_k$ is given by

$$A^i_k = \frac{1}{2} \epsilon_{kjl} \epsilon^{imn} \frac{\partial q^j}{\partial a^m} \frac{\partial q^l}{\partial a^n} \qquad [14]$$

where $\epsilon_{ijk} (= \epsilon^{ijk})$ is the skew-symmetric tensor (density). Evidently, $\partial\mathfrak{J}/\partial q^i_{,j} = A^j_i$ follows from [13].

### Eulerian Variables

In the Lagrangian variable description, one picks out a particular particle, labeled by $a$, and keeps track in time $t$ of where it goes. However, in the Eulerian variable description, one stays at a spatial observation point $r = (x_1, x_2, x_3) \in \Omega$ and monitors the nature of the fluid at $r$ at time $t$.

The most important Eulerian variable is the Eulerian velocity field $v(r, t)$. This quantity is the velocity of the particular fluid element that is located at the spatial point $r$ at time $t$. The label of that particular fluid element is given by $a = q^{-1}(r, t)$, and so

$$v(r, t) = \dot{q}(a, t)|_{a = q^{-1}(r,t)} := \dot{q} \circ q^{-1}(r, t) \qquad [15]$$

where $\cdot$ denotes differentiation with respect to time at fixed label $a$. Attached to a fluid element is a certain amount of mass described by a density

function $\rho_0(a)$. As the fluid moves so that $a \mapsto q$, the volume of an infinitesimal region will change, but its mass must remain fixed. The statement of local mass conservation is $\rho d^3r = \rho_0 d^3a$, where $d^3a$ is an initial infinitesimal volume element that maps to $d^3q$ at time $t$, and $d^3r = \mathfrak{J}\, d^3a$. (When integrating over $\Omega$ we will replace $d^3q$ by $d^3r$.) Thus, we obtain

$$\rho(r,t) = \left.\frac{\rho_0(a)}{\mathfrak{J}(a,t)}\right|_{a=q^{-1}(r,t)} = \frac{\rho_0}{\mathfrak{J}} \circ q^{-1}(r,t) \qquad [16]$$

where recall the Jacobian $\mathfrak{J} = \det(q^i{}_{,j})$. Besides the density, for the ideal fluid, one attaches an entropy per unit mass, $s = s_0(a)$, to a fluid element, and this quantity remains fixed in time. In the Eulerian description this gives rise to the entropy field

$$s(r,t) = s_0(a)|_{a=q^{-1}(r,t)} = s_0 \circ q^{-1}(r,t) \qquad [17]$$

One could attach other scalar, vector, etc., quantities to the fluid element, but we will not pursue this. In the usual ideal fluid closure only the above variables are considered.

Equations [15]–[17] express the Euler–Lagrange map. There is a natural representation of this map in terms of the Eulerian density variables, $M := \rho v, \rho$, and $\sigma := \rho s$, the momentum, mass, and entropy densities, respectively, which, as will be seen, are variables in which the noncanonical Poisson bracket has Lie–Poisson from.

### Other Variables

Fluid mechanics is rife with variables that have been used for its description. For example, Euler, Monge, Clebsch, and others introduced potential representations, of varying generality, for the Eulerian velocity field, an example being

$$v(r,t) = \alpha \nabla \beta + \nabla \phi \qquad [18]$$

where the three components of $v$ are replaced by the functions $\alpha, \beta$, and $\phi$, all of which depend on $(r,t)$.

Often reduced variables that are tailored to specific ideal flows with less generality than those described by $\rho, s$, and $v$ are considered. Examples include incompressible flow with $\nabla \cdot v = 0$, vortex dynamics, including contour dynamics and point vortex dynamics, flow governed by the shallow-water equations, quasigeostrophy, etc. The Hamiltonian structure in terms of these reduced variables derives from that of the parent model in terms of Lagrangian variables. Specific variables may embody constraints, and understanding these constraints, although tractable, can be a cause of confusion. Pursuing this further is beyond the scope here.

## Hamilton's Principle for Fluid

Lagrange, in his famous work of 1788, Mécanique Analytique, produced in essence a variational principle for incompressible fluid flow in terms of Lagrangian variables. The generalization to compressible flow awaited the discovery of thermodynamics, and that is what we describe here. In traditional mechanics nomenclature, this variational principle is an infinite-dimensional generalization of what is known variously as the action principle, the principle of least action, or Hamilton's principle, whereby one constructs, on physical grounds, a Lagrangian function on $T\mathcal{Q}$ used in the action principle, where $\mathcal{Q}$ is the function space of the $q(a,t)$.

Construction of the Lagrangian requires identification of the potential energy, and this requires thermodynamics, because potential energy is stored in terms of pressure and temperature. A basic assumption of the fluid approximation is that of local thermodynamic equilibrium. In the energy representation of thermodynamics, the extensive energy is treated as a function of the entropy and the volume. For a fluid, it is convenient to consider the energy per unit mass, denoted by $U$, to be a function of the entropy per unit mass, $s$, and the mass density, $\rho$, a measure of the volume. The intensive quantities, pressure and temperature, are given by $T = \partial U/\partial s$ and $p = \rho^2 \partial U/\partial \rho$. Choices for $U$ produce equations of state. For barotropic or isentropic flow, $U$ depends only on $\rho$. For an ideal monatomic gas $U(\rho,s) = c\rho^{\gamma-1}\exp(\alpha s)$, where $c, \gamma$, and $\alpha$ are constants. The function $U$ could also depend on additional scalar quantities, such as a quantity known as spice that has been considered in oceanography.

Conventional thermodynamic variables can be viewed as Eulerian variables with a static velocity field. Thus, we write $U(\rho,s)$, where $\rho$ and $s$ are spatially independent or, if the system has only locally relaxed, these variables can be functions of $r$. For the ideal fluid, each fluid element can be viewed as a self-contained isentropic thermodynamic system that moves with the fluid. Thus, the total fluid potential energy functional is given by $V[q] = \int_\Omega d^3a \rho_0 U (s_0, \rho_0/\mathfrak{J})$, which is a functional of $q$ that depends only upon $\mathfrak{J}$ and hence only upon $\partial q/\partial a$.

The next item required for constructing Hamilton's principle is the kinetic energy functional, which is given by $T[q,\dot{q}] = \int_\Omega d^3a \rho_0 \dot{q}^2/2$, where $\dot{q}^2 := \eta_{ij}\dot{q}^i\dot{q}^j$, with the Cartesian metric $\eta_{ij} := \delta_{ij}$. This metric and its inverse can be used to raise and lower indices.

The Lagrangian functional is $L[q,\dot{q}] := T - V$, where $L[q,\dot{q}] = \int_\Omega d^3a \mathcal{L}(q,\dot{q},\partial q/\partial a)$ and $\mathcal{L}$ is the

Lagrangian density, in terms of which the action functional of Hamilton's principle is given by

$$S[q] = \int_{t_0}^{t_1} \mathrm{d}t L[q, \dot{q}] = \int_{t_0}^{t_1} \mathrm{d}t \int_{\Omega} \mathrm{d}^3 a \left[ \frac{1}{2} \rho_0 \dot{q}^2 - \rho_0 U \right] \qquad [19]$$

The end conditions for Hamilton's principle for the fluid are the same as those of mechanics, that is, $\delta q(a, t_0) = \delta q(a, t_1) = 0$. The nonpenetration condition, $\delta q \cdot \hat{n} = 0$ on $\partial\Omega$, where $\hat{n}$ is a unit normal vector is also assumed. Other boundary conditions, such as periodic and free boundary conditions, are also possibilities. Hamilton's principle amounts to $\delta S/\delta q(a, t) = 0$, which, with the end and boundary conditions, implies the following equations of motion:

$$\rho_0 \ddot{q}_i + A_i^j \frac{\partial}{\partial a^j} \left( \frac{\rho_0^2}{\mathfrak{J}^2} \frac{\partial U}{\partial \rho} \right) = 0 \qquad [20]$$

Here we have used $\partial A_i^j / \partial a^j = 0$, which can be seen using [14]. Equation [20] amounts to Newton's second law for the ideal fluid, which is made clearer by using the following useful identity:

$$\frac{\partial}{\partial q^k} = \frac{1}{\mathfrak{J}} A_k^i \frac{\partial}{\partial a^i} \qquad [21]$$

Alternatively, upon using [13], [20] is sometimes written in the form

$$\rho_0 \ddot{q}_j \frac{\partial q^j}{\partial a^i} + \mathfrak{J} \frac{\partial}{\partial a^i} \left( \frac{\rho_0^2}{\mathfrak{J}^2} \frac{\partial U}{\partial \rho} \right) = 0 \qquad [22]$$

The Eulerian variable force law follows from [20] upon using [21]:

$$\rho \left( \frac{\partial v}{\partial t} + v \cdot \nabla v \right) = -\nabla p \qquad [23]$$

where $v = v(r, t)$. The remaining Eulerian equations of mass conservation and entropy advection follow from the constraints that $s_0$ and $\rho_0$ are constant on fluid elements. Time differentiation and the transformations of [16] and [17] yield

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho v) = 0 \qquad [24]$$

$$\frac{\partial s}{\partial t} + v \cdot \nabla s = 0 \qquad [25]$$

Equations [23]–[25] together with a given function $U(\rho, s)$ and the relation $p = \rho^2 \partial U/\partial \rho$ constitute the Eulerian description.

Variational principles similar to that described above exist for essentially all ideal fluid models, including incompressible flow, magnetohydrodynamics, the two-fluid equations of plasma physics, etc.

## Eulerian Action Principles

Some early researchers sought variational principles that directly produce the ideal fluid equations in Eulerian form. Because the Eulerian form of the equations does not treat the fluid as a collection of particles, the resulting action principles possess a certain awkwardness. Below, we describe three approaches to such action principles.

**Clebsch action** The action principle for electromagnetism proceeds by introducing the 4-vector potential. In a similar way, the Clebsch action principle anticipates this idea by using a potential representation of the velocity field, an example being that of [18].

Although compressible flow with an arbitrary equation of state can be treated in full generality, for simplicity and variety we will restrict to incompressible flow and set $\nabla \cdot v \equiv 0$. This constraint is enforced by requiring $\phi$ to be dependent on $\alpha$ and $\beta$ according to $\phi[\alpha, \beta] := -\Delta^{-1}(\alpha \nabla \beta)$, where $\Delta^{-1}$ is the inverse Laplacian. The Clebsch action is then written as follows:

$$S_{\mathrm{C}}[\alpha, \beta] := \int_{t_0}^{t_1} \mathrm{d}t \int_{\Omega} \mathrm{d}^3 r \left[ \beta \alpha_t - \frac{1}{2} v^2 \right] \qquad [26]$$

where the subscript $t$ denotes differentiation at fixed $r$, we have set $\rho \equiv 1$, and $v$ is a shorthand for the expression of [18] with $\phi = \phi[\alpha, \beta]$. The form of $S_{\mathrm{C}}$ is that of the phase-space action that produces Hamilton's equations upon independent variation of the configuration space coordinate and its conjugate momentum, which are here $\alpha$ and $\beta$, respectively. Thus, we require $\delta\alpha(r, t_0) = \delta\alpha(r, t_1) = 0$, but no condition is needed for $\delta\beta$ at $t_{0,1}$. We also require $\hat{n} \cdot v = 0$ on $\partial\Omega$. The variations $\delta S_{\mathrm{C}}/\delta\beta = 0$ and $\delta S_{\mathrm{C}}/\delta\alpha = 0$ imply

$$\alpha_t = \frac{\delta H}{\delta \beta} = -v \cdot \nabla \alpha$$
$$\beta_t = -\frac{\delta H}{\delta \alpha} = -v \cdot \nabla \beta = 0 \qquad [27]$$

an infinite-dimensional version of [1] with $H := \int_{\Omega} \mathrm{d}^3 r\, v^2/2$. Evidently, both $\alpha$ and $\beta$ are advected by the flow.

Because the vorticity, $\zeta := \nabla \times v = \nabla\alpha \times \nabla\beta$, knowledge of $\alpha$ and $\beta$ determines $\zeta$ and one can invert the curl operator to obtain $v$ in the usual way. The intersection of level sets of $\alpha$ and $\beta$ define vortex lines, and, evidently, these quantities, like the entropy for compressible dynamics, are constant on fluid elements. It is not difficult to show that the advection of $\alpha$ and $\beta$ implies the correct dynamical equation for incompressible $v$.

**Herivel–Lin action** The Herivel–Lin action incorporates [24] and [25] as constraints with Lagrange

multipliers, $\varphi$ and $\rho\beta$. (Here $\beta$ is not the Clebsch $\beta$ and the factor of $\rho$ is included for convenience.) It was discovered early on that these constraints were not enough to achieve complete generality and so a new one, known as the Lin constraint, was added. The Lin constraint corresponds to constancy of the fluid particle label. One defines an Eulerian label field by setting $q(a,t) = r$ and solving for the label $a = q^{-1}(r,t) =: a(r,t)$. Conservation of particle identity is thus given by $a_t + v \cdot \nabla a = 0$, and this constraint is associated with a Lagrange multiplier $\gamma = (\gamma_1, \gamma_2, \gamma_3)$. The Herivel–Lin action is thus given by

$$S_{\mathrm{HL}}[v,\rho,s,a;\varphi,\beta,\gamma] = \int_{t_0}^{t_1} \mathrm{d}t \int_\Omega \mathrm{d}^3 r \bigg( \frac{1}{2}\rho v^2 - \rho U(\rho,s) + \varphi[\rho_t + \nabla\cdot(\rho v)] - \rho\beta[s_t + v\cdot\nabla s] - \rho\gamma\cdot[a_t + v\cdot\nabla a] \bigg) \quad [28]$$

Variation of [28] with respect to the Lagrange multipliers just reproduces the constraints; however, variation with respect to $v$, $\rho$, $s$, and $a$ produces equations that imply [23]. Moreover, every flow can be shown to be an extremal of $S_{\mathrm{HL}}$.

**Euler–Poincaré–Hamel action** Another approach is to use directly constrained variations. The essential idea is to only consider Eulerian variable variations that are induced by underlying Lagrangian variable variations $\delta q$, the so-called dynamically accessible variations. Explicitly, a basic Eulerian variation $\eta = (\eta_1, \eta_2, \eta_3)$ is given by $\eta(r,t) = \delta q(a,t)|_{a=q^{-1}(r,t)}$. In terms of this quantity, the dynamically accessible variations of the Eulerian velocity field, density, and entropy are given, respectively, by $\delta v = \eta_t + v\cdot\nabla\eta - \eta\cdot\nabla v$, $\delta\rho = -\nabla\cdot(\rho\eta)$, and $\delta s = -\eta\cdot\nabla s$. Upon inserting them into the variation of

$$S_{\mathrm{EPH}}[\eta] = \int_{t_0}^{t_1} \mathrm{d}t \int_\Omega \mathrm{d}^3 r \left[\frac{1}{2}\rho v^2 - \rho U(\rho,s)\right] \quad [29]$$

and integrating by parts gives

$$\delta S_{\mathrm{EPH}} = \int_{t_0}^{t_1} \mathrm{d}t \int_\Omega \mathrm{d}^3 r[\ldots]\cdot\eta = 0$$

where $[\ldots]$ is equivalent to [23]. Thus, assuming $\eta$ is arbitrary, we obtain directly the equation of motion.

There is a version of this kind of constrained variational principle for all ideal fluid and plasma equations. Also, it possesses a geometric interpretation. In a more practical vein, constrained variations can be used to derive reduced models, and dynamically accessible variations can also be used for stability calculations. Exploring these ideas is outside the present scope.

## Fluid Hamiltonian Description

Having described variational principles, we turn to the associated canonical and noncanonical Hamiltonian descriptions.

### Canonical Description

Because the action of [19] is of standard form, it is convex in $\dot{q}$ and the Legendre transform follows easily: the canonical momentum density is $\pi_i(a,t) := \delta L/\delta\dot{q}^i(a) = \rho_0\dot{q}_i$ and $H[q,\pi] = \int_\Omega \mathrm{d}^3 a[\pi\cdot\dot{q} - \mathcal{L}] = \int_\Omega \mathrm{d}^3 a[\pi^2/(2\rho_0) + \rho_0 U]$. Hamilton's equations are then

$$\dot{q}^i = \frac{\delta H}{\delta \pi_i} = \{q^i, H\}, \qquad \dot{\pi}_i = -\frac{\delta H}{\delta q^i} = \{\pi_i, H\} \quad [30]$$

an infinite-dimensional version of [1], with the canonical Poisson bracket

$$\{F,G\} = \int_\Omega \left[\frac{\delta F}{\delta q}\cdot\frac{\delta G}{\delta \pi} - \frac{\delta G}{\delta q}\cdot\frac{\delta F}{\delta \pi}\right]\mathrm{d}^3 a \quad [31]$$

(Note, $\delta q^i(a)/\delta q^j(a') = \delta^i_j\delta(a-a')$, a relation analogous to $\partial q^i/\partial q^i = \delta^j_i$ for finite systems.)

### Reduction to Noncanonical Poisson Brackets

Reduction is a procedure for reducing the size of a Hamiltonian system. Given constants of motion in involution, that is, with pairwise vanishing Poisson brackets, the dimension of a Hamiltonian system can be reduced by 2 for each such constant of motion. However, when constants do not commute, the situation is more complicated and one must invoke a theory due to Lie, Poincaré, Cartan, and others. Associated with invariants are symmetries, and so a complete discussion of this theory requires examination of symmetry groups and associated geometry. For the ideal fluid, the map from the Lagrangian to the Eulerian descriptions is an example of reduction, whereby the Poisson bracket of [31] is mapped into a noncanonical Poisson bracket. En route to describing this example, a brief discussion of reduction of finite systems is considered first.

### Reduction of Finite-Dimensional Systems

Consider a canonical system with the phase space $\mathcal{M}$, a $2N$-dimensional symplectic manifold. In a coordinate patch with coordinates $z = (q,p)$ the system has the canonical description of [2]–[4]. Suppose we have a map $P: \mathcal{M} \to \mathfrak{m}^*$, where $\mathfrak{m}^*$ is some $M < 2N$-dimensional space described by coordinates $w = (w_1, w_2, \ldots, w_M)$. In coordinates, this map is represented in terms of functions $w_a = w_a(z)$,

with $a = 1, 2, \ldots, M$, which, because $M < 2N$, is always noninvertible. Suppose $f, g : \mathcal{M} \to \mathbb{R}$ obtain their $z$-dependence through the functions $w$, that is, $f(z) = \bar{f}(w(z)) = \bar{f} \circ w$. Making use of the chain rule yields

$$[f, g] = \frac{\partial \bar{f}}{\partial w_a} J_{ab} \frac{\partial \bar{g}}{\partial w_b} \qquad [32]$$

where the quantity

$$J_{ab} := \frac{\partial w_a}{\partial z^\alpha} J_c^{\alpha\beta} \frac{\partial w_b}{\partial z^\beta} \qquad [33]$$

is in general a function of $z$. However, it is possible that $J_{ab}$ may only depend on $w$. When this happens, we have a reduction of the phase space $\mathcal{M}$.

If the original dynamics of interest has the Hamiltonian vector field generated by $H(z)$, and if it is possible that $H(z)$ can be expressed solely in terms of the $w$'s, that is, $H(z) = \bar{H}(w)$, then the system has been reduced. Clearly, this is a statement of symmetry, since the function $H(z)$ in reality depends on a fewer number of variables, the $w$'s.

A beautiful form of reduction occurs when the map $P$ has a special form $w_a = L_a^i(q) p_i$, where the quantity $L$ is associated with a symmetry group. An identity for what is required of $L_a^i$ in order for the transformed bracket to be expressible in terms of the $w$'s can be worked out, but this is explained in terms of Lie groups. If the space $\mathfrak{m}$ is a Lie algebra $\mathfrak{g}$, then the functions $\bar{f}, \bar{g}$ are real-valued functions on $\mathfrak{g}^*$ that can be extended by left or right translation to functions $\bar{f}, \bar{g}$ on $T^*\mathfrak{G}$. Thus, $f$ restricted to $T^*\mathfrak{G}$ at the identity, $T_e^*\mathfrak{G} = \mathfrak{g}^*$, is $\bar{f}$. Because $T^*\mathfrak{G}$ is a cotangent bundle, it carries the canonical Poisson bracket and we get a natural map $P$, called a momentum map, into the dual of a Lie algebra. This geometrical description of obtaining brackets on $\mathfrak{g}^*$ from brackets on $T^*\mathfrak{G}$ is a case of Marsden–Weinstein reduction. In the early 1980s, these authors and others developed the geometrical interpretation of the noncanonical Poisson brackets for the ideal fluid.

### Ideal Fluid Noncanonical Poisson Brackets

The Euler–Lagrange map of the fluid is of the form of the map $P$ above. It maps the canonical bracket of [31] into a noncanonical Poisson bracket. If we use the Eulerian variables $M := \rho v, \rho$, and $\sigma := \rho s$, then the resulting noncanonical bracket is of Lie–Poisson form. To effect this map, one must vary [15]–[17] to relate functional derivatives with respect to $q$ and $\pi$ to those with respect to $M, \rho$, and $\sigma$. This amounts to working out the chain rule for functionals. Upon doing this, one obtains the following noncanonical bracket:

$$\begin{aligned}\{F, G\} = -\int_\Omega \Bigg[ & M_i \left( \frac{\delta F}{\delta M_j} \frac{\partial}{\partial x^j} \frac{\delta G}{\delta M_i} - \frac{\delta G}{\delta M_j} \frac{\partial}{\partial x^j} \frac{\delta F}{\delta M_i} \right) \\ & + \rho \left( \frac{\delta F}{\delta M} \cdot \nabla \frac{\delta G}{\delta \rho} - \frac{\delta G}{\delta M} \cdot \nabla \frac{\delta F}{\delta \rho} \right) \\ & + \sigma \left( \frac{\delta F}{\delta M} \cdot \nabla \frac{\delta G}{\delta \sigma} - \frac{\delta G}{\delta M} \cdot \nabla \frac{\delta F}{\delta \sigma} \right) \Bigg] \mathrm{d}^3 r \end{aligned} \qquad [34]$$

This bracket, together with the Hamiltonian $\bar{H}[M, \rho, \sigma] = \int_\Omega \mathrm{d}^3 r [M^2/(2\rho) + \rho U(\rho, \sigma/\rho)]$ generates the ideal fluid equations. This Hamiltonian follows from $\bar{H}[M, \rho, \sigma] := H[q, \pi]$ with $H[q, \pi] = \int_\Omega \mathrm{d}^3 a\, [\pi^2/(2\rho_0) + \rho_0 U]$. The bracket of [34] is clearly seen to be linear in the variables $M, \rho$, and $\sigma$, and the form of the cosymplectic operator and structure operators $C_{ij}^k$ can be obtained by integration by parts. The Lie group in this case can be seen to be an extension by semidirect product of the diffeomorphism group.

An alternative form of the noncanonical Poisson bracket is given in terms of the variables $v, \rho$, and $s$. Upon changing to these coordinates, the noncanonical Poisson bracket transforms into

$$\begin{aligned}\{F, G\} = -\int_\Omega \Bigg[ & \left( \frac{\delta F}{\delta \rho} \nabla \cdot \frac{\delta G}{\delta v} - \frac{\delta G}{\delta \rho} \nabla \cdot \frac{\delta F}{\delta v} \right) \\ & + \left( \frac{\nabla \times v}{\rho} \cdot \frac{\delta G}{\delta v} \times \frac{\delta F}{\delta v} \right) \\ & + \frac{\nabla s}{\rho} \cdot \left( \frac{\delta F}{\delta s} \frac{\delta G}{\delta v} - \frac{\delta G}{\delta s} \frac{\delta F}{\delta v} \right) \Bigg] \mathrm{d}^3 r \end{aligned} \qquad [35]$$

which, with the Hamiltonian $H[v, \rho, s] = \int_\Omega \mathrm{d}^3 r\, [\rho v^2/2 + \rho U(\rho, s)]$, produces the Eulerian fluid equations of [23]–[25] directly as $v_t = \{v, H\}, \rho_t = \{\rho, H\}$, and $s_t = \{s, H\}$, respectively. Observe that in these variables, the bracket is no longer of Lie–Poisson form.

## Conclusion

In a general sense, Hamiltonian dynamics is about coordinate changes, and it is clear from the above that there is no shortage of coordinates for describing the ideal fluid. The most intuitive form of fluid equations (at present) is the Eulerian form, and this possesses a noncanonical Hamiltonian description. Other noncanonical variables are also used for both less and more general fluid systems than those described above. Vortex dynamics, shallow-water theory, and other equations of geophysical fluid dynamics are possibilities, as well as equations from plasma physics and other disciplines. The general story for these systems is much the same as above, although in some descriptions constraints are involved and they can complicate matters.

There are various motivations for pursuing an understanding of the Hamiltonian structure of fluids, but ultimately these motivations are the same as those for investigating the Hamiltonian dynamics of particle and other finite degree-of-freedom systems. Hamiltonian theory serves as an organizing framework, one that can be used for the derivation and approximation of systems. If one understands something about a particular Hamiltonian system, then often it can be said to be true of a general class of Hamiltonian systems. By now, many applications have been worked out, some of which can be accessed from the literature cited below.

# Hamiltonian Group Actions

**L C Jeffrey**, University of Toronto, Toronto, ON, Canada

## Introduction

The idea of a Hamiltonian flow on a symplectic manifold has its roots in Hamilton's equations, which govern the trajectory of a particle in phase space (the space parametrizing coordinates and momenta of a classical particle). A fundamental idea in theoretical physics (Noether's theorem) is that to every symmetry in a physical system (such as a group action), there is an associated conserved quantity: invariance under translation corresponds to conservation of linear momentum, invariance under rotation corresponds to conservation of angular momentum and so on, and these momenta are functions on the phase space. The mathematical formulation of this idea is the idea of the moment map associated to a group action on a symplectic manifold; the group action is obtained from the Hamiltonian flow of the moment map.

This article will describe some basic features of moment maps associated to Hamiltonian group actions, and some recent results about the geometry and topology of symplectic manifolds which have such group actions. We first define Hamiltonian group actions and list some of their properties. Next we give the definition of the symplectic quotient, which is a means of dividing out the symmetry to form a new symplectic manifold. We also explain some properties of the quotient construction. The convexity theorem and the moment polytope are outlined and toric manifolds (a particular type of symplectic manifold with a Hamiltonian torus action of maximal dimension) are defined. Finally, we list some properties of cohomology rings of symplectic quotients.

Two standard references on this material are the books of Cannas da Silva (2001) and McDuff and Salamon (1995). An authoritative and comprehensive reference is the monograph by Guillemin, Ginzburg and Karshon (2002).

## Hamiltonian Group Actions

Let $(M, \omega)$ be a symplectic manifold. The Hamiltonian vector field $\xi_H$ generated by a function $H$ is defined by

$$\omega_m(\xi_H, Y) = \mathrm{d}H_m(Y)$$

for any $Y \in T_mM$. If $X \in \boldsymbol{g} \mapsto X^\#$ are the vector fields on $M$ generated by the symplectic action of a compact Lie group $G$ with Lie algebra $\boldsymbol{g}$, then the moment map $\mu : M \to \boldsymbol{g}^*$ is defined by two properties:

1. $d\mu_m(Y)(X) = \omega_m(X^\#, Y)$ for any $Y \in T_mM$: in other words the function $\mu_X : M \to \mathbb{R}$ defined by
$$\mu_X(m) \stackrel{\text{def}}{=} \mu(m)(X)$$
is the Hamiltonian function generating the vector field $X^\#$.
2. $\mu : M \to \boldsymbol{g}^*$ is equivariant (where $G$ acts on $\boldsymbol{g}^*$ by the coadjoint action).

**Remark 1** In this article, we shall only consider actions of compact connected Lie groups, although the definition of Hamiltonian group action may be extended to noncompact groups. In particular, unless otherwise specified the term "torus" refers to the compact torus $T \cong \mathrm{U}(1)^n$.

**Remark 2** (Existence and uniqueness of moment maps). One sees that $\mathcal{L}_{X^\#}\omega = d(\iota_{X^\#}\omega)$, so that $\iota_{X^\#}\omega$ is closed. The moment map $\mu_X$ exists if and only if $\iota_{X^\#}\omega$ is also "exact." The moment map need not always exist: for example, if $S^1$ acts on $T^2$ by
$$e^{iX} : (e^{i\theta_1}, e^{i\theta_2}) \mapsto (e^{i(\theta_1+X)}, e^{i\theta_2})$$
we see that for the standard symplectic form $\omega = d\theta_1 \wedge d\theta_2$ we have $\iota_{X^\#}\omega = d\theta_2$. Since $\theta_2$ is only defined mod $2\pi$ we see that the moment map does not exist as a map into $\mathbb{R}$. Conditions guaranteeing the existence of a moment map (other than $M$ being simply connected) include the hypothesis that $G$ is semisimple (Guillemin and Sternberg (1990, theorem 26.1)); conditions on the existence and uniqueness of the moment map can be formulated in terms of Lie algebra cohomology (see Guillemin and Sternberg (1990)). The obstruction to the existence of the moment map for a symplectic action of $G$ is an element of $H^1(\boldsymbol{g})$; the obstruction to uniqueness of the moment map is an element of $H^2(\boldsymbol{g})$, where $\boldsymbol{g}$ is the Lie algebra of $G$. See Guillemin and Sternberg (1990, proposition 24.1).

## Basic Properties of Moment Maps

**Proposition 1** (Guillemin–Sternberg (1982, 1984))
$$\mathrm{Im}(d\mu_m)^\perp = \mathrm{Lie}(\mathrm{Stab}(m))$$
*where $\perp$ denotes the annihilator under the canonical pairing $\boldsymbol{g}^* \otimes \boldsymbol{g} \to \mathbb{R}$.*

**Proof** We have
$$\omega(Y_m^\#, Z) = d\mu_Y(Z) = \langle Y, d\mu_m(Z)\rangle$$
for all $Z \in T_mM$. Thus, $Y$ annihilates all $\xi \in \mathrm{Im}(d\mu_m)$ if and only if $Y \in \mathrm{Lie}(\mathrm{Stab}(m))$.

**Corollary 1** *Zero is a regular value of $\mu$ if and only if $\mathrm{Stab}(m)$ is finite for all $m \in \mu^{-1}(0)$. In this situation, $\mu^{-1}(0)$ is a manifold and the stabilizer of the action at any point in $\mu^{-1}(0)$ is finite.*

**Example 1** Let $T$ be a torus acting on $M$ and let $F \subset M^T$ be a component of the fixed-point set. Then for any $f \in F$, we have $d\mu_f = 0$, so $\mu(F)$ is a point.

**Proposition 2**

(i) *If $H \subset G$ are two groups acting in a Hamiltonian fashion on a symplectic manifold M, then $\mu_H = \pi \circ \mu_G$ where $\pi : \boldsymbol{g}^* \to \boldsymbol{h}^*$ is the projection map. In other words, if $X \in \boldsymbol{h}$, then $\mu_H(m)(X) = \mu_G(m)(X)$ for any $m \in M$. One example that frequently arises is the case when H = T is a maximal torus of a compact Lie group G.*

(ii) *More generally if $f : H \to G$ is a Lie group homomorphism, and the two groups G and H act in a Hamiltonian fashion on a symplectic manifold M, in such a way that the action is compatible with the homomorphism f, then $\mu_H = f^* \circ \mu_G$ where $f^* : \boldsymbol{g} \to \boldsymbol{h}^*$ is induced from the homomorphism f. (The case* (i) *is the special case where f is the inclusion map.)*

(iii) *If two symplectic manifolds $M_1$ and $M_2$ are acted on in a Hamiltonian fashion by a group G with moment maps $\mu_1$ and $\mu_2$, then the moment map for the diagonal action of G on $M_1 \times M_2$ with the product symplectic structure is $\mu_1 + \mu_2$.*

**Example 2** The standard symplectic form on $S^2$ is $\omega = -d\cos\theta \wedge d\phi = -dz \wedge d\phi$ (where $\theta$ is the polar angle, $\phi$ is the azimuthal angle, and $z$ is the height function). The associated moment map for the action of U(1) on $S^2$ by rotation about the $z$ axis is $\mu(z, \phi) = z$.

**Example 3** If $\mathbb{R}^2 = \mathbb{C}$ has the symplectic structure $\omega = dx \wedge dy$, the moment map for the standard action of U(1) on $\mathbb{R}^2$ with multiplicity $m \in \mathbb{Z}$, in other words the action
$$u \in U(1) : z \in \mathbb{C} \mapsto u^m z$$
is $\mu(x, y) = -m(x^2 + y^2)/2$.

**Example 4** Suppose a torus $T$ acts on $\mathbb{C}$ preserving the standard symplectic structure, and suppose the action factors through a homomorphism $\mathcal{B} : T \to \mathrm{U}(1)$ which can be written as
$$\mathcal{B}(\exp_T X) = \exp_{\mathrm{U}(1)}(\beta(X))$$

in terms of a linear map $\beta \in \boldsymbol{t}^*$ that maps the integer lattice of $\boldsymbol{t}$ into $\mathbb{Z}$ (in other words, a weight) and the exponential maps

$$\exp_T : \boldsymbol{t} \to T$$

and

$$\exp_{\mathrm{U}(1)} : \mathbb{R} \to U(1)$$

(the latter being normalized as $\exp_{\mathrm{U}(1)}(t) = \mathrm{e}^{2\pi \mathrm{i} t}$). Then, by Proposition 2(ii) and Example 3 we see that the moment map for the action of $T$ on $\mathbb{C}$ is

$$\mu(z) = -\tfrac{1}{2}\beta |z|^2$$

It follows that if $T$ acts on $\mathbb{C}^n$ via a collection of weights $\beta_1, \ldots, \beta_n \in \boldsymbol{t}^*$, then the moment map is

$$\mu(z_1, \ldots, z_n) = -\frac{1}{2}\sum_{j=1}^{n} |z_j|^2 \beta_j$$

and the image of the moment map is the cone in $\boldsymbol{t}^*$ spanned by $\{\beta_1, \ldots, \beta_n\}$.

## The Symplectic Quotient

Since the moment map $\mu$ is equivariant, we may form the symplectic quotient (or Marsden–Weinstein reduction)

$$M_{\mathrm{red}} = M_0 = \mu^{-1}(0)/G$$

The symplectic structure on $M$ descends to give a symplectic structure on $M_0$. Corollary 1 implies that if 0 is a regular value of $\mu$, then $M_0$ is an orbifold.

**Remark 3** Another way to formulate Corollary 1 is that if $G$ acts freely, 0 is a regular value of $\mu$ so $\mu^{-1}(0)$ is a manifold with a free $G$ action, and hence $\mu^{-1}(0)/G$ is also a manifold. If the $G$ action is only locally free, then $\mu^{-1}(0)$ is still a manifold, but the quotient $\mu^{-1}(0)/G$ is only an orbifold.

**Remark 4** The definition of orbifold is due to Satake (1957); an alternate formulation is given in the paper by Henriques and Metzler (2004) and references cited there.

If $T$ is a torus, then the equivariance condition on the moment map reduces to invariance, so we may form the reduced space $M_t = \mu^{-1}(t)/T$ for any regular value $t \in \boldsymbol{t}^*$ of the moment map $\mu$; the space $M_t$ is a symplectic orbifold for any regular value $t$ of $\mu$.

**Example 5** Let U(1) act diagonally on $\mathbb{C}^n$ equipped with the standard symplectic structure

$$\omega = \frac{\mathrm{i}}{2}\sum_{j=1}^{n} \mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j = \sum_{j=1}^{n} \mathrm{d}x_j \wedge \mathrm{d}y_j \qquad [1]$$

where $z_j = x_j + \mathrm{i}y_j$. The moment map for this action is

$$\mu(z_1, \ldots, z_n) = -\frac{1}{2}\sum_{j=1}^{n} |z_j|^2$$

so the symplectic quotient $\mu^{-1}(-1/2)/\mathrm{U}(1)$ is complex projective space

$$S^{2n-1}/\mathrm{U}(1) \cong \mathbb{C}P^{n-1}$$

More generally we may consider the reduced space $M_\lambda = \mu^{-1}(\mathcal{O}_\lambda)/G$ when $\mathcal{O}_\lambda$ is the orbit in $\boldsymbol{g}^*$ through $\lambda \in \boldsymbol{g}^*$ (coadjoint orbit). All such orbits may be parametrized by $\lambda \in \boldsymbol{t}^*_+$, where $\boldsymbol{t}^*_+$ is a chosen positive Weyl chamber in $\boldsymbol{t}^*$.

**Example 6** Let U($n$) act on $\mathbb{C}^n$ in the standard way, where $\mathbb{C}^n$ is equipped with the standard symplectic structure [1]. The moment map for this action is

$$\mu(z_1, \ldots, z_n)_{jk} = \frac{\mathrm{i}}{2} z_j \bar{z}_k \qquad [2]$$

which is the $(j, k)$ element of a matrix in the Lie algebra of U($n$). The standard symplectic form on $\mathbb{C}^n$ descends under reduction to the standard symplectic form on $\mathbb{C}P^{n-1}$ (which corresponds to the Fubini–Study metric).

**Example 7** (Coadjoint orbits). Let $\lambda \in \boldsymbol{g}^*$. We define a symplectic structure $\omega_\lambda$ on the coadjoint orbit $\mathcal{O}_\lambda$ (in terms of the vector fields $X^\#, Y^\#$ generated by the action of $X, Y \in \boldsymbol{g}$) by $\omega_\lambda(X^\#_\lambda, Y^\#_\lambda) = -\lambda([X, Y])$ at the point $\lambda \in \mathcal{O}_\lambda$ (and everywhere else on the orbit by equivariance). The moment map for the action of $G$ on $\mathcal{O}_\lambda$ with respect to this symplectic structure is the inclusion of $\mathcal{O}_\lambda$ in $\boldsymbol{g}^*$. (The symplectic structure on the orbit was found by Kirillov and Kostant; see, for instance, Berline *et al.* (1992, section 7.5).

**Example 8** (The shifting trick). Define a symplectic structure $\Omega$ on $M \times \mathcal{O}_\lambda$ by

$$\Omega = \omega^M - \omega_\lambda$$

Then for the moment map with respect to the induced action of $G$ on $M \times \mathcal{O}_\lambda$ we have

$$M_\lambda \cong (M \times \mathcal{O}_\lambda)_0$$

**Corollary 2** *Combining Example 6 with Proposition 2*(ii) *we see that for any linear action of a group G on* $\mathbb{C}P^{n-1}$ (*i.e., an action factoring through a representation* $G \to \mathrm{U}(n)$*, or in other words an action descending from a linear action on* $\mathbb{C}^n$) *the moment map factors as*

$$\mu = \pi \circ \hat{\mu}$$

*where* $\hat{\mu} : \mathbb{C}P^{n-1} \to \boldsymbol{u}(n)^*$ *is given in* [3] *below, and* $\pi : \boldsymbol{u}(\boldsymbol{n})^* \to \boldsymbol{g}^*$ *is the projection map.*

In particular, one often requires for a projective manifold $M$ (i.e., a compact complex manifold with an embedding into $\mathbb{C}P^{n-1}$) that the action of $G$ extends to a linear action on $\mathbb{C}P^{n-1}$. Thus, moment maps for such linear actions are given by [3] composed with $\pi$ and with the embedding of $M$ into $\mathbb{C}P^{n-1}$ (*see* also Cotangent Bundle Reduction, Poisson Reduction, Symmetry and Symplectic Reduction).

## Reduction in Stages

Suppose a compact Lie group $G$ acts in a Hamiltonian fashion on a symplectic manifold $M$, and $H$ is a normal subgroup of $G$. (For example, this hypothesis is satisfied if both $H$ and $G$ are tori.) Suppose also that 0 is a regular value for $\mu_H$ and $\mu_G$. Then the symplectic quotient $\mu_H^{-1}(0)/H$ is acted on naturally by the quotient group $G/H$, and this action is Hamiltonian; furthermore, the symplectic quotient of $\mu_H^{-1}(0)/H$ by $G/H$ is naturally isomorphic to $\mu_G^{-1}(0)/G$. (This result is known as "reduction in stages.")

Let $M$ be a symplectic manifold equipped with the Hamiltonian action of a torus $T$. Let $H \subset T$ be a Lie subgroup of $T$ (so $H$ is a torus whose dimension is smaller than the dimension of $T$). Let $\mu_T : M \to \mathrm{Lie}(T)^*$ and $\mu_H : M \to \mathrm{Lie}(H)^*$ be the moment maps: recall that $\mu_H = \pi_H \circ \mu_T$, where $\pi_H : \mathrm{Lie}(T)^* \to \mathrm{Lie}(H)^*$ is the standard projection.

For any $\eta \in \mathrm{Lie}(H)^*$ we may form the reduced space $M_\eta = \phi_H^{-1}(\eta)/H$. This is equipped with a Hamiltonian action of $T/H$.

**Example 9** Let $\mathrm{U}(n)$ act on $\mathbb{C}^n$ in the standard way. This action descends to an action on $\mathbb{C}P^{n-1}$, which is the symplectic quotient of $\mathbb{C}^n$ under the action of the diagonal $\mathrm{U}(1)$ subgroup of $\mathrm{U}(n)$. Hence, the moment map $\hat{\mu}$ for the action of $\mathrm{U}(n)$ on $\mathbb{C}P^{n-1}$ is given by the formula

$$\hat{\mu}([z_1, \ldots, z_n])_{jk} = \frac{\mathrm{i}}{2} \frac{z_j \bar{z}_k}{\sum_{\ell=1}^n |z_\ell|^2} \qquad [3]$$

which comes from the moment map [2] for the action of $\mathrm{U}(n)$ on $\mathbb{C}^n$.

## The Normal Form Theorem

There is a neighborhood of $\mu^{-1}(0)$ on which the symplectic form is given in a standard way related to the symplectic form $\omega_0$ on $M_{\mathrm{red}}$ (see, e.g., Guillemin and Sternberg (1990, sections 39–41)).

**Proposition 3** (Normal form theorem). *Assume 0 is a regular value of* $\mu$ (*so that* $\mu^{-1}(0)$ *is a smooth manifold and G acts on* $\mu^{-1}(0)$ *with finite stabilizers*). *Then there is a neighborhood* $U \cong \mu^{-1}(0) \times \{z \in \boldsymbol{g}^*, |z| \le h\} \subseteq \mu^{-1}(0) \times \boldsymbol{g}^*$ *of* $\mu^{-1}(0)$ *on which the symplectic form is given as follows. Let* $P \stackrel{\mathrm{def}}{=} \mu^{-1}(0) \stackrel{q}{\to} M_{\mathrm{red}}$ *be the orbifold principal G-bundle given by the projection map* $q : \mu^{-1}(0) \to \mu^{-1}(0)/G$, *and let* $\theta \in \Omega^1(P) \otimes \boldsymbol{g}$ *be a connection for it. Let* $\omega_0$ *denote the induced symplectic form on* $M_{\mathrm{red}}$, *in other words* $q^*\omega_0 = i_0^*\omega$. *Then if we define a 1-form* $\tau$ *on* $U \subset P \times \boldsymbol{g}^*$ *by* $\tau_{p,z} = z(\theta)$ (*for* $p \in P$ *and* $z \in \boldsymbol{g}^*$), *the symplectic form on U is given by*

$$\omega = q^*\omega_0 + \mathrm{d}\tau \qquad [4]$$

*Further, the moment map on U is given by* $\mu(p, z) = z$.

**Corollary 3** *Let t be a regular value for the moment map for the Hamiltonian action of a torus T on a symplectic manifold M. Then in a neighborhood of t, all symplectic quotients* $M_t$ *are diffeomorphic to* $M_{t_0}$ *by a diffeomorphism under which* $\omega_t = \omega_{t_0} + (t - t_0, \mathrm{d}\theta)$ *where* $\theta \in \Omega^1(\mu^{-1}(t_0)) \otimes \boldsymbol{t}$ *is a connection for the action of T on* $\mu^{-1}(t_0)$.

**Corollary 4** *Suppose G acts in a Hamiltonian fashion on a symplectic manifold M, and suppose 0 is a regular value for the moment map* $\mu$. *Then the reduced space* $M_\lambda = \mu^{-1}(\mathcal{O}_\lambda)/G$ *at the orbit* $\mathcal{O}_\lambda$ *fibers over* $M_0 = \mu^{-1}(0)/G$ *with fiber the orbit* $\mathcal{O}_\lambda$; *furthermore, if* $\pi : M_\lambda \to M_0$ *is the projection map, then the symplectic form* $\omega_\lambda$ *on* $\mu^{-1}(\mathcal{O}_\lambda)/G$ *is given as* $\omega_\lambda = \pi^*\omega_0 + \Omega_\lambda$, *where* $\omega_0$ *is the symplectic form on* $M_0$ *and* $\Omega_\lambda$ *restricts to the standard Kirillov–Kostant symplectic form on the fiber.*

## Convexity Theorems

**Theorem 1** (Atiyah (1982); Guillemin–Sternberg (1982 and 1984)). *Suppose M is a connected compact symplectic manifold equipped with a Hamiltonian action of a torus T. Then the image* $\mu(M)$ *is a convex polytope, the convex hull of* $\{\mu(F)\}$, *where F are the components of the fixed-point set of T in M.*

**Example 10** Consider the orbits $\mathcal{O}_t$ of $\mathrm{SU}(2)$ in $\mathbf{su}(2) \cong \mathbb{R}^3$ through $t \in \mathbb{R}^+$. The image of the moment map for the action of the maximal torus $T \cong \mathrm{U}(1)$ is the interval $[-t, t]$.

**Example 11** When $\mathcal{O}_t$ is the coadjoint orbit (through $t \in \boldsymbol{t}^*$) for a compact Lie group $G$ with maximal torus $T$, the image $\mu_T(\mathcal{O}_t)$ of the moment map $\mu_T$ for the action of the maximal torus $T$ is the convex hull $\text{Conv}\{wt : w \in W\}$, where $W$ is the Weyl group.

The convexity theorem above can be generalized to actions of nonabelian groups. If $M$ is a connected compact symplectic manifold equipped with a Hamiltonian action of a compact Lie group $G$ with maximal torus $T$ and positive Weyl chamber $\boldsymbol{t}_+$, then the intersection of the image $\mu(M)$ of the moment map with the positive Weyl chamber $\boldsymbol{t}_+$ (in other words, a fundamental domain for the action of the Weyl group on $\boldsymbol{t}$) is a convex polytope. This result is due to Kirwan (1984b) and for Kähler manifolds to Guillemin and Sternberg (1982 and 1984).

The proofs of Atiyah and Guillemin–Sternberg are based on Morse theory applied to the moment map. A key ingredient in the proofs is to establish that the fibers of the moment map are connected.

### The Moment Polytope

Given a compact symplectic manifold $M$ equipped with the Hamiltonian action of a torus $T$, we see that there is an associated polytope $P$, the "moment polytope." The fibers of the moment map $\mu$ are preserved by the action of $T$, so the value of $\mu$ parametrizes a family $\{M_t\}$ of symplectic quotients. By Theorem 1 the moment polytope is the convex hull of the images of the fixed-point set under the moment map.

By Proposition 1, we see that the moment polytope is decomposed according to the stabilizers of points in the preimage, and the critical values of the moment map are the images $\mu_T(W_j)$ of the fixed-point sets $W_j$ of one-parameter subgroups $S_j$ of $T$. These critical values form hyperplanes ("walls") which subdivide the moment polytope: the complement of the walls is a collection of open regions consisting of regular values of the moment map.

**Example 12** The group SU(3) has maximal torus $T \cong \text{U}(1)^2$. We identify $\boldsymbol{g}^*$ with $\boldsymbol{g}$ via the bi-invariant inner product (i.e., the Killing form) on $\boldsymbol{g}$, and thus identify $\boldsymbol{t}^*$ with $\boldsymbol{t}$. For $\lambda \in \boldsymbol{t}$, the Weyl group images of $\lambda$ are the six vertices of a hexagon: the "walls" in the moment polytope for the action of $T$ on the coadjoint orbit $\mathcal{O}_\lambda$ arising from the action of $G$ on $\boldsymbol{g}^*$ through $\lambda \in \boldsymbol{t}^*$ are the edges of the hexagon (exterior walls) and the three lines connecting opposite vertices (interior walls).

## Toric Manifolds

**Definition 1** *A toric manifold is a compact symplectic manifold $M$ of dimension $2n$ equipped with the effective Hamiltonian action of a torus $T$ of dimension $n$.*

**Example 13** Complex projective space $\mathbb{C}P^n$ with the obvious Hamiltonian action of $\text{U}(1)^n \subset \text{U}(1)^{n+1}$ is a toric manifold.

**Example 14** A special case of Example 13 is the 2-sphere $S^2 \cong \mathbb{C}P^1$ (with the action of U(1) given by rotation around one axis). The 2-sphere is a toric manifold.

### Elementary Properties of Toric Manifolds

If $M$ is a toric manifold, the fiber of the moment map for the action of $T$ is an orbit of the action. Hence, the symplectic quotient $M_t$ at any value $t \in \boldsymbol{t}^*$ is a point (if it is nonempty).

The regular values of $\mu$ are the interior points of the moment polytope $P$. All points in the preimage $\mu^{-1}(\partial P)$ are fixed points of some one-parameter subgroup of $T$. Points in the interior of a face $P_j$ of dimension $j$ are fixed by a subtorus of $T$ of dimension $n - j$. Hence, each fiber of $\mu$ over a point in $P_j$ is a quotient torus of dimension $j$. In particular, the vertices of the polytope are the images of the components of the fixed-point set of the whole torus $T$, and the inverse image of a vertex is contained in the fixed-point set of $T$.

The push-forward function $\mu_*(\omega^n/n!)$ under the moment map is just the characteristic function of the moment polytope.

### Delzant's Theorem

In fact, toric manifolds are characterized by their moment polytopes. A theorem of Delzant (1988) says that any polytope $P$ satisfying appropriate hypotheses (a simple polytope) is the moment polytope for some toric manifold; furthermore, if two toric manifolds acted on effectively by a torus $T$ have the same moment polytope, then they are $T$-equivariantly symplectomorphic. The first statement is proved by constructing a toric manifold which has the polytope $P$ as its moment polytope; if $P$ has $d$ faces of codimension 1, one constructs the toric manifold $M$ as a symplectic quotient of a vector space $V \cong \mathbb{C}^d$ by the linear action of a torus $T' \cong \text{U}(1)^{d-n}$. The torus $T \cong \text{U}(1)^n$ acting on $M$ is then obtained by reduction in stages, as the quotient of $\text{U}(1)^d$ by $T'$.

The construction of a toric manifold whose moment polytope is a given simple polytope is

given in Guillemin (1994, chapter 1). The second statement (namely that toric manifolds are classified by their moment polytopes) is proved in Delzant (1988).

**Example 15** The moment polytope for the action of $U(1)^n$ on $\mathbb{C}P^n$ is the $n$-simplex. This action descends from the action of $U(1)^{n+1}$ on $\mathbb{C}^{n+1}$, using reduction in stages: recall from Example 5 that we constructed $\mathbb{C}P^n$ as the symplectic quotient of $\mathbb{C}^{n+1}$ by the standard action of U(1).

## Cohomology Rings of Symplectic Quotients

For material on the equivariant cohomology of symplectic manifolds equipped with Hamiltonian group actions and the relation to the fixed-point set, we refer to Equivalent Cohomology and the Cartan Model. As in that reference we shall describe the equivariant cohomology of a Hamiltonian $G$-manifold using the Cartan model.

Two fundamental results of Kirwan give complementary descriptions of the equivariant cohomology of a symplectic manifold.

### Kirwan Injectivity

Kirwan's first theorem is the injectivity theorem:

**Theorem 2** (Injectivity theorem). *If $T$ is a compact torus and $M$ is a Hamiltonian $T$-space, then the direct sum of restriction maps to all components of the fixed-point set*

$$\oplus_F : H_T^*(M) \to H^*(F) \otimes S(\boldsymbol{t}^*)$$

*is injective.*

The proof appears in Kirwan (1984a); this material is treated in Equivalent Cohomology and the Cartan Model (theorem 6.6).

### Kirwan Surjectivity

Let $G$ be a complex torus, and let 0 be a regular value of the moment map $\mu$. Suppose $M$ is a compact symplectic manifold equipped with a Hamiltonian action of a compact Lie group $G$. There is a natural map $\kappa : H_G^*(M) \to H^*(M_{\text{red}})$ defined by

$$\kappa : H_G^*(M) \mapsto H_G^*(\mu^{-1}(0)) \cong H^*(M_{\text{red}})$$

(where the first map is the restriction map and the second is the identification of $H_G^*(Z)$ with $H^*(Z/G)$ when $G$ acts locally freely on $Z$ and the cohomology is taken with rational coefficients). The map $\kappa$ is obviously a ring homomorphism. Kirwan's second theorem treats the image of $\kappa$.

**Theorem 3** (Surjectivity theorem). *Under the above hypotheses, the map $\kappa$ is surjective.*

The proof of this theorem (Kirwan (1984a, 5.4 and 8.10); see also Kirwan (1992, section 6)) uses the Morse theory of the "Yang–Mills function" $|\mu|^2 : M \to \mathbb{R}$ to define an equivariant stratification of $M$ by strata $S_\beta$ which flow under the gradient flow of $|\mu|^2$ to a critical set $C_\beta$ of $|\mu|^2$. One shows that the function $|\mu|^2$ is equivariantly perfect (i.e., that the Thom–Gysin (long) exact sequence in equivariant cohomology decomposes into short exact sequences, so that one may build up the cohomology as

$$H_G^*(M) \cong H_G^*(\mu^{-1}(0)) \oplus \bigoplus_{\beta \neq 0} H_G^*(S_\beta)$$

Here, the stratification by $S_\beta$ has a partial order $>$; thus, one may define an open dense set $U_\beta = M - \cup_{\gamma > \beta} S_\gamma$ which includes the open dense stratum $S_b$ of points that flow into $\mu^{-1}(0)$ (note $S_b$ retracts onto $\mu^{-1}(b)$). The equivariant Thom–Gysin sequence is

$$\cdots \to H_G^{n-2d(\beta)}(S_\beta) \xrightarrow{i_{\beta *}} H_G^n(U_\beta) \to H_G^n(U_\beta - S_\beta) \to \cdots$$

To show that the Thom–Gysin sequence splits into short exact sequences, it suffices to know that the maps $(i_\beta)_*$ are injective. Since $i_\beta^*(i_\beta)_*$ is multiplication by the equivariant Euler class $e_\beta$ of the normal bundle to $S_\beta$, injectivity follows because this equivariant Euler class is not a zero divisor (see Kirwan (1984a, 5.4) for the proof).

Because $\kappa$ is a surjective ring homomorphism, it follows that

$$H_G^*(M_{\text{red}}) \cong H_T^*(M)/\text{Ker}(\kappa)$$

The above theorem is also valid when $G$ is the complexification of a compact semisimple Lie group. In this case, one must reduce at 0 (because of the condition that the moment map is equivariant, since $b = 0$ is the only value which is invariant under the coadjoint action). The case of reducing at coadjoint orbits can be treated using the proof for the case of reducing at 0 via the shifting trick (Example 8).

Several recent articles (Jeffrey and Kirwan (1995, 1997), Tolman and Weitsman 2003) compute Ker($\kappa$). Some articles compute Ker($\kappa$) in specific examples, notably the action of $S^1$ on products of two-dimensional spheres of general radii.

### The Residue Formula

One approach to identifying Ker($\kappa$) is the "residue formula," Jeffrey and Kirwan (1995), theorem 8.1:

**Theorem 4** (Jeffrey and Kirwan (1995), *corrected as in* Jeffrey and Kirwan (1997)).

*Let* $\eta \in H^*_G(M)$ *induce* $\eta_0 \in H^*(M_{\text{red}})$. *Then we have*

$$\int_{M_{\text{red}}} \kappa(\eta) e^{i\omega_{\text{red}}} = n_0 C^G \text{Res}\left(\mathcal{D}^2(X) \sum_{F \in \mathcal{F}} h_F^\eta(X)[dX]\right) \qquad [5]$$

*where* $n_0$ *is the order of the stabilizer in* $G$ *of a generic element of* $\mu^{-1}(0)$, *and the constant* $C^G$ *is defined by*

$$C^G = \frac{(-1)^{s+n_+}}{|W|\text{vol}(T)} \qquad [6]$$

*We have introduced* $s = \dim G$ *and* $l = \dim T$; *here* $n_+ = (s-l)/2$ *is the number of positive roots. Also,* $\mathcal{F}$ *denotes the set of components of the fixed-point set of* $T$, *and if* $F$ *is one of these components, then the meromorphic function* $h_F^\eta$ *on* $\boldsymbol{t} \otimes \mathbb{C}$ *is defined by*

$$h_F^\eta(X) = e^{i\mu(F)(X)} \int_F \frac{i_F^*\eta(X) e^{i\omega}}{e_F(X)} \qquad [7]$$

*and the polynomial* $\mathcal{D} : \boldsymbol{t} \to \mathbb{R}$ *is defined by* $\mathcal{D}(X) = \prod_{\gamma > 0} \gamma(X)$, *where* $\gamma$ *runs over the positive roots of* $G$.

The residue map Res is defined on (a subspace of) the meromorphic differential forms on $\boldsymbol{t} \otimes \mathbb{C}$: its definition depends on some choices, but the sum of the residues over all $F \in \mathcal{F}$ is independent of these choices. When $T = U(1)$, we define the residue on meromorphic functions of the form $e^{i\lambda X}/X^N$ when $\lambda \neq 0$ (for $N \in \mathbb{Z}$) by

$$\text{Res}\left(\frac{e^{i\lambda X}}{X^N}\right) = \text{Res}_{X=0} \frac{e^{i\lambda X}}{X^N}, \quad \text{if } \lambda > 0$$
$$= 0, \quad \text{if } \lambda < 0$$

More generally, the residue is specified by certain axioms (see Jeffrey and Kirwan (1995, proposition 8.11)), and may be defined as a sum of iterated multivariable residues $\text{Res}_{X_1 = \lambda_1} \ldots \text{Res}_{X_l = \lambda_l}$ for a suitably chosen basis of $\boldsymbol{t}$ yielding coordinates $X_1, \ldots, X_l$ (see Jeffrey and Kirwan (1997)).

### The Tolman–Weitsman Theorem

The Tolman and Weitsman (2002) theorem is as follows:

**Theorem 5** *We have*

$$\text{Ker}(\kappa) = \sum_S (K_-^S \oplus K_+^S) \qquad [8]$$

*Here,* $S$ *is a generic circle subgroup of* $T$ *and* $K_-^S$ *(resp.* $K_+^S$*) denote the set of all equivariant cohomology classes* $\eta$ *whose restriction to* $\mathcal{F}_-^S$ *(resp.* $\mathcal{F}_+^S$*) is zero. Here,*

$$\mathcal{F}_\pm = \{F \in \mathcal{F} : \pm\mu_S(F) > 0\}$$

*where* $\mu_S$ *is the component of the moment map in the direction of the Lie algebra of* $S$.

# Hamiltonian Reduction of Einstein's Equations

**A E Fischer**, University of California, Santa Cruz, CA, USA
**V Moncrief**, Yale University, New Haven, CT, USA

## Introduction

In general relativity there are several levels within the framework of symplectic reduction of Einstein's equations at which one could attempt to define a Hamiltonian for the gravitational dynamics of a spatially closed universe. At the most basic unreduced level, this Hamiltonian is simply a linear function of the Einstein constraints and thus vanishes for any solution of the field equations. At the other extreme, at the deepest fully reduced level, one affects a transformation to a complete set of new canonical variables, the so-called "observables," which Poisson-commute with all of the constraints. At this level, the relevant Hamiltonian vanishes identically since each of the new canonical variables is a constant of the motion.

There is, however, an intermediate level wherein, after making a suitable choice of coordinate gauge and imposing the constraint equations, one can define a nonvanishing Hamiltonian that generates the gauge-fixed and constrained evolution equations and whose global infimum as a function on the relevant reduced phase space has direct topological significance. For the large class of manifolds on which this Hamiltonian can be defined, it has the attractive feature of globally monotonically decaying in the direction of cosmological expansion and thus evolves in such a way so as to seek and, in certain cases at least, to asymptotically attain its infimum value in the limit of this expansion. This Hamiltonian provides in these cases a weak Lyapunov function for the dynamics that can be used to partially control its global behavior. Since understanding the global behavior of solutions to Einstein's equations and its dependence upon the spatial topology is one of the central open problems in classical general relativity, the mathematical properties of this quantity are worthy of study.

Further information and details regarding the authors' work discussed in this article can be found in Fischer and Moncrief (2000, 2002a, b) and in the references therein.

## Topological Background

Einstein's field equations are nonvacuous and compatible with the introduction of material sources in $(n+1)$ dimensions for all $n \geq 2$, the case of most physical interest being of course $n=3$. For the field equations to be deterministic in a classical sense, that is, for the Cauchy problem to be well-posed, it is essential that they be formulated on a manifold that is globally hyperbolic and, in particular, has a product topology $M \times \boldsymbol{R}$ (roughly, space $\times$ time $=$ spacetime) where $M$ is a smooth ($C^\infty$) connected manifold of dimension $n$ and $\boldsymbol{R}$ is the real line. For the case of spatially closed universes of interest here, $M$ should be closed, that is, compact and without boundary. To simplify the analysis further, we also assume that $M$ is oriented, that is, orientable and an orientation has been chosen. Thus, unless stated otherwise, throughout this article $M$ will denote a smooth closed connected oriented $n$-manifold, $n \geq 2$, and all maps will be smooth.

Let "$\approx$" denote the diffeomorphic equivalence relation between smooth manifolds. Let $S^n$ denote the unit $n$-sphere in Euclidean $(n+1)$ space $\boldsymbol{R}^{n+1}, n \geq 1$. An $n$-manifold $M$ is trivial if $M \approx S^n$ and nontrivial if $M \not\approx S^n$.

The connected sum $M\#N$ of two closed connected oriented $n$-manifolds $M$ and $N$ is constructed by removing the interior of an embedded closed $n$-ball in $M$ and $N$, respectively, and then identifying the resulting $S^{n-1}$-boundary components by an orientation-reversing diffeomorphism of the $(n-1)$ spheres. The resulting manifold is smooth, connected, closed, and orientable, and is naturally oriented by the orientations on $M$ and $N$. Up to orientation-preserving diffeomorphism, this construction is independent of the choice of the embeddings of the $n$-balls and of the choice of the orientation-reversing diffeomorphism used to join the manifolds together.

Let $M$ be a nontrivial closed connected oriented $n$-manifold. Then $M$ is prime if $M \approx M_1 \# M_2$ implies that either $M_1 \approx S^n$ or $M_2 \approx S^n$ (but not both since we are assuming that $M$ is nontrivial). $M$ is a composite if $M$ can be written as a nontrivial connected sum, that is, if $M \approx M_1 \# M_2$ where both $M_1 \not\approx S^n$ and $M_2 \not\approx S^n$.

Note that with this definition, $S^n$ itself is not prime. This is analogous to the fact that for the positive integers, the unit 1 is not prime.

Now let $M$ be a connected $n$-manifold without boundary (not necessarily compact or orientable) and let $\boldsymbol{\pi}$ be a group. Then $M$ is a $K(\boldsymbol{\pi}, 1)$-manifold if $M$ is an Eilenberg–MacLane space, that is, if its first homotopy group (or fundamental group) $\pi_1(M) = \boldsymbol{\pi}$ and if all of its higher homotopy groups are trivial, that is, $\pi_i(M) = 0$ for $i > 1$ (equivalently, the universal covering space $\widetilde{M}$ of $M$ is contractible). Since the higher homotopy groups $\pi_i(M)$, $i > 1$, can be interpreted as the homotopy classes of continuous maps $S^i \to M$, each such map must be homotopic to a constant map. Thus a $K(\boldsymbol{\pi}, 1)$-manifold is said to be aspherical. Moreover, at the level of homotopy, all of the information about the topology of $M$ is contained in $\pi_1(M) = \boldsymbol{\pi}$. Thus, in particular, if $f$ is a map between connected aspherical manifolds that induces an isomorphism on their fundamental groups, then $f$ is a homotopy equivalence. Consequently, any two connected aspherical manifolds are homotopy equivalent if and only if their fundamental groups are isomorphic.

It is useful to define a connected $n$-manifold $M$ to be hyperbolizable if there exists a complete Riemannian metric $g$ on $M$ with constant negative sectional curvature, $K(g) = \text{constant} < 0$. We introduce this terminology to emphasize the underlying topology of manifolds that can support hyperbolic metrics rather than the geometry of such metrics. Similarly, $M$ is of flat type if $M$ admits a complete flat Riemannian metric $g, K(g) = 0$, and $M$ is of spherical type if $M$ admits a complete Riemannian metric $g$ on $M$ with constant positive sectional curvature, $K(g) = \text{constant} > 0$. In this latter case, by the Bonnet–Myers theorem, $M$ is necessarily compact and if $n$ is odd, then by Synge's theorem, $M$ is necessarily orientable. In fact, all such manifolds have been classified. As an important example, we note that a connected 3-manifold $M$ is of spherical type if and only if it is diffeomorphic to a spherical space form $S^3/\boldsymbol{\Gamma}$, where $\boldsymbol{\Gamma}$ is a finite subgroup of $\mathbf{SO}(4)$ acting freely and orthogonally, that is, isometrically, on $S^3$.

Within the class of $K(\boldsymbol{\pi}, 1)$-manifolds are all flat-type and hyperbolizable $n$-manifolds, since any such manifold is isometrically covered by $\boldsymbol{R}^n$ in the flat case and homothetically covered by $\boldsymbol{H}^n$ in the hyperbolic case, where $\boldsymbol{H}^n$ is the standard single-sheeted spacelike hyperboloid with constant sectional curvature $K = -1$ embedded in $(n+1)$-Minkowski space $\boldsymbol{R}_1^{n+1}$.

We now return to our standard assumptions on $M$, so that $M$ is connected, closed, and oriented. For $n = 2$, these assumptions restrict the possibilities to $S^2, \boldsymbol{T}^2$, and the orientable higher genus surfaces $\boldsymbol{\Sigma}_p^2 = \boldsymbol{T}^2 \# \boldsymbol{T}^2 \# \cdots \# \boldsymbol{T}^2$ ($p$ factors) consisting of the connected sum of $p$ copies of $\boldsymbol{T}^2, p \geq 2$. However, from the point of view of $(2+1)$ gravity, unless one includes material sources or a cosmological constant, the spherical case is vacuous in that there are no vacuum solutions of the field equations on $S^2 \times \boldsymbol{R}$. The torus case is nonvacuous but the solutions, the so-called flat Kazner spacetimes, can all be found by elementary means. Thus only the case of genus $p \geq 2$ surfaces presents problems of interest.

For $n = 3$, although not essential for the program of reduction, it is convenient to assume the elliptization conjecture of 3-manifold topology. This conjecture asserts that a closed connected 3-manifold $M$ with finite fundamental group $\pi_1(M)$ must be diffeomorphic to a spherical space form $S^3/\boldsymbol{\Gamma}$, where, in such a quotient, $\boldsymbol{\Gamma}$ will always be a finite subgroup of $\mathbf{SO}(4)$ acting freely and orthogonally on $S^3$ and thus $\boldsymbol{\Gamma}$ is isomorphic to $\pi_1(M)$.

The simply connected case is the Poincaré conjecture. The full elliptization conjecture is equivalent to the Poincaré conjecture and a conjecture asserting that the only free actions of finite groups on $S^3$ are equivalent to the standard orthogonal ones. The elliptization conjecture is part of Thurston's geometrization program (Thurston 1997). For background information regarding 3-manifold topology, see Hempel (1976) and Jaco (1980).

Under the assumption of the elliptization conjecture, the Kneser–Milnor prime decomposition theorem asserts that if $M$ is nontrivial, then up to order, $M$ is uniquely diffeomorphic to a finite connected sum of the following form:

$$M \approx \left( \underbrace{S^3/\boldsymbol{\Gamma}_1 \# \cdots \# S^3/\boldsymbol{\Gamma}_k}_{k \text{ spherical factors}} \right) \# \left( \underbrace{(S^1 \times S^2) \# \cdots \# (S^1 \times S^2)}_{l \text{ wormholes (or handles)}} \right) \# \left( \underbrace{K(\boldsymbol{\pi}_1, 1) \# \cdots \# K(\boldsymbol{\pi}_m, 1)}_{m \text{ aspherical factors}} \right) \qquad [1]$$

where $k$, $l$, and $m$ are integers $\geq 0, k + l + m \geq 1$, and if either $k$, $l$, or $m$ is 0, terms of that type do not appear. Moreover, if $k \geq 1$, then each $\boldsymbol{\Gamma}_i, 1 \leq i \leq k$, is a finite nontrivial ($\boldsymbol{\Gamma}_i \neq \{I\}$) subgroup of $\mathbf{SO}(4)$

acting freely and orthogonally on $S^3$, and if $m \geq 1$, then each aspherical factor is a $K(\boldsymbol{\pi}_j, 1)$-manifold, $1 \leq j \leq m$, and thus is universally covered by a contractible manifold.

We remark that although in general a contractible 3-manifold need not be $\boldsymbol{R}^3$, conjecturally the universal covering manifold of a $K(\boldsymbol{\pi}, 1)$ 3-manifold is diffeomorphic to $\boldsymbol{R}^3$.

In 3-manifold topology, a concept closely related to that of a prime manifold is that of an irreducible manifold. A closed 3-manifold $M$ is irreducible if every embedded 2-sphere in $M$ is the boundary of an embedded closed 3-ball.

An embedded 2-sphere that does not bound such a 3-ball is essential. Thus in the prime decomposition [1] above, $M$ is decomposed along essential 2-spheres. For this reason, the prime decomposition is sometimes referred to as the sphere decomposition.

With the exception of $S^3$ which is irreducible but not prime (by definition of prime) and $S^1 \times S^2$ which is prime but not irreducible, a closed oriented 3-manifold is prime if and only if it is irreducible. We also remark that the Poincaré conjecture, when taken in the form that there do not exist any fake 3-cells, is equivalent to every $K(\boldsymbol{\pi}, 1)$ 3-manifold being irreducible. Thus in this article, since we are assuming the elliptization conjecture and hence the Poincaré conjecture, every $K(\boldsymbol{\pi}, 1)$ 3-manifold will automatically be irreducible.

Examples of the kinds of $K(\boldsymbol{\pi}, 1)$-factors that can occur in the decomposition [1] are as follows (we will explain the Seifert and graph designations below):

1. **Non-Seifert manifolds**. Closed oriented hyperbolizable manifolds diffeomorphic to $\boldsymbol{H}^3/\boldsymbol{\Gamma}$, where $\boldsymbol{\Gamma}$ is a discrete torsion-free (i.e., no nontrivial element has finite order) co-compact subgroup of the Lie group $\mathrm{Isom}^+(\boldsymbol{H}^3)$ of orientation-preserving isometries of $\boldsymbol{H}^3$ which is Lie-group isomorphic to the proper orthochronous Lorentz group $\mathbf{SO}^{\uparrow}(1,3)$.
2. **Seifert manifolds**. $\boldsymbol{T}^3$ and five other 3-manifolds of flat type which are finitely covered by $\boldsymbol{T}^3$. Noting that $\boldsymbol{\Sigma}_1^2 = \boldsymbol{T}^2$, we remark that the product manifold $S^1 \times \boldsymbol{\Sigma}_1^2 = S^1 \times T^2 = \boldsymbol{T}^3$ is included in this class.
3. **Seifert manifolds.** Product manifolds $S^1 \times \boldsymbol{\Sigma}_p^2, p \geq 2$.
4. **Seifert manifolds**. Nontrivial circle bundles over $\boldsymbol{\Sigma}_p^2, p \geq 1$.
5. **Graph manifolds**. Any 3-manifold which fibers nontrivially over a circle with fiber $\boldsymbol{\Sigma}_p^2, p \geq 1$. Any such manifold is obtained by identifying the boundary components of $[0,1] \times \boldsymbol{\Sigma}_p^2$ with an orientation-reversing diffeomorphism of $\boldsymbol{\Sigma}_p^2$.

Since the handle $\boldsymbol{S}^1 \times \boldsymbol{S}^2$ and spherical manifolds $\boldsymbol{S}^3/\boldsymbol{\Gamma}$ are well understood, under the assumption of the elliptization conjecture the task of 3-manifold topology now reduces to understanding the topology of the (automatically irreducible) $K(\boldsymbol{\pi}, 1)$-factors that can occur in the prime decomposition [1]. Since essential 2-spheres have already been used to decompose $M$ into its prime components, the idea now is to use the next simplest 2-manifold, the 2-torus, to probe the irreducible $K(\boldsymbol{\pi}, 1)$-factors.

Let $i: \boldsymbol{T}^2 \to M$ be an embedding of $\boldsymbol{T}^2$ into a closed oriented 3-manifold $M$. Then the embedded torus $i(\boldsymbol{T}^2)$, identified with $\boldsymbol{T}^2$, is incompressible if the induced mapping of fundamental groups $i_*: \pi_1(\boldsymbol{T}^2) \to \pi_1(M)$ is injective. Thus noncontractible loops in $\boldsymbol{T}^2$ remain noncontractible when $\boldsymbol{T}^2$ is embedded in $M$, or, in other words, the ambient manifold $M$ does not fill in any homotopy hole that exists in $\boldsymbol{T}^2$ when standing alone.

A closed oriented 3-manifold $M$ is a Seifert-fibered space, or a Seifert manifold, if $M$ admits a foliation by circles. For example, if $\boldsymbol{S}^1$ acts freely on $M$, then $M$ is the total space of an $\boldsymbol{S}^1$-bundle over a surface $M/\boldsymbol{S}^1$ and $M$ is a Seifert-fibered space (see examples 2, 3, and 4 above). More generally, if $\boldsymbol{S}^1$ acts without fixed points (locally free), then $M$ is a Seifert-fibered space, and in either case the fibers of $M$ are the orbits of the $\boldsymbol{S}^1$-action.

All spherical 3-manifolds are Seifert fibered with base $\boldsymbol{S}^2$. Also, the product manifold $\boldsymbol{S}^1 \times \boldsymbol{S}^2$ is Seifert fibered, as are all manifolds finitely covered by $\boldsymbol{T}^3$, and thus all 3-manifolds of flat type are Seifert fibered. The only nontrivial connected sum that is a Seifert-fibered space is $\boldsymbol{P}^3 \# \boldsymbol{P}^3$. No hyperbolizable manifold is Seifert fibered. Thus the remaining Seifert manifolds are among the nonhyperbolizable nonflat type $K(\boldsymbol{\pi}, 1)$-manifolds (i.e., those for which $M$ does not admit either a hyperbolic or a flat Riemannian metric).

A generalization of Seifert-fibered spaces are the graph manifolds. A closed oriented 3-manifold $M$ is a graph manifold if there exists a finite collection $\{\boldsymbol{T}_i^2\}$ of disjoint embedded incompressible tori $\boldsymbol{T}_i^2 \subset M$ such that each component $M_j$ of $M \backslash \cup \boldsymbol{T}_i^2$ is a Seifert-fibered space. Thus a graph manifold is a union of Seifert-fibered spaces glued together by toral automorphisms along toral boundary components. The collection of tori may be empty so that, in particular, a Seifert-fibered manifold is a graph manifold.

We remark that the manifolds described by example 5 above are graph manifolds. We also remark that graph manifolds are closed under connected sums so that a graph manifold may be a composite. This contrasts with the situation for Seifert spaces which, with the exception of $\boldsymbol{P}^3 \# \boldsymbol{P}^3$, are not composites.

Conjecturally, the most general $K(\boldsymbol{\pi}, 1)$-manifold, not included in the list above, consists of "gluing together" across disjoint embedded incompressible

tori a finite collection of finite-volume-type hyperbolizable manifolds, that is, noncompact manifolds that admit a finite-volume complete hyperbolic metric, together with a possibly empty finite collection of irreducible graph manifolds with toral boundaries. Thus, overall, in this picture, to decompose an arbitrary closed oriented 3-manifold $M$ into its elementary constituents, one first cuts along essential 2-spheres to break $M$ down into its prime factors, that is, the nontrivial spherical $S^3/\Gamma$-factors, the wormhole $(S^1 \times S^2)$-factors, and the aspherical $K(\pi, 1)$-factors, as given by [1]. Then one cuts each nonelementary $K(\boldsymbol{\pi}, 1)$-factor along incompressible tori to separate these factors into their final finite-volume-type hyperbolizable and irreducible graph manifold components. The graph manifold components can then be further broken down along incompressible tori into Seifert-fibered pieces, finally yielding the toral decomposition of Jaco, Shalen, and Johannson (see Anderson (1997), Jaco (1980), and the end of the section "The Reduced Hamiltonian" for further details).

The Thurston (1997) geometrization program, which implies that every closed oriented 3-manifold has the structure described by the above prime (or spherical) and toroidal decomposition, has been the subject of recent work by G Perelman (see Anderson (2003) and the references therein) who has argued that it can be proved by an enhancement of the Ricci flow program of R Hamilton (see the collected papers edited by Cao *et al*. (2003)). Without entering into the technical issues surrounding the completeness of Perelman's proof, one can simply limit one's attention to 3-manifolds of the above type. If geometrization is correct, then no 3-manifolds of interest have been excluded.

Returning to the general case of $n$-manifolds, in the program of Hamiltonian reduction of Einstein's equations, an important consideration is under what topological conditions on $M$ can the conformal classes of $M$ be uniquely represented by a given metric in each class. To analyze that question, we introduce the concept of the Yamabe type of a manifold.

Let $M$ be a connected closed oriented $n$-manifold, $n \geq 3$. There is no topological obstruction to the existence of Riemannian metrics with constant negative scalar curvature, so all such manifolds admit a Riemannian metric $g$ such that $R(g) = -1$. However, there are topological obstructions for zero scalar curvature and positive constant scalar curvature metrics on $M$. To help categorize these topological obstructions, we introduce the following terminology:

1. $M$ is of *positive Yamabe type* if $M$ admits a Riemannian metric $g_1$ with scalar curvature $R(g_1) = 1$;
2. $M$ is of *zero Yamabe type* if $M$ admits a Riemannian metric $g_0$ with $R(g_0) = 0$, but no Riemannian metric $g$ with $R(g) = 1$; and
3. $M$ is of *negative Yamabe type* if $M$ admits no Riemannian metric $g$ with $R(g) = 0$.

The definition of Yamabe type partitions the class of connected closed oriented $n$-manifolds, $n \geq 3$, into three classes that are mutually exclusive and exhaustive. The following rather complete topological information regarding 3-manifolds of negative Yamabe type is known.

Let $M$ be a connected closed oriented 3-manifold. Assume that the Poincaré conjecture is true. Then $M$ is of negative Yamabe type if and only if $M$ satisfies one of the following three mutually exclusive conditions:

1. $M$ is hyperbolizable (and thus is a $K(\boldsymbol{\pi}, 1)$-manifold; see example 1 of $K(\boldsymbol{\pi}, 1)$-manifolds);
2. $M$ is a nonhyperbolizable nonflat type $K(\boldsymbol{\pi}, 1)$-manifold (see examples 3, 4, and 5 of $K(\boldsymbol{\pi}, 1)$-manifolds);
3. $M$ has a nontrivial connected sum decomposition (i.e., $M$ is a composite) in which at least one factor is a $K(\boldsymbol{\pi}, 1)$-manifold; that is, $M \approx M' \# K(\boldsymbol{\pi}, 1)$, where $M' \not\approx S^3$. In this case the $K(\boldsymbol{\pi}, 1)$-factor may be either of flat type or hyperbolizable.

We remark that (1) is the vast class of closed oriented hyperbolizable 3-manifolds. We also remark that the six closed orientable 3-manifolds of flat type, although $K(\boldsymbol{\pi}, 1)$-manifolds, are excluded from (2) as they are not of negative Yamabe type (they are of zero Yamabe type). Lastly we remark that if $M$ is of negative Yamabe type and Seifert fibered, then $M$ must be of type (2) (see remarks on Seifert-fibered spaces above).

In any dimension $n \geq 3$, a manifold $M$ of negative Yamabe type has the property that it admits no Riemannian metric $g$ having scalar curvature $R(g) \geq 0$ everywhere on $M$, or, in other words, every Riemannian metric on $M$ has scalar curvature which is negative somewhere. For such a manifold $M$, Yamabe's theorem asserts that each Riemannian metric $g$ on $M$ is uniquely globally conformal to a metric $\gamma$ with scalar curvature $R(\gamma) = -1$ (see also [21]). Thus one can represent the conformal classes of Riemannian metrics on $M$ in a suitable function space setting by an infinite-dimensional submanifold

$$\mathcal{M}_{-1} = \mathcal{M}_{-1}(M) = \{\gamma \in \mathcal{M} \mid R(\gamma) = -1\} \quad [2]$$

of the space $\mathcal{M} = \mathcal{M}(M) = \text{Riem}(M)$ of Riemannian metrics on $M$ (see Fischer and Marsden (1975) for details). For this reason, we refer to metrics $\gamma$ in $\mathcal{M}_{-1}$ as conformal metrics.

The quotient of $\mathcal{M}_{-1}$ by the natural action of $\mathcal{D}_0 = \mathcal{D}_0(M) = \mathrm{Diff}_0(M)$, the connected component of the identity of the diffeomorphism group $\mathcal{D} = \mathcal{D}(M) = \mathrm{Diff}(M)$ of $M$, defines an orbit space (not necessarily a manifold) $\mathcal{T} = \mathcal{T}(M)$,

$$\mathcal{T} = \frac{\mathcal{M}_{-1}}{\mathcal{D}_0} \qquad [3]$$

which, when $M$ is of negative Yamabe type, we define as the Teichmüller space of conformal structures on $M$.

In two dimensions in the case of a higher genus manifold $\mathbf{\Sigma}_p^2, p \geq 2$, this construction leads precisely to the conventional Teichmüller space, as discussed by Fischer and Tromba (1984). In this case the resulting Teichmüller space

$$\mathcal{T}_p = \mathcal{T}(\mathbf{\Sigma}_p^2) = \frac{\mathcal{M}_{-1}(\mathbf{\Sigma}_p^2)}{\mathcal{D}_0(\mathbf{\Sigma}_p^2)} \approx \boldsymbol{R}^{6p-6} \qquad [4]$$

is then a manifold diffeomorphic to $\boldsymbol{R}^{6p-6}$, which then plays the role of the natural reduced configuration space for the Einstein equations in $(2+1)$ dimensions. Moreover, these constructions can be carried out globally using known global cross sections for the $\mathcal{D}_0(\mathbf{\Sigma}_p^2)$ action on $\mathcal{M}_{-1}(\mathbf{\Sigma}_p^2)$. These global cross sections can then be used to provide an explicit model for the Teichmüller space $\mathcal{T}_p$ as a finite-dimensional subspace of $\mathcal{M}_{-1}(\mathbf{\Sigma}_p^2)$.

For $n = 3, \mathcal{T} = \mathcal{T}(M)$ plays the analogous role for the reduced field equations in $(3+1)$ dimensions. Moreover, for many 3-manifolds it is possible to show that $\mathcal{T}$ is itself an infinite-dimensional contractible manifold, rather than something more general such as an orbifold or a stratified union of manifolds. For technical simplicity, we shall assume throughout this article that $\mathcal{T}$ is a manifold. Our results remain valid in the more general case but in that case one must work on stratified spaces (see Fischer (1970) for results on the structure of orbit spaces when they are not manifolds).

For higher-dimensional manifolds there is no analog of the Thurston geometrization program. Indeed, it is known that the set of closed $n$-manifolds for $n \geq 4$ is so rich that no purely algebraic classification is possible. Nevertheless, for manifolds of negative Yamabe type, every Riemannian metric $g$ is still uniquely conformal to a metric $\gamma \in \mathcal{M}_{-1}$ so that the orbit space $\mathcal{T} = \mathcal{M}_{-1}/\mathcal{D}_0$ still represents the Teichmüller space of conformal equivalence classes on $M$. However, in these higher-dimensional cases, very little is known about the structure of $\mathcal{T}$.

## The Field Equations

Relative to a global time coordinate $t = x^0$ and local spatial coordinates $(x^1, \ldots, x^n)$ on a connected closed oriented $n$-manifold $M$, one can express the line element of an arbitrary $(n+1)$-Lorentzian metric with signature $(-+\cdots+)$ ($n$ positive signs) in the form

$$\begin{aligned} \mathrm{d}s^2 &= {}^{(n+1)}g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu \\ &= -N^2\mathrm{d}t^2 + g_{ij}(\mathrm{d}x^i + X^i\mathrm{d}t)(\mathrm{d}x^j + X^j\mathrm{d}t) \end{aligned} \qquad [5]$$

where ${}^{(n+1)}g_{\mu\nu}$ denotes the components of the space-time metric, $0 \leq \mu, \nu \leq n$, where the Riemannian metric $g$ with components $g_{ij}$ is the first fundamental form induced on each $t =$ constant hypersurface, where the time-dependent positive function $N = N(x,t) > 0$ is referred to as the lapse function, and where the time-dependent spatial vector field $X = X(x,t)$ with components $X^i = {}^{(n+1)}g_{0j}\, g^{ij}$, where $g^{ij}$ denotes the inverse of the spatial metric $g_{ij}$, is referred to as the shift vector field.

Let $\ell$ denote the dimension *length*. In this article we use the convention that the spatial coordinates $(x^1, \ldots, x^n)$ are always dimensionless, but the time coordinate $t$ may have a dimension (see [19] and [36]). Since the line element $\mathrm{d}s^2$ [5] has dimension $\ell^2$ and the spatial coordinates are dimensionless, the physical spatial metric coefficients $g_{ij}$ also have dimension $\ell^2$. If the time coordinate $t$ has a dimension, then the dimension of the lapse function $N$ is such that the quantity $N\mathrm{d}t$ has dimension $\ell$ and the dimension of the shift vector field $X$ is such that the quantity $X\mathrm{d}t$ is dimensionless.

We now briefly consider the canonical formulation of Einstein's equations. For more information regarding this formulation, see Arnowitt, Deser, and Misner (1962) (ADM) or Fischer and Marsden (1972) for a global perspective. We remark that the canonical formulation of gravity itself is local and is valid for any spatial topology of $M$. However, as we shall see, Hamiltonian reduction of gravity along the lines described in this article requires the topological restriction that $M$ be of negative Yamabe type.

The standard definition of the second fundamental form $k$, or extrinsic curvature, induced on a $t =$ constant hypersurface leads to the coordinate formula

$$k_{ij} = -\frac{1}{2N}\left(\frac{\partial g_{ij}}{\partial t} - X_{i|j} - X_{j|i}\right) \qquad [6]$$

where the vertical bar signifies covariant differentiation with respect to the spatial metric $g$ and spatial indices are raised and lowered using this metric. The

natural momentum variable conjugate to $g$ turns out to be the 2-contravariant symmetric tensor density $\pi$ (that is, $\pi$ is a relative tensor of weight 1) whose components in a positively oriented local coordinate chart $(x^1, \ldots, x^n)$, that is, in a chart in the orientation atlas of $M$, are given by

$$\pi^{ij} = -\sqrt{\det g_{kl}}\left(k^{ij} - (\mathrm{tr}_g k)g^{ij}\right) \qquad [7]$$

where $k^{ij} = g^{ik}g^{jl}k_{kl}$ is the contravariant form of $k$, and where

$$\tau = \tau(g, k) = \mathrm{tr}_g k = g^{ij}k_{ij} \qquad [8]$$

is the trace of the second fundamental form, or the mean (extrinsic) curvature. From the coordinate formula [6] for the extrinsic curvature, we see that the components $k_{ij}$ have dimension $\ell^{-1}\ell^2 = \ell$ and thus the mean curvature $\tau = \mathrm{tr}_g k = g^{ij}k_{ij}$ has the dimension $\ell^{-2}\ell = \ell^{-1}$.

Let $\sqrt{\det g}$ denote the (global) scalar density and $\mathrm{d}\mu_g$ denote the (global) Riemannian measure on $M$ determined by the Riemannian metric $g$ (note that here $d$ is not the exterior derivative). Similarly, let $\mu_g$ denote the volume element, a nonvanishing $n$-form on $M$, determined by $g$ and the orientation on $M$. In a positively oriented local coordinate chart $(x^i) = (x^1, \ldots, x^n)$ on $M$, $(\sqrt{\det g})_{(x^i)} = \sqrt{\det g_{ij}}$, $(\mathrm{d}\mu_g)_{(x^i)} = \sqrt{\det g_{ij}}\,\mathrm{d}x^1\mathrm{d}x^2\cdots\mathrm{d}x^n = \sqrt{\det g_{ij}}\,\mathrm{d}^n x$, where $\mathrm{d}^n x = \mathrm{d}x^1\mathrm{d}x^2\cdots\mathrm{d}x^n$ is the Lebesque measure in $\boldsymbol{R}^n$, and $(\mu_g)_{(x^i)} = \sqrt{\det g_{ij}}\,\mathrm{d}x^1 \wedge \mathrm{d}x^2 \wedge \cdots \wedge \mathrm{d}x^n$. We adopt the convention of suppressing the coordinate-chart designation $(x^i)$ so that one can, for example, write with some ambiguity $\sqrt{\det g} = (\sqrt{\det g})_{(x^i)} = \sqrt{\det g_{ij}}$.

We let

$$\mathrm{vol}(M, g) = \int_M \mu_g = \int_M \mathrm{d}\mu_g = \int_M \sqrt{\det g}\,\mathrm{d}^n x \qquad [9]$$

denote the volume of the Riemannian manifold $(M, g)$, given by either the integral of the volume $n$-form $\mu_g$ or the Riemannian measure $\mathrm{d}\mu_g$ over $M$, which is given in the last integral in its coordinate form using the suppressed coordinate-chart convention adopted above. As expected, the spatial physical volume has dimension $(\ell^2)^{n/2} = \ell^n$.

We shall refer to the canonical variables $(g_{ij}, \pi^{ij})$ as the physical variables, in contrast to the reduced or conformal variables $(\gamma_{ij}, (p^{\mathrm{TT}})^{ij})$ to be introduced later.

Note that the mean curvature $\tau = \mathrm{tr}_g k$ is a scalar function on $M$ whereas $\mathrm{tr}_g\pi$ is a scalar density on $M$. Taking the trace of [7] expresses the mean curvature in terms of the canonical variables $(g, \pi)$,

$$\tau = \tau(g, \pi) = \mathrm{tr}_g k = \frac{1}{(n-1)\sqrt{\det g}}\mathrm{tr}_g \pi \qquad [10]$$

Using [10], eqn [7] can be inverted to give $k$ in terms of $g$ and $\pi$,

$$k_{ij} = -\frac{1}{\sqrt{\det g}}\left(\pi_{ij} - \frac{1}{(n-1)}(\mathrm{tr}_g\pi)g_{ij}\right) \qquad [11]$$

and then combined with [6] to give the kinematical equation

$$\frac{\partial g_{ij}}{\partial t} = \frac{2N}{\sqrt{\det g}}\left(\pi_{ij} - \frac{1}{(n-1)}(\mathrm{tr}_g\pi)g_{ij}\right) + X_{i|j} + X_{j|i} \qquad [12]$$

In terms of the canonical variables $(g, \pi)$, a Hamiltonian form for the action for Einstein's vacuum field equations can be expressed as

$$I_{\mathrm{ADM}}(g, \pi) = \int_I \mathrm{d}t \int_M \left(\pi^{ij}\frac{\partial g_{ij}}{\partial t} - N\mathcal{H}(g, \pi) - X^i \mathcal{J}_i(g, \pi)\right)\mathrm{d}^n x \qquad [13]$$

where $I = [t_0, t_1] \subset \boldsymbol{R}$ is a closed interval and where the Hamiltonian (scalar) density $\mathcal{H}(g, \pi)$ and the momentum (1-form) density $\mathcal{J}(g, \pi)$ are given by

$$\mathcal{H}(g, \pi) = \frac{1}{\sqrt{\det g}}\left(\pi \cdot \pi - \frac{1}{n-1}(\mathrm{tr}_g\pi)^2\right) - \sqrt{\det g}\,R(g) \qquad [14]$$

$$= \frac{1}{\sqrt{\det g}}\left(g_{ij}g_{kl}\pi^{ik}\pi^{jl} - \frac{1}{n-1}(g_{ij}\pi^{ij})^2\right) - \sqrt{\det g}\,R(g) \qquad [15]$$

$$\mathcal{J}_i(g, \pi) = 2(\delta_g \pi)_i = -2g_{ij}\pi^{jk}{}_{|k} \qquad [16]$$

where $\pi \cdot \pi$ is the $g$-metric contraction of $\pi$ with itself, and where, as above, $R(g)$ is the scalar curvature of the spatial metric. We also note that each of the three terms in the integrand of [13] are global scalar densities and thus can be integrated over $M$ without any further involvement of the metric $g$.

Variation of $I_{\mathrm{ADM}}$ with respect to the lapse function and shift vector field yields the constraint equations

$$\mathcal{H}(g, \pi) = 0 \qquad [17]$$

$$\mathcal{J}_i(g, \pi) = 0 \qquad [18]$$

which comprise that subset of the empty space $(n+1)$-Einstein field equations corresponding to the normal–normal and normal–tangential projections of the Einstein tensor relative to a $t = $ constant initial hypersurface. Variation of $I_{\mathrm{ADM}}$ with respect to $\pi^{ij}$ reproduces the kinematical equation [12], whereas

variation of $I_{ADM}$ with respect to $g_{ij}$ generates the complementary tangential–tangential projections of Einstein's equations.

There are no evolution or constraint equations for either the lapse function $N$ or the shift vector field $X$ and therefore these quantities must be fixed by either externally imposed or implicitly defined gauge conditions. A convenient choice, for which a local existence and well-posedness theorem for the corresponding field equations can be established in any dimension $n \geq 2$, is given indirectly by imposing constancy of the mean curvature and a spatial harmonic gauge condition on each $t = \text{constant}$ slice (see Andersson and Moncrief (2003, 2004)). These constant mean curvature spatial harmonic (CMCSH) gauge conditions are given, respectively, by the equations

$$t = \tau \qquad [19]$$

$$g^{ij}(\Gamma^k_{ij}(g) - \Gamma^k_{ij}(\hat{g})) = 0 \qquad [20]$$

where from [10], $\tau$ is a function of the canonical variables $(g, \pi)$ and where $\hat{g}$ is some convenient fixed spatial reference metric (or background metric) on $M$. The latter condition corresponds to the requirement that the identity map between the Riemannian manifolds $(M, g)$ and $(M, \hat{g})$ be harmonic. Neither of these conditions involves the lapse function or shift vector field directly but their preservation in time implemented by the demand that the time derivatives of the given conditions be enforced leads immediately to a linear elliptic system for $(N, X^i)$ which determines these variables. The foregoing formalism is easily extended to the nonvacuum field equations in the presence of suitable material sources whose field equations are amenable to a constrained Hamiltonian treatment. To simplify the analysis, such sources will be ignored in the present discussion.

For the special case of Einstein gravity in $(2+1)$ dimensions, there is an elegant, alternative, triad-based formulation of the action functional as an $\mathrm{Isom}(\boldsymbol{R}^3_1)$-invariant gauge-theoretic Chern–Simons action, where $\mathrm{Isom}(\boldsymbol{R}^3_1)$ denotes the full isometry group, or the Poincaré group (= the inhomogeneous Lorentz group), of $(2+1)$-Minkowski space $\boldsymbol{R}^3_1$. For nondegenerate triads the resulting field equations for this alternative formulation can easily be shown to be equivalent to those of the conventional formalism when the latter is re-expressed in terms of triads but the new formulation allows for meaningful field equations in the case of degenerate triads as well and thus suggests a potentially interesting generalization of the theory (see Carlip (1998) for details).

In any dimension $n \geq 2$, there is a well-known technique, pioneered by Lichnerowicz (1955), for solving the constraint equations on a constant mean curvature (CMC) hypersurface (see Choquet-Bruhat and York (1980) and Isenberg (1995)). Of major importance for the treatment of Hamiltonian reduction is that if $n = 2$ and $M = \boldsymbol{\Sigma}^2_p, p \geq 2$, or if $n \geq 3$ and $M$ is of negative Yamabe type, then every Riemannian metric $g$ on $M$ is uniquely globally pointwise conformal to a metric $\gamma$ which satisfies $R(\gamma) = -1$ (see remark above [2]). Thus, from now on, we assume this topological condition on $M$. In this case, every Riemannian metric $g$ on $M$ can be uniquely expressed as

$$g = \begin{cases} e^{2\varphi}\gamma & \text{if } n = 2 \text{ and } M = \boldsymbol{\Sigma}^2_p,\ p \geq 2 \\ \varphi^{4/(n-2)}\gamma & \text{if } n \geq 3 \text{ and } M \text{ is of negative Yamabe type} \end{cases} \qquad [21]$$

with the conformal metric $\gamma$ normalized so that $R(\gamma) = -1$ and with the specific form of the coefficient conformal factor being chosen to simplify calculations involving the curvature tensors. In the case $n \geq 3, \varphi$ is positive and thus the space of all Riemannian metrics on $M$ is parametrized by $\mathcal{M}_{-1}$ and the space of scalar functions $\varphi > 0$ on $M$. The function $\varphi$ is then determined by solving the Hamiltonian constraint [17] (see also the remark before [33]).

In the given CMC slicing and imposing the vacuum field equations, since by the momentum constraint $\pi$ must have zero divergence (see [16] and [18]), one finds that $\pi^{ij}$ must be expressible in the form

$$\pi^{ij} = \left(\pi^{\mathrm{TT}}\right)^{ij} + \frac{1}{n}(\mathrm{tr}_g\pi)g^{ij} \qquad [22]$$

where $\pi^{\mathrm{TT}}$ is transverse (i.e., divergence-free) and traceless with respect to $g$. In the nonvacuum case, $\pi^{ij}$ picks up an additional summand determined by the sources in the modified momentum constraint [18].

Substitution of the foregoing decompositions of $(g_{ij}, \pi^{ij})$ into the Hamiltonian constraint leads to a nonlinear elliptic equation for $\varphi$ which, under the conditions assumed here, determines this function uniquely, provided $\tau \neq 0$. No solutions exist for $\tau = 0$ (equivalently, $\mathrm{tr}_g\pi = 0$) since from [14], [17], and [22], the Hamiltonian constraint would then immediately imply that

$$R(g) = \frac{1}{\det g}(\pi \cdot \pi) = \frac{1}{\det g}\left(\pi^{\mathrm{TT}} \cdot \pi^{\mathrm{TT}}\right) \geq 0 \qquad [23]$$

everywhere on $M$, which is not possible for a manifold $M$ of negative Yamabe type. Instantaneous vanishing of the mean curvature, the defining property of a maximal hypersurface, would correspond to a moment at which an expanding universe

ceases to expand or a collapsing universe ceases to collapse. From [23], such behavior is topologically excluded here by the requirement that $M$ be of negative Yamabe type (see also the discussion after [36]).

In the unreduced formalism of $I_{\mathrm{ADM}}$, the role of a super-Hamiltonian is played by the functional

$$H_{\mathrm{super}}(g,\pi) = \int_M (N\mathcal{H}(g,\pi) + X^i \mathcal{J}_i(g,\pi))\,\mathrm{d}^n x \qquad [24]$$

which evidently vanishes whenever the constraints are satisfied. To achieve a fully reduced formulation wherein again the effective Hamiltonian would vanish, one could endeavor to solve the associated Hamilton–Jacobi equations

$$\mathcal{H}(g_{ij}, \delta S/\delta g_{ij}) = 0 \qquad [25]$$

$$\mathcal{J}_k(g_{ij}, \delta S/\delta g_{ij}) = 0 \qquad [26]$$

for a real-valued functional $S = S(g, \alpha^A)$ of the metric $g$ and a set of additional independent parameters $\alpha^A$. A complete solution $S(g_{ij}, \alpha^A)$ would be one for which an arbitrary solution $(g_{ij}, \pi^{ij})$ of the constraints could be realized as $(g_{ij}, \delta S/\delta g_{ij})$ for a suitable (unique) choice of the $\alpha^A$. A complementary set of reduced canonical variables $\beta_A$ (the momenta conjugate to the $\alpha_A$'s) could then be defined by $\beta_A = \delta S/\delta\alpha^A$ and one could in principle solve the equations

$$\pi^{ij} = \frac{\delta S}{\delta g_{ij}} \qquad [27]$$

$$\beta_A = \frac{\delta S}{\delta \alpha^A} \qquad [28]$$

for $(\alpha^A, \beta_A)$ as functionals of the canonical variables $(g_{ij}, \pi^{ij})$. This procedure, if it could be carried out, would ensure that these functionals $(\alpha^A(g,\pi), \beta_A(g,\pi))$ Poisson-commute with all of the constraints and hence are conserved for an arbitrary slicing of spacetime. Conversely, if a suitable set of gauge conditions such as the CMCSH conditions were imposed, one could in principle solve for the remaining independent canonical variables as functionals of the $(\alpha^A, \beta_A)$ and an internal variable, such as the mean curvature $\tau$, which plays the role of time, and hence solve the field equations for $(g_{ij}, \pi^{ij})$ in the chosen gauge.

This proposal is purely heuristic in $(3+1)$ and higher dimensions in that there is no known procedure for finding the needed complete solution of the Hamilton–Jacobi equations in these cases. However, by exploiting the Chern–Simons analogy discussed earlier in this section, a complete solution can be found in $(2+1)$ dimensions and the corresponding complete set of "observables" $(\alpha^A, \beta_A)$ identified. The latter are equivalent, up to a diffeomorphism of the associated reduced phase space, to a complete set of traces of holonomies of the flat $\mathrm{Isom}(\boldsymbol{R}^3_1)$-connections defined in this Chern–Simons formulation (see Carlip (1998) for more details).

## The Reduced Hamiltonian

We continue with the assumption that $M$ is a connected closed oriented $n$-manifold, with either $n=2$ and $M = \boldsymbol{\Sigma}^2_p, p \geq 2$, or $n \geq 3$ and $M$ of negative Yamabe type. We now define the reduced phase space as the set of conformal variables given by

$$P_{\mathrm{reduced}} = \{(\gamma, p^{\mathrm{TT}}) \mid \gamma \in \mathcal{M}_{-1} \text{ and } p^{\mathrm{TT}} \text{ is a 2-contravariant symmetric tensor density that is transverse and traceless with respect to } \gamma\} \qquad [29]$$

We remark that the fully reduced phase space is given by $P_{\mathrm{reduced}}/\mathcal{D}_0$, where $\mathcal{D}_0$ is the group of diffeomorphisms of $M$ isotopic to the identity. However, here, for clarity of exposition, we work on $P_{\mathrm{reduced}}$ rather than the fully reduced phase space.

Given a scalar function $\varphi$, with $\varphi > 0$ if $n \geq 3$, the physical variables $(g, \pi^{\mathrm{TT}})$ are related to the conformal variables $(\gamma, p^{\mathrm{TT}})$ by

$$(g, \pi^{\mathrm{TT}}) = \begin{cases} (\mathrm{e}^{2\varphi}\gamma, \mathrm{e}^{-2\varphi}p^{\mathrm{TT}}) & \text{if } n = 2 \\ (\varphi^{4/(n-2)}\gamma, \varphi^{-4/(n-2)}p^{\mathrm{TT}}) & \text{if } n \geq 3 \end{cases} \qquad [30]$$

We adopt the convention that raising and lowering of indices on either momentum variable $\pi^{\mathrm{TT}}$ or $p^{\mathrm{TT}}$ will be with respect to its own conjugate metric, either $g$ or $\gamma$, respectively. With this convention, the mixed forms of $\pi^{\mathrm{TT}}$ and $p^{\mathrm{TT}}$ are equal, since for $n \geq 3$,

$$(\pi^{\mathrm{TT}})^i{}_j = g_{jl}\pi^{\mathrm{TT}il} = \varphi^{4/(n-2)}\gamma_{jl}\varphi^{-4/(n-2)}p^{\mathrm{TT}il} = \gamma_{jl}p^{\mathrm{TT}il} = (p^{\mathrm{TT}})^i{}_j \qquad [31]$$

(and similarly for the $n=2$ case). Thus the squared norms of $p^{\mathrm{TT}}$ and $\pi^{\mathrm{TT}}$ are equal,

$$p^{\mathrm{TT}} \cdot p^{\mathrm{TT}} = \gamma_{ik}\gamma_{jl}p^{\mathrm{TT}ij}p^{\mathrm{TT}kl} = g_{ik}g_{jl}\pi^{\mathrm{TT}ij}\pi^{\mathrm{TT}kl} = \pi^{\mathrm{TT}} \cdot \pi^{\mathrm{TT}} \qquad [32]$$

where in the first term the center dot is $\gamma$-metric contraction and in the last term the center dot is $g$-metric contraction.

The uniquely determined scalar factor $\varphi$ relating the physical metric $g$ to the conformal metric $\gamma$ is obtained by solving the Hamiltonian constraint

equation [17]. In the special case that $p^{\mathrm{TT}}=0$ (or equivalently, from [30], that $\pi^{\mathrm{TT}}=0$), $\varphi$ is constant and is given in the $n \geq 3$ case by

$$\varphi=\left(\frac{n}{(n-1)\tau^2}\right)^{(n-2)/4} \qquad [33]$$

Thus in this case

$$\gamma=\varphi^{-4/(n-2)}g=\frac{(n-1)}{n}\tau^2 g \qquad [34]$$

In particular, since $\tau$ has the dimension $\ell^{-1}$ (see the remark after [8]) and the components $g_{ij}$ have the dimension $\ell^2$, we see from this formula that the conformal metric $\gamma_{ij}$ is dimensionless. Although $\varphi$ is not constant in the general case when $p^{\mathrm{TT}} \neq 0$, its dimension, as in [33], is still $\ell^{(n-2)/2}$ and thus the components $\gamma_{ij}$ are still dimensionless in the general case. Since in the conventions used in this article, the spatial coordinates are dimensionless, the volume $\mathrm{vol}(M,\gamma)$ of the Riemannian manifold $(M,\gamma)$, as well as all curvature tensors of $\gamma$, are also dimensionless. Having a dimensionless conformal metric $\gamma$ with a dimensionless volume has its advantages over the physical metric $g$ with dimension $\ell^2$ inasmuch, as we shall see below, an infimum of the volume of the conformal metric is related to a dimensionless topological invariant of $M$ (see [48] and the remark thereafter).

If one now uses the conformal variables given by [30] and the decomposition [22] in the ADM action given by [13], one finds the reduced action to be

$$I_{\mathrm{reduced}}=\int_I \mathrm{d}t\int_M\left(p^{\mathrm{TT}ij}\frac{\partial\gamma_{ij}}{\partial t}-\frac{2(n-1)}{n}\frac{\partial\tau}{\partial t}\sqrt{\det g}+\frac{2}{n}\frac{\partial \mathrm{tr}_g\pi}{\partial t}\right)\mathrm{d}^n x \qquad [35]$$

In this expression one can discard the final time derivative which contributes only a boundary integral and so does not contribute to the equations of motion. Moreover, the conformal metric $\gamma_{ij}$ is constrained to lie in the intersection of $\mathcal{M}_{-1}$ and a slice for the action of $\mathcal{D}_0$ on $\mathcal{M}_{-1}$. This space can be regarded as a local chart for the reduced configuration space $\mathcal{T}=\mathcal{M}_{-1}/\mathcal{D}_0$, under the technical assumption that $\mathcal{T}$ is a manifold. Thus, taken together, the conformal variables $(\gamma_{ij}, p^{\mathrm{TT}ij})$ can be viewed as local canonical coordinates for the cotangent bundle $T^*\mathcal{T}$ of Teichmüller space $\mathcal{T}$, where $T^*\mathcal{T}$ now plays the role of the reduced phase space.

For $n=2$, these constructions can be carried out globally for the Teichmüller space $\mathcal{T}_p$ of an arbitrary closed oriented surface $\boldsymbol{\Sigma}_p^2, p \geq 2$ (see the remarks after [4]). Using these global constructions, the reduced phase space $T^*\mathcal{T}_p$ for the $(2+1)$-reduced Einstein equations can be modeled explicitly.

Having restricted the slices to be CMC, one need only choose the relationship between the time coordinate and the CMC $\tau$ in order to fix a corresponding reduced Hamiltonian. The most natural choice of time coordinate from the present point of view is to take

$$t=t(\tau)=\frac{2}{n(-\tau)^{n-1}} \qquad [36]$$

Note that this choice of time coordinate, although also denoted $t$, is no longer dimensionless but has dimension $\ell^{n-1}$.

This choice of time coordinate is motivated by three considerations. Firstly, we remark that since $\tau=0$ is excluded in the setting used in this article (see [23] and the discussion after), $\tau$ can range in either the domain $\boldsymbol{R}^-=(-\infty,0)$ or $\boldsymbol{R}^+=(0,\infty)$. The usual convention on the sign of $k$, as adopted here, is that the sign of $k$ is negative when the tips of the normals on a spacelike hypersurface are further apart than their bases, as for example in the expansion of a model universe, in which case $\tau=\mathrm{tr}_g k<0$. Thus, with this convention, $\tau$ in the range $\boldsymbol{R}^-$ corresponds to an expanding universe and $\tau$ in the range $\boldsymbol{R}^+$ corresponds to a collapsing one in the future direction of increasing $t$. Thus for manifolds of negative Yamabe type that we consider here, the expected maximal range of the CMC $\tau$ is $\boldsymbol{R}^-$ for which $\tau\to-\infty$ corresponds to a "crushing singular" big bang of vanishing spatial volume and $\tau\to 0^-$ corresponds to the limit of infinite volume expansion. Then, with the time function given by [36], the coordinate time $t$ ranges in the interval $\boldsymbol{R}^+$, vanishes at the big bang, and tends to positive infinity in the limit of infinite cosmological expansion.

We remark that to prove that a solution determined by Cauchy data prescribed at some initial coordinate time $t_0 \in \boldsymbol{R}^+$ actually exhausts the range $\boldsymbol{R}^+$ is a difficult global existence problem that is not dealt with here. Nevertheless, one of the main motivations for this work is the hope that Hamiltonian reduction will lead to advances in the study of the global existence question for Einstein's equations.

We also remark that with the choice of temporal gauge function given by [36] and with $\tau$ in its natural range $\boldsymbol{R}^-$,

$$\frac{\mathrm{d}\tau}{dt}=\frac{n}{2(n-1)}(-\tau)^n>0 \qquad [37]$$

so that this temporal coordinate choice preserves the time orientation of the flow for all $n \geq 2$.

Secondly, with this choice of temporal gauge, the reduced action given by [35] simplifies to

$$I_{\text{reduced}} = \int_I \mathrm{d}t \int_M \left( p^{\mathrm{TT}ij} \frac{\partial \gamma_{ij}}{\partial t} - (-\tau)^n \sqrt{\det g} \right) \mathrm{d}^n x \qquad [38]$$

from which one can read off an effective reduced Hamiltonian density,

$$\mathcal{H}_{\text{reduced}}(\tau, \gamma, p^{\mathrm{TT}}) = (-\tau)^n \sqrt{\det g} \qquad [39]$$

and an effective reduced Hamiltonian,

$$\begin{aligned} H_{\text{reduced}}(\tau, \gamma, p^{\mathrm{TT}}) &= \int_M (-\tau)^n \sqrt{\det g}\, \mathrm{d}^n x \\ &= (-\tau)^n \int_M \mathrm{d}\mu_g \\ &= (-\tau)^n \mathrm{vol}(M, g) \end{aligned} \qquad [40]$$

where $\mathrm{vol}(M,g) = \int_M \mathrm{d}\mu_g$ is the volume of the Riemannian manifold $(M, g)$. Thus in terms of the physical variables $(g_{ij}, \pi^{ij})$, the reduced Hamiltonian $H_{\text{reduced}}$ at "time" $\tau$ is simply the volume of the CMC slice with mean curvature $\tau$ rescaled by the factor $(-\tau)^n$. With this reduced Hamiltonian density, the reduced action [38] takes the canonical form

$$I_{\text{reduced}} = \int_I \mathrm{d}t \int_M \left( p^{\mathrm{TT}ij} \frac{\partial \gamma_{ij}}{\partial t} - \mathcal{H}_{\text{reduced}} \right) \mathrm{d}^n x \qquad [41]$$

As the third consideration for the given choice of the time function, we note that rescaling the physical volume $\mathrm{vol}(M, g)$ by the factor $(-\tau)^n$ yields a dimensionless quantity. Indeed, as we have seen, the spatial physical volume has the dimension $\ell^n$ and the constant mean curvature $\tau$ has the dimension $\ell^{-1}$, so that the reduced Hamiltonian $(-\tau)^n \mathrm{vol}(M, g)$ is dimensionless.

The main advantage of having a dimensionless reduced Hamiltonian is that only such a reduced Hamiltonian can have a topological significance, and indeed, the infimum of $H_{\text{reduced}}$ is closely related to a dimensionless topological invariant of $M$ (see the remarks after [48]).

In terms of the conformal variables $(\gamma, p^{\mathrm{TT}})$, the reduced Hamiltonian is found from [21] and [40] to be given for $n \geq 3$ by

$$\begin{aligned} H_{\text{reduced}}(\tau, \gamma, p^{\mathrm{TT}}) &= (-\tau)^n \int_M \sqrt{\det g}\, d^n x \\ &= (-\tau)^n \int_M \sqrt{\det(\varphi^{4/(n-2)}\gamma)}\, \mathrm{d}^n x \\ &= (-\tau)^n \int_M (\varphi^{4/(n-2)})^{n/2} \sqrt{\det \gamma}\, d^n x \\ &= (-\tau)^n \int_M \varphi^{2n/(n-2)}\, \mathrm{d}\mu_\gamma \end{aligned} \qquad [42]$$

where $\mathrm{d}\mu_\gamma$ is the Riemannian measure on $M$ determined by $\gamma$ (locally, $\mathrm{d}\mu_\gamma = \sqrt{\det \gamma}\, \mathrm{d}^n x$) and $\varphi = \varphi(\tau, \gamma, p^{\mathrm{TT}})$ is the conformal factor which, through the solution of the Hamiltonian constraint [17], is expressed as a function of the "time" $\tau$ and the independent conformal (or canonical) variables $(\gamma, p^{\mathrm{TT}})$.

In the special case $n = 2, M = \boldsymbol{\Sigma}_p^2, p \geq 2$, a simple formula for $H_{\text{reduced}}$ can be derived. In terms of the conformal variables $(\gamma, p^{\mathrm{TT}})$, we find from [40], [10], [14], [17], [21], [22], and [32] that

$$\begin{aligned} &H_{\text{reduced}}(\tau, \gamma, p^{\mathrm{TT}}) \\ &= \int_{\Sigma_p^2} (-\tau)^2 \mathrm{d}\mu_g = 2 \int_{\Sigma_p^2} \left( (\det g)^{-1} (\pi^{\mathrm{TT}} \cdot \pi^{\mathrm{TT}}) - R(g) \right) \mathrm{d}\mu_g \\ &= 2 \int_{\Sigma_p^2} (\det(\mathrm{e}^{2\varphi}\gamma))^{-1} (p^{\mathrm{TT}} \cdot p^{\mathrm{TT}})\, \mathrm{d}\mu_{(\mathrm{e}^{2\varphi}\gamma)} - 2 \int_{\Sigma_p^2} R(g)\, \mathrm{d}\mu_g \\ &= 2 \int_{\Sigma_p^2} (\mathrm{e}^{2\varphi})^{-2} (\det \gamma)^{-1} (p^{\mathrm{TT}} \cdot p^{\mathrm{TT}})\, \mathrm{e}^{2\varphi} \mathrm{d}\mu_\gamma - 8\pi \chi(\boldsymbol{\Sigma}_p^2) \\ &= 2 \int_{\Sigma_p^2} \mathrm{e}^{-2\varphi} (\det \gamma)^{-1} (p^{\mathrm{TT}} \cdot p^{\mathrm{TT}}) \mathrm{d}\mu_\gamma + 16\pi(p-1) \end{aligned} \qquad [43]$$

where $\varphi = \varphi(\tau, \gamma, p^{\mathrm{TT}}), \chi(\boldsymbol{\Sigma}_p^2) = 2(1-p)$ is the Euler characteristic of the genus $p$ surface $\boldsymbol{\Sigma}_p^2$, and where we have used the Gauss–Bonnet theorem

$$\int_{\Sigma_p^2} R(g)\, \mathrm{d}\mu_g = 4\pi \chi(\boldsymbol{\Sigma}_p^2) = 8\pi(1-p) \qquad [44]$$

Since

$$\begin{aligned} &H_{\text{reduced}}(\tau, \gamma, p^{\mathrm{TT}}) \\ &\quad = 2 \int_{\Sigma_p^2} \mathrm{e}^{-2\varphi} (\det \gamma)^{-1} (p^{\mathrm{TT}} \cdot p^{\mathrm{TT}}) \mathrm{d}\mu_\gamma \\ &\qquad + 16\pi(p-1) \geq 16\pi(p-1) \end{aligned} \qquad [45]$$

the infimum of $H_{\text{reduced}}$ is attained precisely when $p^{\mathrm{TT}} = 0$ and this infimum coincides with the topological invariant $-8\pi\chi(\boldsymbol{\Sigma}_p^2) = 16\pi(p-1)$, which characterizes the surface $\boldsymbol{\Sigma}_p^2$ (see also [51] below). As we shall see shortly, an analogous result holds for $n \geq 3$.

A straightforward but lengthy calculation, which is valid in arbitrary dimensions, shows that the reduced Hamiltonian is strictly monotonically decreasing in the direction of cosmological expansion except for a family of continuously self-similar spacetimes for which this Hamiltonian is constant (Fischer and Moncrief 2002b). The latter solutions exist if and only if $M$ admits a Riemannian metric $\gamma \in \mathcal{M}_{-1}$ which is an Einstein metric, that is, for which the Ricci tensor satisfies $\mathrm{Ric}(\gamma) = -(1/n)\gamma$. Using the mean curvature as a convenient time coordinate, that is, temporarily taking $t = \tau$, the

corresponding self-similar vacuum spacetime metrics then have the line element

$$ds^2 = -\left(\frac{n}{\tau^2}\right)^2 d\tau^2 + \frac{n}{(n-1)}\frac{1}{\tau^2}\gamma_{ij}dx^i\,dx^j \qquad [46]$$

In the case that $n = 3$, the Einstein metric $\gamma$ is actually hyperbolic with constant sectional curvature $K(\gamma) = -1/6$ and Ricci curvature $\mathrm{Ric}(\gamma) = -(1/3)\gamma$. Although the conformal variables $(\gamma, p^{\mathrm{TT}}) = (\gamma, 0)$ are static in this model, the physical variables $(g, \pi)$ are not. In this case, the resulting spacetimes (which depend on the underlying topology of $M$) have expanding closed hyperbolic spacelike hypersurfaces where the physical volume $\mathrm{vol}(M, g)$ "starts" at zero at the big bang and expands to infinity in the forward time direction, as befits a universe endlessly expanding from the big bang. Such a universe is depicted in Figure 1, where the genus-2 surface is used to represent a generic closed hyperbolic 3-manifold. The Bianchi and Thurston types of this model are discussed in the next section.

The line element [46] is locally isometric to the vacuum Friedmann–Lemaître–Robertson–Walker (FLRW) $k = -1$ spacetime, which is well known to be flat. Although these spatially compactified models are technically not classical FLRW spacetimes since the expanding compact hypersurfaces are not homogeneous (and thus not isotropic), they are Lorentz-covered by the FLRW $k = -1$ spacetime and thus are locally isometric to this classical spacetime.

The same result leading to [46] holds even if matter sources are allowed, provided they satisfy a suitable energy condition, in which case the corresponding reduced Hamiltonian will only be stationary in the vacuum limit and then only when the metric is of the above type; otherwise it monotonically decays. This result even has a quasilocal

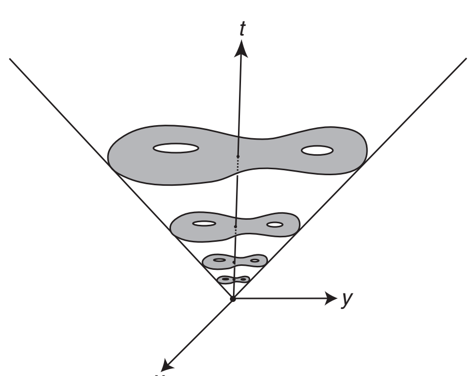

**Figure 1** Expansion of the physical universe in the Bianchi V, Thurston type $H^3$, spatially compactified FLRW flat spacetime cosmology.

generalization expressible in terms of the corresponding quasilocal reduced Hamiltonian defined for an arbitrary domain $D_\tau$ within the CMC slice $\tau = \text{constant}$ by restricting $H_{\text{reduced}}$ in [42] to the domain $D_\tau$, so that for $n \geq 3$,

$$\begin{aligned} H_{D_\tau}(\tau, \gamma, p^{\mathrm{TT}}) &= (-\tau)^n \int_{D_\tau} d\mu_g \\ &= (-\tau)^n \int_{D_\tau} \varphi^{2n/(n-2)}\, d\mu_\gamma \qquad [47] \end{aligned}$$

If $D_\tau$ is determined from its specification on some initial slice $\tau = \tau_0$, by letting the domain flow along the normal trajectories of the CMC foliation, one can then verify that $H_{D_\tau}$ is monotonically decreasing except for the vacuum solutions of self-similar type described above, in which case $H_{D_\tau}$ is constant. This result is independent of the initial domain chosen.

We remark that one cannot use the quasilocal Hamiltonian to get equations of motion (even quasilocally) since the full true Hamiltonian is nonlocal and so one gets contributions from the whole manifold.

Since the reduced Hamiltonian $H_{\text{reduced}}$ as well as its quasilocal variant $H_{D_\tau}$ is monotonically decreasing for generic solutions of Einstein's equations, it is natural to ask what its infimum is and whether this infimum is ever attained, at least asymptotically, by solutions of the field equations. The infimum of the reduced Hamiltonian for $n \geq 3$ and for a spatial manifold $M$ of negative Yamabe type can be characterized in terms of a certain topological invariant of $M$ called the sigma constant $\sigma(M)$ of $M$. For manifolds of negative Yamabe type, this quantity can be defined in terms of the infimum of the volume of all metrics which range over the space of conformal metrics $\mathcal{M}_{-1}$. The precise definition leads to the formula

$$\sigma(M) = -\left(\inf_{\gamma \in \mathcal{M}_{-1}} \mathrm{vol}(M, \gamma)\right)^{2/n} \qquad [48]$$

Interestingly, this equation defines the topological invariant $\sigma(M)$ by a purely geometrical equation involving the volume functional restricted to $\mathcal{M}_{-1}$. We also remark that [48] is a dimensionless equation, the left-hand side being dimensionless since it is a topological invariant of $M$ and the right-hand side being dimensionless since the conformal metric and its volume are dimensionless (see the remarks after [34]).

Although the $\sigma$-constant can be defined for all Yamabe types, [48] holds only for manifolds of negative Yamabe type. From this equation, one can conclude that for such manifolds

$$\sigma(M) \leq 0 \qquad [49]$$

One can relate the foregoing to the reduced Hamiltonian by showing that the infimum of $H_{\text{reduced}}$ defined for arbitrary $\tau < 0$ as a functional on the reduced phase space

$$T^*\mathcal{T} = T^*\left(\frac{\mathcal{M}_{-1}}{\mathcal{D}_0}\right) \qquad [50]$$

is given by

$$\inf_{(\gamma, p^{\text{TT}}) \in T^*\mathcal{T}} H_{\text{reduced}}(\tau, \gamma, p^{\text{TT}}) = \begin{cases} -8\pi\chi(\boldsymbol{\Sigma}_p^2) = 16\pi(p-1) & \text{if } n=2 \text{ and } p \geq 2 \\ \left(\frac{n}{n-1}(-\sigma(M))\right)^{n/2} & \text{if } n \geq 3 \end{cases} \qquad [51]$$

where for $n \geq 3, M$ is of negative Yamabe type and thus $\sigma(M) \leq 0$ (see [49]).

One proves this result by first showing that within an arbitrary fiber of the cotangent bundle $T^*(\mathcal{M}_{-1}/\mathcal{D}_0)$, one minimizes $H_{\text{reduced}}$ by setting the fiber variable $p^{\text{TT}}$ to zero. In this case, the solution for the conformal factor $\varphi$ reduces to a spatial constant which is a function of $\tau$ alone (see [33]), and thus the formula for $H_{\text{reduced}}$ given in [42] reduces to

$$H_{\text{reduced}}(\tau, \gamma, 0) = \left(\frac{n}{n-1}\right)^{n/2} \text{vol}(M, \gamma) \qquad [52]$$

The infimum over all conformal metrics $\gamma \in \mathcal{M}_{-1}$ of this latter functional yields the $\sigma$-constant as outlined above. If matter sources obeying a suitable energy condition are allowed, the argument goes through in much the same way with the additional implication that the infimum is achieved only for a vacuum solution so that in fact the matter must be "turned off."

Thus, as a consequence of the above analysis, one has

$$\begin{aligned} &H_{\text{reduced}}(\tau, \gamma, p^{\text{TT}}) \\ &\geq H_{\text{reduced}}(\tau, \gamma, 0) = \left(\frac{n}{n-1}\right)^{n/2} \text{vol}(M, \gamma) \\ &\geq \left(\frac{n}{n-1}\right)^{n/2} \inf_{\gamma' \in \mathcal{M}_{-1}} \text{vol}(M, \gamma') \\ &= \left(\frac{n}{n-1}(-\sigma(M))\right)^{n/2} \end{aligned} \qquad [53]$$

where the last equality follows by inverting [48] to give

$$\inf_{\gamma \in \mathcal{M}_{-1}} \text{vol}(M, \gamma) = (-\sigma(M))^{n/2} \qquad [54]$$

Moreover, if $\gamma \in \mathcal{M}_{-1}$ actually achieves the $\sigma$-constant, that is, if $\text{vol}(M, \gamma) = (-\sigma(M))^{n/2}$ (and not just asymptotically approaches it as a curve or sequence), then $\gamma$ must be an Einstein metric with

$$\text{Ric}(\gamma) = -\frac{1}{n}\gamma \qquad [55]$$

If, additionally, $n = 3$, then $\gamma$ must be hyperbolic (with constant sectional curvature $K(\gamma) = -1/6$).

Although Thurston's conjectures do not refer to the $\sigma$-constant, Anderson (1997) has been able to reformulate and somewhat refine the Thurston geometrization conjectures for 3-manifolds of arbitrary Yamabe type in terms of conjectured properties of the $\sigma$-constant. Additionally, if Perelman's results are technically complete, they would provide a proof of Anderson's conjectures as well as those of Thurston's (see Anderson (2003)).

The conjectured behavior for a sequence of conformal metrics $\{\gamma_i\}, \gamma_i \in \mathcal{M}_{-1}, i = 1, 2, \ldots,$ which seeks to minimize the volume of a stand-alone $K(\boldsymbol{\pi}, 1)$ 3-manifold $M$ of negative Yamabe type can be described as follows:

1. If $M$ is hyperbolizable, then $\sigma(M) < 0$ is attained by a hyperbolic metric $\gamma_h \in \mathcal{M}_{-1}$, unique up to diffeomorphism, and the sequence of conformal metrics $\{\gamma_i\}$ converges to this metric in a suitable function space topology.
2. If $M$ is a pure graph manifold, then $\sigma(M) = 0$ and the sequence $\{\gamma_i\}$ of conformal metrics "volume collapses" $M$ with bounded curvature. Typically this occurs through collapse of circular or toroidal fibers in the associated circle or 2-torus bundle structure (see examples 3, 4, and 5 in the section "Topological Background" and see also the penultimate section). The six manifolds of flat type are not included here as they are of zero Yamabe type.
3. If $M$ is a generic $K(\boldsymbol{\pi}, 1)$-manifold (not of type 1 or 2 above), then $M$ can be decomposed along incompressible tori into its final finite-volume-type hyperbolizable and (possibly empty set of) graph-manifold pieces. In this case, $\sigma(M) < 0$ and the sequence $\{\gamma_i\}$ of conformal metrics collapses the graph-manifold components and converges to finite-volume complete hyperbolic metrics on the hyperbolizable components (normalized to have $R(\gamma) = -1$) yielding a $\sigma$-constant that is entirely determined by the volumes of these final hyperbolic components (see the final section).

We shall return to this conjectured characterization of sequences of conformal metrics in the next two sections.

## Reduction of Bianchi Models and Conformal Volume Collapse

For manifolds of negative Yamabe type, the strict monotonic decay of $H_{\text{reduced}}$ in the direction of cosmological expansion along nonconstant integral curves of the reduced Einstein equations suggests

that the reduced Hamiltonian is seeking to achieve its infimum $\inf H_{\text{reduced}} = ((n/(n-1))(-\sigma(M)))^{n/2}$. But does this ever happen? Does the reduced Einstein flow of the conformal geometry asymptotically approach $\inf H_{\text{reduced}}$ in the limit of infinite cosmological expansion?

To answer this question, one can consider for $n = 3$ known locally homogeneous vacuum solutions of Einstein's equations which spatially compactify to manifolds of negative Yamabe type. Applying the theory of Hamiltonian reduction to these classical models, one can show that the reduced Hamiltonian behaves as expected under the reduced Einstein flow defined by these models. Since these models existed long before this theory, it is somewhat satisfying to see that they can be interpreted in terms of Hamiltonian reduction and how, with this interpretation, new properties of these classical solutions can be found.

Since $H_{\text{reduced}}$ is a strictly monotonically decreasing function along nonconstant integral curves of the reduced Einstein flow, it is expected that under certain conditions, the reduced Hamiltonian is monotonically seeking to decay to its infimum. Thus, it is of interest to look at Hamiltonian reduction under the consequence of the following two assumptions:

1. The reduced Einstein field equations give rise to the existence of a positive semiglobal nonconstant solution $(\gamma(t), p^{\text{TT}}(t))$ defined for all $t \in (0, \infty)$ (or equivalently, for all $\tau \in (-\infty, 0)$;
2. The reduced Hamiltonian strictly monotonically decays to its infimum along nonconstant integral curves,

$$H_{\text{reduced}}(\tau(t), \gamma(t), p^{\text{TT}}(t)) \longrightarrow \inf H_{\text{reduced}} \quad \text{as } t \longrightarrow \infty \qquad [56]$$

From [40] and [51], in terms of the physical variables $(g, \pi)$ (or $(g, k)$), [56] can be written equivalently as

$$-\tau^3 \operatorname{vol}(M,g) = -(\operatorname{tr}_g k)^3 \operatorname{vol}(M,g) \longrightarrow \left(\frac{3}{2}(-\sigma(M))\right)^{3/2} \quad \text{as } t \longrightarrow \infty \qquad [57]$$

As a consequence of these assumptions, it follows from [53] that the conformal volume $\operatorname{vol}(M,\gamma)$ must also decay to its infimum [54] (although not necessarily monotonically),

$$\operatorname{vol}(M, \gamma(t)) \longrightarrow \inf_{\gamma \in \mathcal{M}_{-1}} \operatorname{vol}(M, \gamma) = (-\sigma(M))^{3/2} \quad \text{as } t \longrightarrow \infty \qquad [58]$$

Now suppose that $\sigma(M) = 0$. A large class of manifolds for which this is true are the graph manifolds (and thus also the Seifert manifolds) of negative Yamabe type since $\sigma(M) \geq 0$ for graph manifolds in general and since $\sigma(M) \leq 0$ for manifolds of negative Yamabe type. In this case the curve $\gamma(t) \in \mathcal{M}_{-1}$ of conformal metrics must necessarily (conformally) volume collapse $M$ in the direction of cosmological expansion,

$$\operatorname{vol}(M, \gamma(t)) \longrightarrow (-\sigma(M))^{3/2} = 0 \quad \text{as } t \longrightarrow \infty \qquad [59]$$

Consequently, the curve of conformal metrics $\gamma(t)$ must undergo some form of degeneration as its volume collapses. The details of this metric degeneration are of importance and are discussed below.

Not all locally homogeneous vacuum Bianchi models admit spatially compact quotients. Fortunately, the general theory of which Bianchi models admit spatially compact quotients has been worked out in detail by Tanimoto, Koike, and Hosoya (see Tanimoto *et al.* (1997) and the references therein). These Bianchi models together with their corresponding Thurston classification and typical examples of their closed quotient manifolds are listed in **Table 1**, where "K–S" indicates "Kantowski–Sachs," "P," "Z," and "N" denote manifolds of Yamabe type positive, zero, and negative, respectively (see the section "Topological Background"), "Seifert" means Seifert fibered, "Hyper" means hyperbolizable, "?" indicates "unknown, but conjectured to be so," and "manifold collapse" denotes the type of collapse that the conformal manifold $(M, \gamma(t))$ goes through as the conformal volume $\operatorname{vol}(M, \gamma(t))$ collapses. We also remark that all of the manifolds

**Table 1** Bianchi, Thurston, and Yamabe type of a connected closed oriented irreducible 3-manifold

| *Bianchi type* | *Thurston type* | *Typical examples* | *Yamabe type* | *σ-constant* | *Manifold structure* | *Manifold collapse* |
|---|---|---|---|---|---|---|
| K–S | $S^2 \times R$ | $S^2 \times S^1$ | $P$ | $>0$ | Seifert | |
| IX | $S^3$ | Nontrivial $S^1$-bundles over $S^2$ | $P$ | $>0$ | Seifert | |
| I | $R^3$ | $T^3$ | $Z$ | 0 | Seifert | |
| II | Nil | Nontrivial $S^1$-bundles over $T^2$ | $N$ | 0 | Seifert | Total |
| III | $H^2 \times R$ | $\Sigma_p^2 \times S^1, p \geq 2$ | $N$ | 0 | Seifert | Pancake |
| VIII | $\widetilde{SL}(2, R)$ | Nontrivial $S^1$-bundles over $\Sigma_p^2$ | $N$ | 0 | Seifert | Pancake |
| $VI_0$ | Sol | Nontrivial $T^2$-bundles over $S^1$ | $N$ | 0 | Graph | Barrel |
| V, $VII_h$ | $H^3$ | Closed hyperbolizable manifolds | $N$ | $<0$ ? | Hyper | None |

listed in the "Typical examples" column are irreducible with the exception of $S^1 \times S^2$, which is prime but not irreducible. Also, in this column, $p \geq 2$.

In this table, the eight Thurston types are grouped into three sets according to their Yamabe type. The first set of such Bianchi models are those that spatially compactify to yield 3-manifolds of positive Yamabe type which allow metrics with positive constant scalar curvature, for example, Bianchi IX models defined over spherical space forms. The second set (consisting of one type) yields manifolds of zero Yamabe type which allow zero scalar curvature metrics but not constant positive scalar curvature metrics, for example, Bianchi I models defined over $T^3$ or one of the other five manifolds of flat type finitely covered by $T^3$. The third set (the last five entries in Table 1 and the set of most interest in this article) yields manifolds of negative Yamabe type which do not allow metrics with zero scalar curvature.

These latter models are the five Bianchi models of types II, III, VIII, $\mathrm{VI}_0$, and V (and in part $\mathrm{VII}_h$), which in turn correspond in Thurston's classification to manifolds of type Nil, $H^2 \times R, \widetilde{\mathrm{SL}(2, R)}$, Sol, and $H^3$, respectively.

In the first three cases, the models of Bianchi type II, III, and VIII compactify to a nontrivial $S^1$-bundle over $T^2$ or to a trivial or nontrivial $S^1$-bundle over $\Sigma_p^2, p \geq 2$, respectively. Each of these spaces is Seifert fibered. In the fourth case, the model of Bianchi type $\mathrm{VI}_0$ compactifies to a nontrivial $T^2$-bundle over $S^1$ which is an irreducible graph manifold. Since each of these manifolds is also of negative Yamabe type, in each of these four cases, as discussed in the beginning of this section, $\sigma(M) = 0$. In the fifth case, we consider vacuum Bianchi V metrics as well as a special case of Bianchi type $\mathrm{VII_h}$ which compactify to an arbitrary closed oriented hyperbolizable manifold $M$.

For these latter five Bianchi models that spatially compactify to manifolds of negative Yamabe type, one can consider the classical solutions from the point of view of Hamiltonian reduction. The starting point for this point of view is to use explicitly known vacuum metrics for the simplest "standard" metric forms, given, for example, in Wainwright and Ellis (1997). One need not consider all such possible spatially compact quotients, even though that would appear to be quite feasible, but one need only consider some representative examples for each of the Bianchi types listed.

It can be shown by explicit calculation, using the known solutions, that in the four nonhyperbolizable cases where $\sigma(M) = 0$, each of the classical Bianchi solutions gives rise to the existence of a positive semiglobal nonconstant solution to the reduced Einstein field equations and that along this solution, the reduced Hamiltonian asymptotically approaches 0 under the reduced Einstein flow, thereby confirming the expectation that the reduced Hamiltonian asymptotically approaches its infimum $((3/2)(-\sigma(M)))^{3/2} = 0$. Thus in these cases the reduced Einstein flow conformally volume-collapses the 3-manifold.

The explicit calculations also show the details of this collapse. In the second and third models of Bianchi type III, Thurston type $H^2 \times R$, and Bianchi type VIII, Thurston type $\widetilde{\mathrm{SL}(2, R)}$, respectively, the conformal metric degenerates along embedded circular fibers and this metric degeneration causes $M$ to collapse to its base manifold $\Sigma_p^2$, $p \geq 2$. Since the collapse is along one-dimensional fibers and since the two-dimensional base manifold $\Sigma_p^2$ does not collapse, we refer to this type of collapse as pancake collapse (see Figure 2).

In the fourth model of Bianchi type $\mathrm{VI}_0$, Thurston type Sol, the conformal metric degenerates along embedded $T^2$-fibers and this metric degeneration causes $M$ to collapse to its base manifold $S^1$. Since the collapse is along two-dimensional fibers and since the one-dimensional base manifold $S^1$ does not collapse, we refer to this type of collapse as barrel collapse (see Figure 3).

In the first model of Bianchi type II, Thurston type Nil, as in the second and third models, the conformal metric degenerates along embedded circular fibers. Additionally, not only do the circular fibers collapse but simultaneously the flat quotient 2-torus base manifold $T^2 \simeq M/S^1$ of $M$ modulo its circular fibers also collapses. Thus the metric degeneration collapses $M$ to a point, exhibiting a

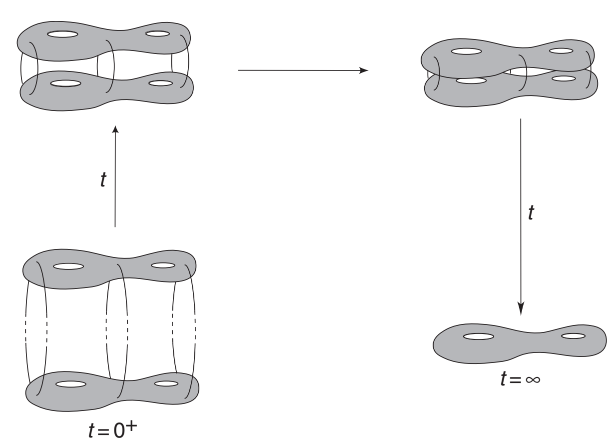

**Figure 2** Bianchi III, Thurston type $H^2 \times R, M = \Sigma_p^2 \times S^1$, pancake collapses to $\Sigma_p^2, p = 2$. The conformal geometry starts with an infinite $S^1$-fiber at the big bang ($t = 0^+$) and pancake collapses with bounded curvature to $\Sigma_2^2$ at infinite cosmological expansion ($t \rightarrow \infty$).

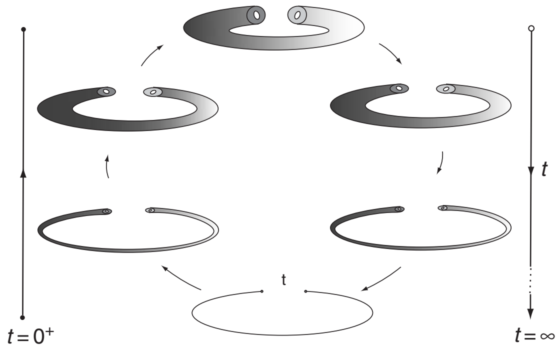

**Figure 3** Bianchi $VI_0$, Thurston type Sol, nontrivial $T^2$-bundle over $S^1$, barrel collapses to $S^1$. The conformal geometry evolves from a base manifold $S^1$ at the big bang ($t=0^+$). Instantaneously after the big bang, flat $T^2$-fibers bloom out of the collapsed $S^1$ state. The conformal metric then expands to a maximum volume and then barrel collapses with bounded curvature back to the base manifold $S^1$ at infinite physical cosmological expansion ($t \to \infty$). The two facial 2-tori are flat and are glued together by an orientation-reversing toral automorphism so as to give a nontrivial $T^2$-bundle over $S^1$. The gray-scale density grading along the tube also indicates the nontriviality of the bundle.

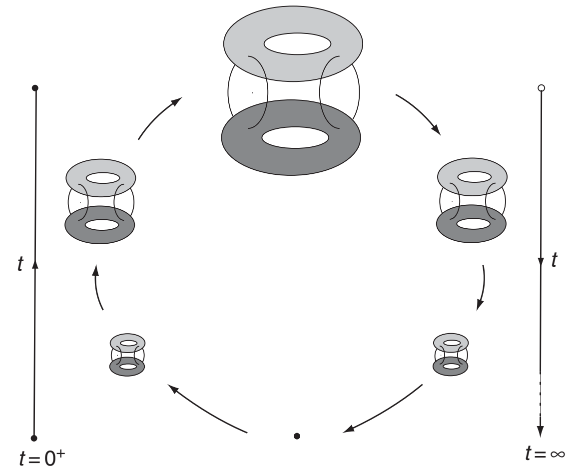

**Figure 4** Bianchi II, Thurston type Nil, nontrivial $S^1$-bundle over $T^2$, totally collapses to a point. The conformal geometry evolves from a point at the big bang ($t=0^+$). Instantaneously after the big bang, the full 3-manifold blooms out from that point. The conformal geometry then evolves to a metric of maximum volume and then totally collapses with bounded curvature back to a point at infinite physical cosmological expansion ($t \to \infty$). The two 2-tori, represented here by doughnuts, are flat and are glued together by an orientation-reversing toral automorphism so as to give a nontrivial $S^1$-bundle over $T^2$.

case of total collapse. Thus these model universes provide examples of nonflat almost-flat manifolds that exhibit total collapse with bounded curvature. Since the conformal geometries of these model universes collapse to a point, they aptly deserve their name Nil (see Figure 4).

Remarkably, in each of these four cases of collapse, the collapse occurs with bounded curvature, precisely as occurs in the totally different setting of the Cheeger–Gromov theory of collapsing Riemannian manifolds, recognized many years ago to be of importance in the understanding of the behavior of sequences of metrics with uniform curvature bound (see Gromov (1999) for references and Anderson (2004) for other applications of Cheeger–Gromov theory to general relativity). What is somewhat remarkable is that the above cosmological models were constructed completely independently of that setting and thus provide naturally occurring cosmological models whose closed spatial hypersurfaces undergo conformal volume collapse and metric degeneration exactly as occurs in the theory of collapsing Riemannian manifolds.

Of course, this volume collapse and metric degeneration only occur as described in the conformal variables. The physical variables behave differently. Indeed, in contrast to the conformal volume which collapses to zero in the first four cases and is constant in the hyperbolizable case (see below), the volume of the physical metric in all five cases goes to infinity since the flow is temporally oriented in the direction of infinite cosmological expansion.

In the fifth case where $M$ is hyperbolizable, $\sigma(M)$ is conjectured to be negative and to be determined by the hyperbolic volume, $\sigma(M) = -(\mathrm{vol}(M, \gamma_h))^{2/3}$, of the hyperbolic conformal metric $\gamma_h$ normalized so that $R(\gamma_h) = -1$. In this case, $\gamma_h$ together with $p^{\mathrm{TT}} = 0$ is a fixed point for the reduced Einstein flow so that trivially the conformal volume does not collapse. Moreover, if $\sigma(M)$ is determined by the volume of $\gamma_h$, then the constant reduced Hamiltonian also trivially achieves its infimum $H_{\mathrm{reduced}}(\tau, \gamma_h, 0) = ((3/2)\ (-\sigma(M)))^{3/2} = (3/2)^{3/2}$ (vol $(M, \gamma_h)$), again confirming the expectation for the behavior of $H_{\mathrm{reduced}}$ on these Bianchi models.

Note that for this static case, the physical variables behave as described after [46] and as shown in Figure 1. Also note that in contrast to Figures 2–4 where the conformal geometry is depicted, Figure 1 depicts the physical geometry.

Overall, in all five cases, subject in the hyperbolizable case to a hyperbolic metric realizing the $\sigma$-constant, the reduced Hamiltonian asymptotically approaches its $\sigma$-constant infimum along the flow lines of the reduced Einstein system. In doing so, the volumes of the conformal metrics either go to zero (in the first four cases) or to the hyperbolic volume (in the hyperbolic case). In all five cases, the curvature of the conformal metrics is uniformly bounded.

Because the reduced Einstein field equations behave as expected for the Bianchi models that we have considered with spatially compactified manifolds being either Seifert fibered, graph, or hyperbolizable, it seems plausible that for a more complicated starting manifold $M$, the reduced Einstein flow may induce a decomposition of $M$ into geometric pieces. Indeed, Anderson's conjectures (Anderson 1997) predict how a sequence of geometries with bounded curvature approaching $\sigma(M)$ degenerate. Assuming these conjectures, the asymptotic behavior of large classes of Einstein spacetimes may perhaps be characterized rather explicitly in terms of the geometrization program of 3-manifolds (see the next section).

Conversely, it is conceivable that the damped hyperbolic system of equations defined by the reduced Einstein flow (with its strictly monotonically decreasing reduced Hamiltonian on nonconstant curves) could be used to try to establish some form of the geometrization conjectures for 3-manifolds, much like the parabolic system of equations defined by Ricci flow is currently being used. If such a program were to be successful, it would amount to a spectacular consequence of Einstein's equations, implying as it does that geometrization may actually occur in nature.

## Possible Cosmological Applications of the Reduced Hamiltonian

Astronomical observations strongly support the view that in a sufficiently coarse-grained sense, the universe is homogeneous and isotropic. Furthermore, it is expanding at such a rate, relative to its observable energy density, that it will continue to expand forever. The simplest cosmological model consistent with these properties and which has a vacuum limit is the $k=-1$ FLRW model. Spatially compactified variants of this model are still locally homogeneous and isotropic even though they are no longer globally so (see the discussion after [46]). Evidence for one or another of the infinitely many compactifications possible could be sought in patterns of fluctuations of the cosmic microwave background radiation and the detection of such patterns could be strong evidence for a spatially closed universe.

However, is one really justified in extrapolating local observations of that portion of the universe visible to astronomers to a conclusion about its global topology? Could it be instead that there is a dynamical reason, provided by Einstein's equations, for the observed fact that the universe seems to be locally homogeneous and isotropic and in such a state as to continue expanding forever?

Suppose for the sake of argument that the universe has a more complicated topology, such as that of one of the generic $K(\boldsymbol{\pi},1)$-manifolds which does not admit a locally homogeneous and isotropic metric even though its hyperbolizable components would each individually do so. A plausible scenario suggested by the results in this article is that under the Einstein evolution, the reduced Hamiltonian given by [40] consisting of the rescaled spatial volume becomes asymptotically dominated in the future direction of cosmological expansion by the contribution of the hyperbolizable components. On each of these components, the limiting conformal metric approaches local homogeneity and isotropy with the relative contribution of the graph-manifold constituents, if any are present, collapsing asymptotically to a negligible fraction of the whole. The idea is that if structure formation develops sufficiently late in the evolution of such a universe, then it should occur, with overwhelmingly high probability, in those regions which dominate the conformal volume and admit an asymptotically locally homogeneous and isotropic metric of constant negative curvature, locally indistinguishable from a $k=-1$ FLRW model.

One can speculate still further and imagine what happens if the spatial topology is not of prime type but rather consists of a connected sum of several $K(\boldsymbol{\pi},1)$'s together perhaps with nontrivial spherical manifolds $S^3/\Gamma$ and handles $S^1\times S^2$. Here it seems conceivable, especially in view of the expected tendency of spherical manifolds to "recollapse," that the evolving universe would develop pinch-off singularities along the essential 2-spheres that separate the individual prime factors. Such singularities might occur in finite time between connected sums of spherical recollapsing factors or in infinite time between connected sums of $K(\boldsymbol{\pi},1)$-factors. Similar patterns of singularity formation are seen to occur in Ricci flow and must be treated in the resolution of the 3-manifold geometrization program.

Of course there is no proof of such behavior for the full $(3+1)$-dimensional Einstein gravity but for the model problem of Einstein's theory in $(2+1)$ dimensions, something close to a proof of the analogous conjecture is already at hand. In the vacuum case, which can be described rather explicitly, one can construct the generic solution for a higher genus surface topology by cutting open the corresponding $k=-1$ FLRW model and gluing in the so-called Kazner wedges. These wedges play the role of the graph-manifold constituents of a generic $K(\boldsymbol{\pi},1)$-manifold in three dimensions and evolve anisotropically. However, it is known rigorously in this case that the rescaled spatial area $H_{\mathrm{reduced}}(\tau,\gamma,p^{\mathrm{TT}})=(-\tau)^2\mathrm{Area}(\Sigma_p^2,g)$ is asymptotically exhausted by the FLRW components with the contribution from the flat Kazner anisotropic pieces shrinking to zero in this

limit. If certain types of matter sources are included, for example, those analogous to terms which result from Kaluza–Klein reduction of vacuum gravity in $(3+1)$-dimensions, then a similar result can be proved at least for sufficiently small but fully nonlinear perturbations away from the vacuum backgrounds (see Choquet-Bruhat (2004)).

In fully general $(3+1)$-dimensional gravity, there are few known topologically general results beyond those mentioned earlier and the problem is complicated by the presence of gravitational waves (which are absent in $(2+1)$ dimensions) and the fact that on such more general manifolds, there are no known "background" solutions to perturb about. However, for the special case of (future) vacuum evolution on a pure closed hyperbolizable manifold, one can show that if the initial data is sufficiently close to that of an FLRW model, then the fully nonlinear gravitational perturbations eventually die out leaving a locally homogeneous and isotropic model in the asymptotic limit (see Andersson and Moncrief (2004)). It seems likely that this result can be generalized to allow for the inclusion of various types of matter sources as in the $(2+1)$-dimensional case.

## Acknowledgments

This research was supported in part by NSF grant PHY-0354391 to Yale University. We would also like to thank the Institut des Hautes Études Scientifiques, the Max-Planck-Institut für Gravitationsphysik, Albert-Einstein-Institut, and The Erwin Schrödinger International Institute for Mathematical Physics for their hospitality and support for several periods during which this research was carried out.

# Hamiltonian Systems: Obstructions to Integrability

**M Irigoyen**, Université P.-M. Curie, Paris VI, Paris, France

## Introduction

In the study of differential systems, and particularly of Hamiltonian differential equations, a fundamental problem is the question of their integrability. Because there are different definitions of this notion, a system which is integrable according to one definition can be nonintegrable according to another one. The notion of integrability is connected to the existence of a sufficiently large number of first integrals, which are linked to conservation laws. For a real analytic Hamiltonian system with $n$ degrees of freedom, the "complete integrability" means the existence of $n$ first integrals, which are functionally independent, and "in involution," in the entire phase space. These integrals can be functions of class $C^r$ ($r$ finite), $C^\infty$, or analytic.

For the classical problems of Hamiltonian mechanics which are integrable, their first integrals can be continued into the complex domain of the variables, as one-valued holomorphic, or meromorphic, functions of complex time. This fact leads to the concept of "complex integrability" of a system. Note that a real Hamiltonian system which is integrable may be nonintegrable in the complex domain, if the real first integrals cannot be continued as one-valued holomorphic functions of the complex time.

Generally, the branching of solutions of a system, as functions of complex time, is an obstruction to the existence of one-valued first integrals. To study this problem, one can, following Poincaré, expand the solutions in convergent series of a small parameter: this is the base of "perturbation methods," and the main fact is that a small perturbation of an integrable Hamiltonian system generally destroys its integrability. Another method of proving nonintegrability consists of studying the linearized equations along a particular solution. This last direction has been exploited recently, in particular, through methods based on algebraic results inspired by differential Galois theory.

## Hamiltonian Systems and Mechanics

Let us consider a conservative holonomic real dynamical system with $n$ degrees of freedom: the positions of this system are points of an $n$-dimensional real manifold $N$ (the state space or configuration space) with local coordinates $x_1, x_2, \ldots, x_n$. If the velocities are denoted by $\dot{x}_i = \mathrm{d}x_i/\mathrm{d}t$, we consider the Lagrangian function $L$ associated to this system:

$$L(x_1, \ldots, x_n, \dot{x}_1, \ldots, \dot{x}_n) = T(x_1, \ldots, x_n, \dot{x}_1, \ldots, \dot{x}_n) + V(x_1, \ldots, x_n)$$

where $\dot{x} = (\dot{x}_1, \ldots, \dot{x}_n)$ is a tangent vector to the manifold $N$ at the point $x = (x_1, \ldots, x_n)$. The kinetic energy $T(x, \dot{x})$ is a positive-definite quadratic form in $\dot{x}_1, \ldots, \dot{x}_n$, and $V(x)$ is the potential energy, whose gradient determines the forces acting on the system.

The motions $(x_1(t), x_2(t), \ldots, x_n(t))$ of the system on the manifold $N$ are the extremals of the action integral: $\int_{t_1}^{t_2} L(x_1, \ldots, x_n, \dot{x}_1, \ldots, \dot{x}_n)\,\mathrm{d}t$ ("principle of stationary action of Hamilton") and they are the solutions of the Euler–Lagrange system, which consists in $n$ differential equations of second order for the coordinates $x_1, x_2, \ldots, x_n$ (Whittaker 1904):

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{x}_i}\right) - \frac{\partial L}{\partial x_i} = 0, \quad 1 \leq i \leq n$$

This system can be written in the Hamiltonian form: the Lagrangian $L$ is a function defined on the tangent bundle $TN$ of the state space $N$, with local coordinates $x_1, \ldots, x_n, \dot{x}_1, \ldots, \dot{x}_n$ (i.e., an element of $TN$ consists in a point $\boldsymbol{x}$ of $N$, joint with a tangent vector to $N$ at $\boldsymbol{x}$). Now, we consider the cotangent bundle $T^*N$: an element of $T^*N$ consists in a point $\boldsymbol{x}$ of $N$ joint with a cotangent vector to $N$ at $\boldsymbol{x}$, that is, a linear form defined in the tangent space to $N$ at $\boldsymbol{x}$. In local coordinates, the components of this linear form are $y_1, \ldots, y_n$, defined by: $y_i = \partial L/\partial \dot{x}_i$ ; $y_1, \ldots, y_n$ are called the generalized momenta, or impulsions. $x_i$ and $y_i$ are called conjugate canonical variables.

The mapping from $TN$ to $T^*N$ thus defined is the Legendre transformation (Abraham and Marsden 1967). Through it, the Euler–Lagrange equations become a system of $2n$ differential equations of first order:

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = \frac{\partial H}{\partial y_i}, \quad \frac{\mathrm{d}y_i}{\mathrm{d}t} = -\frac{\partial H}{\partial x_i}, \qquad 1 \leq i \leq n$$

where $H(x_1, \ldots, x_n, y_1, \ldots, y_n) = T(x_1, \ldots, x_n, y_1, \ldots, y_n) - V(x_1, \ldots, x_n)$.

$H$ is the Hamiltonian function of this system. The solutions of these differential equations are curves on the $2n$-dimensional manifold $T^*N$, whose projections in the $n$-dimensional state manifold $N$ coincide with the solutions of the Lagrangian system. $T^*N$ is

called the phase space of the system. The second members of the differential system define a vector field in the phase space.

Let $M = T^*N$. On this $2n$-dimensional manifold, consider the standard symplectic form $\Omega = \sum_{i=1}^{n} \mathrm{d}y_i \wedge \mathrm{d}x_i$. If $f$ and $g$ are $C^\infty$-functions on $M$, we define their Poisson bracket $\{f, g\}$ in local coordinates by

$$\{f, g\} = \sum_{i=1}^{n} \left( \frac{\partial f}{\partial x_i} \frac{\partial g}{\partial y_i} - \frac{\partial f}{\partial y_i} \frac{\partial g}{\partial x_i} \right)$$

It defines the space $C^\infty(M)$ as a Lie algebra over $R$.

Then, if $H \in C^\infty(M)$ is the Hamiltonian function associated to a system, the corresponding Hamiltonian equations can be written as the following $2n$ "canonical equations" (Arnol'd 1976):

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = \{x_i, H\} = \frac{\partial H}{\partial y_i}, \quad \frac{\mathrm{d}y_i}{\mathrm{d}t} = \{y_i, H\} = -\frac{\partial H}{\partial x_i}, \quad 1 \le i \le n \qquad [1]$$

A function $F \in C^\infty(M)$ is a (first) integral of eqns [1] if it is constant along any solution of [1], that is, if it verifies: $\{F, H\} = 0$. Thus, a first integral is a quantity which is preserved along a solution ("conservation law"). In particular, $H$ itself is a first integral of the eqns [1]. It represents the "total energy" of the system.

1. The simplest example of Hamiltonian system is the harmonic oscillator defined by the one degree of freedom Hamiltonian:

$$H(x, y) = \tfrac{1}{2} y^2 + \tfrac{1}{2} x^2$$

It possesses the energy integral $H$. Thus, the trajectories in the phase space $R^2$ (phase plane) are given by $x^2 + y^2 = 2h$, which are concentric circles if the constant energy verifies $h \ge 0$. The phase space $R^2$ is foliated by these circles. The system is said to be "integrable." Obviously, it is also possible to construct Hamiltonian systems with $n$ degrees of freedom ($n \succ 1$), by coupling $n$ harmonic oscillators, with a Hamiltonian defined by

$$H(x_1, \ldots, x_n, y_1, \ldots, y_n) = \frac{1}{2} \sum_{i=1}^{n} {y_i}^2 + \sum_{i=1}^{n} a_i {x_i}^2$$

with $n$ constant coefficients $a_i \succ 0$.

2. Another example of Hamiltonian system with one degree of freedom is the simple mathematical pendulum. The state coordinate is the angle $\theta$ of the pendulum with the vertical axis, defined modulo $2\pi$. The phase space is: $M = S^1 \times R$ ($x = \theta (\mathrm{mod}\, 2\pi) \in S^1, y \in R$),that is, a cylinder. The Hamiltonian function is: $H(x, y) = (1/2)y^2 - \cos x$; $H$ is a first integral of the differential equations, the system is integrable and the trajectories on the cylinder $S^1 \times R$ are defined by $(1/2)y^2 - \cos x = h$. According to the constant value of $h$ on each phase curve, the solutions are periodic oscillations of the pendulum (if $h \prec h_0$), periodic solutions of rotation where the angle varies monotonically with time (if $h \succ h_0$), two equilibria (one stable, one unstable) and solutions which "begin" when $t \to -\infty$ at the unstable equilibrium and "finish" when $t \to +\infty$ at the same point (if $h = h_0$): the corresponding phase curves are called "separatrices."

3. The system of Hénon–Heiles (Hénon and Heiles 1964) is a system with two degrees of freedom. The phase space is $R^2 \times R^2$ and the Hamiltonian is defined by

$$H(x_1, x_2, y_1, y_2) = \tfrac{1}{2}({y_1}^2 + {y_2}^2) + \tfrac{1}{2}({x_1}^2 + {x_2}^2) + {x_1}^2 x_2 - \lambda {x_2}^3$$

where $\lambda$ is a real constant. This system is "integrable" for some isolated values of the parameter $\lambda$ (Ziglin 1983) and "nonintegrable" otherwise. Of course, it is necessary to define the integrability of a Hamiltonian system, although according to Poincaré: "A system of differential equations is only more or less integrable."

## Integrability of Hamiltonian Systems

Generally, if a differential system is of order $p$, it is necessary to know $p$ first integrals to integrate it. But if the system is Hamiltonian of order $2n$, only $n$ first integrals are sufficient to integrate it "by quadratures," that is, by "algebraic" operations such as integrations and inverting of functions. The reason is that the existence of one first integral allows us to reduce the order of the system by two: a system of order $2n$ with one first integral can be reduced to order $2n - 2$.

**Theorem of Liouville** (see Arnol'd (1976)). *Suppose that $F_1, F_2, \ldots, F_n \in C^\infty(M)$ are $n$ first integrals of the Hamiltonian system [1] which are "in involution," that is, such that: $\{F_i, F_j\} = 0, \forall i, j$, and suppose that they are functionally independent, that is, the $n$ differentials, $\mathrm{d}F_i$, are linearly independent at each point of the level set $M_f$ defined by*

$$M_f = \{(x_1, \ldots, x_n, y_1, \ldots, y_n) \in M : F_i(x_1, \ldots, y_1, \ldots) = f_i, i = 1, 2, \ldots, n\}$$

*Then*

(i) *the set $M_f$ is a manifold which is invariant along the solutions of the system [1];*

(ii) *if $M_f$ is compact and connected, it is diffeomorphic to an $n$-dimensional torus*

$$T^n = S^1 \times S^1 \times \cdots \times S^1 = \{(\varphi_1, \ldots, \varphi_n) : \varphi_i \in R/2\pi Z\};$$

(iii) *the Hamiltonian flow on each torus* $M_f$ *is linear and "quasiperiodic" with frequencies* $\omega_i$ *defined by* $\mathrm{d}\varphi_i/\mathrm{d}t = \omega_i(f_1, f_2, \ldots, f_n)$; *and*
(iv) *the Hamiltonian equations are integrable by quadratures.*

If a Hamiltonian verifies the assumptions of the theorem of Liouville, one can prove that it exists, locally, canonical coordinates $\boldsymbol{\varphi} = (\varphi_1, \ldots, \varphi_n)$ and $\boldsymbol{I} = (I_1, \ldots, I_n)$ such that the Hamiltonian function depends only on the variables $I_i$. Then

$$\frac{\mathrm{d}\varphi_i}{\mathrm{d}t} = \frac{\partial H}{\partial I_i}$$
$$\frac{\mathrm{d}I_i}{\mathrm{d}t} = -\frac{\partial H}{\partial \varphi_i} = 0$$

These equations are immediately integrated as follows:

$I_i = \text{constant}$, and $\varphi_i = \omega_i \cdot t + \varphi_i(0)$, with

$$\omega_i(I_1, I_2, \ldots, I_n) = \left.\frac{\partial H}{\partial I_i}\right|_{I=cst}$$

Such local coordinates $(\varphi_i, I_i)$ are called "action-angle" variables. They were defined for the first time by Delaunay and they play an important part in the theory of perturbations.

**Remark** An invariant torus $T^n$ of the theorem of Liouville is characterized by the constant values of the actions $I_i$, which determine the frequencies $\omega_i$ on it. Such a torus is said to be nonresonant if the relation between the frequencies $\omega_i$: $\sum_{i=1}^{n} k_i \omega_i = 0$ (where $k_1, \ldots, k_n$ are integers) implies that $k_i = 0, \forall i$. The frequencies $\omega_i$ are then rationally independent. If a torus is nonresonant, the phase trajectories are dense everywhere and the motion is quasiperiodic on it.

A torus is said to be resonant, if the frequencies $\omega_i$ are rationally dependent: they verify a relation $\sum_{i=1}^{n} k_i \cdot \omega_i = 0$, with $(k_1, \ldots, k_n) \neq (0, \ldots, 0)$. Then the phase trajectories are not dense on the torus; they belong to tori of lower dimension.

A consequence of the theorem of Liouville is that, if a two-degree-of-freedom Hamiltonian system possesses one first integral $F$ (in addition to $H$, and independent of $H$), it is integrable because $F$ is necessarily in involution with $H$: $\{F, H\} = 0$.

An example of system with three degrees of freedom which is integrable is the Lagrangian symmetric top with one fixed point (there exists a cylindric symmetry for the inertia momenta and the center of mass is on the symmetry axis). This system possesses three first integrals that are in involution and independent: $H$, and the angular momenta $M_z$ and $M_3$, which correspond to the (constant) frequencies of precession and nutation of the top. The level sets $M_f$ are here tori of dimension 3, which are indexed by the three frequencies (or by the constant values of the three integrals).

There are other integrable cases for this problem of a rigid body with a fixed point (see Kozlov (1983)): the Euler's case (when the fixed point is the center of mass); the Kowalevskaya's case (in which the inertia momenta verify two relations and the third coordinate of the center of mass vanishes – see Kowalevski (1889)); and the Goryachev–Chaplygin's case, which is integrable only on a single integral level.

A fundamental and classical example of integrable Hamiltonian system is the Kepler's problem: the motion of a ponctual mass in the gravitational (Newtonian) field of a center, for instance, a planet in the field of attraction of the Sun.

Another example is the problem of two fixed centers: an infinitesimal mass in the field of two centers, problem which was integrated by Lagrange (Lagrange, 1810).

## Isolated Periodic Orbits and Nonintegrability

We consider a real Hamiltonian system with $n$ degrees of freedom and we suppose that there exists a particular $T$-periodic solution $\Gamma_T$ (which is not an equilibrium). Along $\Gamma_T$, we consider the linearized equations deduced from the Hamiltonian system. They can be decoupled into the tangential equation (one degree of freedom) which possesses the first integral $\mathrm{d}H$ and the normal variational system which can be written as

$$\frac{\mathrm{d}\xi}{\mathrm{d}t} = J \cdot K(\Gamma_T(t)) \cdot \xi \qquad [2]$$

where

$$J = \begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix}$$

is the standard symplectic matrix of order $2(n-1)$ and $K(\Gamma_T(t))$ is a $T$-periodic matrix depending on the solution $\Gamma_T$.

The solutions of the linear system [2] form a vector space. As a definition, the monodromy matrix $M(T)$ expresses how fundamental solutions of the linear system [2] are transformed after one period $T$, that is, along the periodic closed orbit $\Gamma_T$:

$$\xi(t+T) = M(T) \cdot \xi(t)$$

Poincaré showed that if one of the eigenvalues of $M(T)$ is different from 1, then the periodic solution $\Gamma_T$ is isolated. Furthermore, if the number of first

integrals of the Hamiltonian system, independent along $\Gamma_T$, is equal to $k$, then at least $2k$ eigenvalues of $M(T)$ are equal to 1.

**Theorem** (Poincaré 1892). *If the Hamiltonian system possesses n integrals in involution, and independent along a periodic solution $\Gamma_T$, then $\Gamma_T$ is nonisolated.*

Then, if the Hamiltonian system possesses a dense set of isolated periodic orbits, it cannot have $n$ integrals in involution and independent in an open domain.

## Nearly Integrable Hamiltonian Systems, Theorem of Poincaré

Consider the Hamiltonian system with $n$ degrees of freedom, depending on a small real parameter $\varepsilon \in (-\varepsilon_0, +\varepsilon_0)$, defined by the analytic function $H$:

$$H(\boldsymbol{\varphi}, \boldsymbol{I}, \varepsilon) = H_0(\boldsymbol{I}) + \varepsilon \cdot H_1(\boldsymbol{\varphi}, \boldsymbol{I}) \qquad [3]$$

where $\boldsymbol{\varphi} = (\varphi_1, \ldots, \varphi_n) \in T^n, \boldsymbol{I} = (I_1, \ldots, I_n) \in R^n$, and where $H_1$ is periodic in the angles $\varphi_i$.

This system is called "nearly integrable" because when $\varepsilon = 0$, the "unperturbed system" $H_0$ is integrable in the action-angle variables $\boldsymbol{\varphi}, \boldsymbol{I}$:

$$H(\boldsymbol{\varphi}, \boldsymbol{I}, 0) = H_0(\boldsymbol{I})$$

then

$$\frac{\mathrm{d}\boldsymbol{I}}{\mathrm{d}t} = 0, \quad \frac{\mathrm{d}\boldsymbol{\varphi}}{\mathrm{d}t} = \frac{\partial H_0}{\partial \boldsymbol{I}} = \boldsymbol{\omega}(\boldsymbol{I})$$

system which can be integrated by quadratures:

$$\boldsymbol{I} = \boldsymbol{I}^0 \quad \text{and} \quad \boldsymbol{\varphi} = \boldsymbol{\varphi}^0 + \boldsymbol{\omega}(\boldsymbol{I}^0) \cdot t$$

According to the theorem of Liouville, the motion of the unperturbed problem takes place on $n$-dimensional tori $(S^1)^n$ in the phase space. On these invariant tori, indexed by the actions $\boldsymbol{I}$, the motion is generally quasiperiodic (if the frequencies $\boldsymbol{\omega}(\boldsymbol{I})$ are rationally independent).

We are now interested in studying the perturbed system [3] with $\varepsilon \neq 0$, and its integrability which is, according to Poincaré (1892), "the fundamental problem of dynamics." This problem of nearly integrable Hamiltonian systems is directly inspired by celestial mechanics where the motions in the solar system are, in a first approximation, described by the (integrable) Kepler's problem. In particular, the "restricted three-body problem" is the study of the motion of a planet in the gravitational field of the Sun, with the perturbative attraction of Jupiter. It is also the problem of the Moon in the field of the Earth, with the perturbative attraction of the Sun (Poincaré 1892).

**Theorem of Poincaré** (Poincaré 1892). *Assume that, in the Hamiltonian function* [3]:

(i) (*nondegeneracy condition*) *the unperturbed Hamiltonian $H_0$ is nondegenerate, that is,*

$$\det\left|\frac{\partial^2 H_0}{\partial I_i \partial I_j}\right| = \det\left|\frac{\partial \omega_i}{\partial I_j}\right| \neq 0$$

*in an open domain of the phase space;*

(ii) (*genericity condition*) *no coefficient $h_{\boldsymbol{k}}(\boldsymbol{I})$ in the Fourier expansion of $H_1$ with*

$$H_1(\boldsymbol{\varphi}, \boldsymbol{I}) = \sum_{\boldsymbol{k} \in Z^n} h_{\boldsymbol{k}}(\boldsymbol{I}) \cdot \mathrm{e}^{\mathrm{i}\langle \boldsymbol{k}, \boldsymbol{\varphi}\rangle}$$

*does identically vanish in the nonresonant domain $G \in R^n$ of the actions defined by*

$$G = \left\{ \boldsymbol{I} \in R^n : \sum_{i=1}^n k_i \cdot \omega_i(\boldsymbol{I}) = 0, \right.$$
$$\left. \text{iff } (k_1, \ldots, k_n) = (0, \ldots, 0) \right\}$$

*then, there is no analytic first integral $F(\boldsymbol{\varphi}, \boldsymbol{I}, \varepsilon)$ independent of the Hamiltonian function H.*

Thus, a perturbation of a nondegenerate integrable Hamiltonian system is generically nonintegrable.

When one wants to apply this theorem to celestial mechanics, a peculiarity is that the unperturbed problem corresponds to the Keplerian system, which is degenerate, and this is a specific difficulty of these systems.

## Splitting of Separatrices and Nonintegrability

Consider a Hamiltonian system with $n = 2$ (degrees of freedom) defined as in eqn [3] by a perturbation of an integrable Hamiltonian:

$$H(\varphi_1, \varphi_2, I_1, I_2, \varepsilon) = H_0(I_1, I_2) + \varepsilon \cdot H_1(\varphi_1, \varphi_2, I_1, I_2) \qquad [4]$$

The unperturbed problem is integrable and its four-dimensional phase space is foliated by two-dimensional invariant tori $T^2 : \boldsymbol{I} = \text{constant}$. If $H_0$ is nondegenerate, the nonresonant tori are dense and the resonant tori also are dense in the phase space.

According to Kolmogorov's theorem and the Kolomogorov–Arnol'd–Moser (KAM) theory (Arnol'd 1985), the majority of the nonresonant tori of the unperturbed problem $H_0$ are preserved in the full problem [4]: they are slightly deformed, and are invariant in the perturbed

system. The resonant tori of $H_0$ are destroyed in the perturbed problem.

Now we consider, in the phase space, a transverse surface $S$ to the invariant tori $T^2$ of the perturbed system. A trajectory of the system generated by [4], which crosses $S$ through a point $w_0$, will cross $S$ again, for the first time, through a point $w_1$: this defines the "first return map" or "Poincaré's map" $R: w_0 \mapsto R(w_0) = w_1$. $S$ is called a Poincaré's section. If $w_0$ belongs to a preserved invariant torus of the perturbed system, the successive points $w_0, w_1 = R(w_0)$, $w_2 = R(w_1)$, $w_3 = R(w_2), \dots$ belong to the intersection of this torus with $S$; thus, they belong to a curve diffeomorphic to a circle, which is an invariant curve of the map $R$. If $w_0$ does not belong to a preserved invariant torus of [4], the sequence of points $w_0, w_1, w_2, \dots$ through the Poincaré's map belongs to a curve much more complicated than a curve diffeomorphic to a circle (Poincaré 1890, Arnol'd 1985) and the "chaotic" behavior of this sequence is the mark of the nonintegrability of the system [4].

The best way of numerically showing the "evidence" of nonintegrability is to study the example of a system with "one and a half" degree of freedom, that is, a system with one degree of freedom whose Hamiltonian depends on time: $H(\varphi, I, t)$. An example of such a system is the problem of a mathematical pendulum whose length $l$ performs periodic oscillations, defined by the Hamiltonian function

$$H(\varphi, p, t) = \frac{p^2}{2} - \omega^2(1 + \varepsilon \cdot f(t)) \cdot \cos\varphi \qquad [5]$$

where $\varphi \in S^1$, $p \in R$, and $f$ is periodic of period $T$.

The unperturbed system ($\varepsilon = 0$) is integrable (one degree of freedom with a Hamiltonian independent of $t$):

$$H_0(\varphi, p) = \frac{p^2}{2} - \omega^2 \cdot \cos\varphi$$

The phase portrait of this problem is similar to the one of the simple mathematical pendulum of constant length: on the cylinder $S^1 \times R$ there are two equilibria (stable and unstable) and separatrices "beginning" and "finishing" at the hyperbolic point $\chi$. The invariant stable and unstable manifolds associated to $\chi$ and represented by these separatrices were called by Poincaré as "homoclinic" trajectories, because each of them, drawn on the phase cylinder, joins equilibrium $\chi$ to itself.

If $\varepsilon \neq 0$, we define a Poincaré section of the perturbed system [4] in the following way: from an initial point $w_0(\varphi_0, p_0, t_0)$, we consider the successive planes perpendicular to the $t$-axis in the "extended" phase space $\{(\varphi, p, t)\}$, defined by: $t_0, t_1 = t_0 + T$, $t_2 = t_0 + 2T$, $t_3 = t_0 + 3T, \dots$ and we look at the successive intersections of the orbit of $w_0$ with these planes: $w_0, w_1, w_2, \dots$. If we identify all the successive planes and if we draw on the same picture, the points $w_0, w_1, w_2, \dots$, we obtain a phase portrait in which the equilibria of the unperturbed problem are present, but the separatrix which "leaves" the point $\chi$ is not confounded with the separatrix which "ends" at $\chi$, as in the unperturbed problem: the two invariant curves are transversal to each other: they "split" and have an infinite number of intersections. This splitting is the traduction of the nonintegrability of the perturbed system [5].

A method to detect this splitting of separatrices consists in computing the Melnikov's function which gives a measure of the angle between the separatrices at their first intersection when they split.

Many concrete Hamiltonian systems have been studied by this method and numerical investigations on the splitting have permitted detection of their nonintegrability.

## Topological Obstructions to Integrability

We are interested in a natural mechanical system with two degrees of freedom and we suppose that the state space $N$ is a real analytic surface which is compact and orientable. Then, $N$ consists of a two-dimensional sphere with $k$ handles (or a torus with $k$ holes). The number $k$ is a topological invariant of the surface and is called the genus of $N$.

Let $H$ be the Hamiltonian function associated to this problem. The Hamiltonian system possesses the first integral $H$. It is completely integrable if and only if another analytic integral $F$ exists, functionally independent of $H$. In this case, the state space $N$ belongs necessarily to a very restrictive class of surfaces.

**Theorem** (Kozlov 1983). *If the genus $k$ of the state manifold $N$ is not equal to 0 or 1 (i.e., if $N$ is neither diffeomorphic to the sphere $S^2$ nor to the torus $T^2$), then the Hamiltonian system generated by $H$ does not possess a first integral, analytic on $T^*N$ and functionally independent of the energy integral $H$.*

Note that this theorem does not apply to first integrals which are $C^\infty$ only, and examples can be given which illustrate this case (Kozlov 1983, 1989).

For systems with more than two degrees of freedom, an open question is to know whether the complete integrability imposes restrictions to the topology of the state manifold $N$.

## Singular Point Analysis, Branching of Solutions and Ziglin's Theory

If we look at the classical Hamiltonian problems which have been integrated, their first integrals are real functions which can be continued in the complex domain as one-valued holomorphic or meromorphic functions of the complex time $t$ (polynomials, rational functions, etc.). This fact leads to the concept of "complex integrability." But the nonintegrability of a complex Hamiltonian system does not imply the nonintegrability of its restriction to the real domain: it may happen that a real analytic first integral does not possess a continuation in the complex domain as a meromorphic function.

Adopting this point of view, S Kowalevskaya (Kowalevski 1889) studied the problem of a top rotating around a fixed point, and she discovered a new case of integrability for this classical problem of Hamiltonian mechanics. She searched for conditions on the parameters such that the movable singularities of the solutions in the complex plane of time are poles (as a definition, a singularity is movable if its location in the complex domain depends on the initial conditions). Such differential systems are said to be of "Painlevé's type." In this case, the solutions are single valued in the complex $t$-plane and there is no branching of these solutions. The leading idea is the following: a first integral must be constant along a solution, and an eventual branching would change its value along a loop around a singularity in the complex $t$-plane. However, finite branchings of solutions can be compatible with integrability.

The main tool in this analysis is the calculation of the "Kowalevski's exponents" which determine the eventual branching of a solution around a singularity.

In spite of the efficiency of the Painlevé analysis for the search of integrable (or nonintegrable) systems, the relation between the analytic properties of their solutions (Painlevé) and their integrability in the sense of Liouville remains mysterious. The most fundamental result obtained in this field is a theorem of Adler and van Moerbeke which proves that, if a system has the Painlevé property and if it is integrable in the sense of Arnol'd–Liouville, then it is algebraically integrable (Adler and van Moerbeke 1989).

The discovery of S Kowalevskaya inspired Ziglin, who related the existence of meromorphic first integrals for a Hamiltonian system, to the properties of the linearized equations along a particular periodic solution of this system, especially to the monodromy group associated to this linear system. Ziglin used the constraints imposed to this monodromy group by the existence of first integrals.

Let us consider a Hamiltonian system defined on a complex analytic symplectic manifold of dimension $2n$, and suppose that there exists a family of periodic solutions $\Gamma$. The linearized equations deduced from the Hamiltonian system along $\Gamma$ are decoupled into tangential and normal equations. We are interested by the normal equations, which are linear with periodic coefficients.

**Ziglin's Theorem** (Ziglin 1983). *Assume that a Hamiltonian system has a family of particular solutions $\Gamma_h$ (which are not equilibria) parametrized by periodic functions of the complex time and depending analytically on a real parameter $h \in (h_1, h_2)$. Let $G$ be the monodromy group of the normal variational equation associated to the solution $\Gamma_h$. A monodromy matrix $g \in G$ is said to be nonresonant if every eigenvalue of $g$ is different from a root of unity. If the Hamiltonian system has a meromorphic integral $F$, functionally independent of the Hamiltonian $H$ in a neighborhood of $\Gamma_h$, and if the monodromy group $G$ contains a nonresonant element $g_1$, then for any $g_2 \in G$, the commutator $g^* = g_2^{-1} \cdot g_1^{-1} \cdot g_2 \cdot g_1$ satisfies either $g^* = \mathrm{Id}$ or $g^* = (g_1)^2$.*

As a corollary of this theorem, we have sufficient conditions of nonintegrability: if the necessary conditions of integrability of Ziglin are not satisfied by a Hamiltonian system, it is not analytically integrable. For instance, this will happen if we can find two nonresonant monodromy matrices $g_1$ and $g_2$ which do not commute. If the periodic solution $\Gamma_h$ has two complex periods, the monodromy group $G$ has generators $g_1$ and $g_2$, respectively associated to each of these periods and their commutativity can be sometimes studied.

These sufficient conditions of nonintegrability were studied for particular Hamiltonian systems, first by Ziglin himself.

Several concrete systems with two degrees of freedom were proved to be nonintegrable by Ito, Yoshida, Churchill, Rod, and many other mathematicians who applied this "Ziglin's method": for instance, the Hénon–Heiles system, the Yang–Mills system, and Hamiltonian systems with a homogeneous potential.

## Nonintegrability and Differential Galois Theory (Morales-Ruiz 1999)

Recently, the integrability of Hamiltonian systems was studied with algebraic tools from the differential Galois theory, applied to linear differential

systems. As in Ziglin's theory, we consider a particular solution $\Gamma$ (not necessarily periodic) of a differential system generated by an analytic Hamiltonian $H$ with $n$ degrees of freedom, and the (linear) variational equations along $\Gamma$. The idea is that, if the Hamiltonian system is integrable, we can assume that the linearized equations along $\Gamma$ must also have a "regular behavior." If the Hamiltonian system is integrable, it will also be the case for the variational equations.

The normal variational system (of order $2n-2$) can be written as

$$\frac{d\xi}{dt} = J \cdot K(\Gamma(t)) \cdot \xi \qquad [6]$$

with

$$J = \begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix}$$

$K(\Gamma(t))$ is a matrix depending on the particular solution $\Gamma$.

We have to define the "Galois group" of the linear equation [6]. Recall that in the classical Galois theory of algebraic equations, the Galois group is defined by the automorphisms which map roots onto roots of the equation. In an analogous way, in the differential Galois theory, we consider the maps which send a fundamental solution of eqn [6] on a fundamental solution. In order to define the Galois group $G$ associated to [6], we consider a differential field $K$ of functions over $C$ (i.e., a field of functions equipped with a derivation). The field of constants of $K$ is $C$; it is the subfield of $K$ whose elements have a derivative equal to zero. We denote by $K\langle\xi, \eta, \ldots\rangle$ the differential field extension obtained from $K$ by the adjunction of the functions $\xi, \eta, \ldots$. If $(\varphi, \psi)$ is a fundamental system of solutions of eqn [6], then $L = K\langle\varphi, \psi\rangle$ is the smallest differential field extension which contains all the solutions of [6]. The field of constants of $L$ is the same as the one of $K$, that is, $C$. By definition, $L$ is a Picard–Vessiot extension of $K$.

The differential Galois group of $L$ is defined as the group of the automorphisms $\gamma$ of $L$ (that map a solution of [6] onto a solution) leaving the field of constants fixed. Given a fundamental system of solutions $(\varphi, \psi)$, we can associate to each automorphism $\gamma$ the matrix $M$ such that $(\gamma(\varphi), \gamma(\psi)) = (\varphi, \psi).M$. By definition, the set of these matrices $M$ is the Galois group $G$ of eqn [6]. It is a linear algebraic group (because, the matrices $M$ being symplectic, their coefficients verify polynomial equations) and a subgroup of the linear group of matrices GL($C$). We note that, for a given linear system, the monodromy group is contained in the Galois group and both are subgroups of the symplectic group Sp($C$).

In the Galois group $G$ of eqn [6], we consider $G^0$, the connected component of the identity. The integrability of the initial Hamiltonian system is connected to the integrability of the variational equation [6] and, through it, to the properties of its Galois group:

**Theorem of Morales and Ramis** (Morales-Ruiz 1999). *If an analytic Hamiltonian system is completely integrable, then the Galois group associated to the variational equation along a particular solution $\Gamma$ is such that its connected component of identity $G^0$ is Abelian.*

Thus, if a Hamiltonian system is such that $G^0$ is not Abelian, there cannot exist a complete set of first integrals in involution in a neighborhood of the particular solution $\Gamma$ and the system is not integrable.

In the concrete applications of this theory, an algorithm of Kovacic allows us to determine the Galois group explicitly. By this method, several Hamiltonian systems were proved to be nonintegrable: for instance, systems of points on a line with a potential in $1/r^2$, studied by Julliard-Tosel (1998), but also ancient proofs of nonintegrability of homogeneous potentials, which were improved by Yoshida and Umeno, thanks to the theorem of Morales–Ramis.

# Hamiltonian Systems: Stability and Instability Theory

**P Bernard**, Université de Paris Dauphine, Paris, France

The solar system has long appeared to astronomers and mathematicians as a model of stability. On the other hand, statistical mechanics relies on the assumption that large assemblies of particles form highly unstable systems (at the microscopic scale). Yet all these physical situations are described, at least to a certain degree of approximation, by Hamiltonian systems.

One may hope that Hamiltonian systems can be classified in two different categories, stable and unstable ones. However, the situation is much more complicated and both stable and unstable behaviors cohabit in typical systems. Even our examples are not perfect paradigms of stability and instability. Indeed, it is now clear from numerical as well as theoretical points of views that some instability is present over long timescales in the solar systems, so that for example future collisions between planets cannot be completely ruled out in view of our present understanding. On the other hand, unexpected patterns of stability have been discovered in systems involving a large number of particles.

Understanding the impact of stable and unstable effects in Hamiltonian systems has been considered ever since Poincaré as one of the most important questions in dynamical systems. In this article, we will discuss model Hamiltonian systems of the form

$$H_\epsilon(q,p) = h(p) + \epsilon G_\epsilon(q,p)$$

where $(q,p) \in \mathbb{T}^d \times U$, with $U$ a bounded open subset of $\mathbb{R}^n$. Recall that the equations of motion are

$$\dot{q}(t) = \partial_p h(p) + \epsilon \partial_p G_\epsilon(q,p) \quad [1]$$

$$\dot{p}(t) = -\epsilon \partial_q G_\epsilon(q,p) \quad [2]$$

The textbook by Arnol'd (1964) is a good general introduction on Hamiltonian systems. We will always denote by $\omega(p)$ the frequency map $\partial_p h(p)$, which plays a crucial role. Here, as is obvious in [2], the action variables $p$ are preserved under the evolution in the unperturbed case $\epsilon = 0$. We will try to explain what is known on the evolution of these action variables for the perturbed system. As we will see, in many situations, these variables are extremely stable. For example, KAM theorem implies that, for a positive measure of initial conditions $(q_0, p_0)$ the trajectory $(q(t), p(t))$ satisfies $\|p(t) - p(0)\| \le C\epsilon$ for all times. Examples show that some initial conditions may lead to unstable trajectories, that is, trajectories such that $\|p(t) - p(0)\| \ge 1/C$ for some $t$ (depending on $\epsilon$) and some fixed constant $C$ independent of $\epsilon$. However, this is, as we will see, possible only for very large time $t$ (meaning that $t$ as a function of $\epsilon$ has to go to infinity very quickly when $\epsilon \longrightarrow 0$). The main questions here are to understand in what situation instability is or is not possible, and what kind of evolutions can have the action variable $p$. Another important question is to estimate the speed (as a function of the parameter $\epsilon$) of the evolutions of $p$.

### A Convention

We assume, unless otherwise stated, that the Hamiltonians are real analytic. The norm $|H|$ of the Hamiltonian $H$ is the uniform norm of its holomorphic extension to a certain complex strip. We do not specify the width of this strip. Whenever we consider a family $H_\epsilon, F_\epsilon \ldots$ of Hamiltonians, we mean that the norm $|H_\epsilon|$ is bounded when $\epsilon \longrightarrow 0$.

## Averaging and Exponential Stability

The first observation concerning the action variables is that they should evolve at a speed of the order of $\epsilon$. However, averaging effects occur. More precisely, in the equation $\dot{p}(t) = -\epsilon \partial_q H_\epsilon(q(t), p(t))$, the variable $q(t)$ is moving fast compared to $p(t)$. If the evolution of $q(t)$ nicely fills the torus $\mathbb{T}^n$, it is tempting to think that the averaged equation

$$\dot{\bar{p}}(t) = -\epsilon \bar{V}_\epsilon(\bar{p}(t))$$

should approximate accurately the actual behavior of $p(t)$, where

$$\bar{V}_\epsilon(p) := \int_{\mathbb{T}^d} \partial_q H(q,p)\, \mathrm{d}q$$

We have $\bar{V} \equiv 0$, which leads us to think that the evolution should consist mainly of oscillations of small amplitude with no large evolution. This reasoning is limited by the presence of resonances.

### Frequencies

A frequency $\omega \in \mathbb{R}^d$ is said to be resonant if there exists $k \in \mathbb{Z}^d_*(= \mathbb{Z}^d - \{0\})$ such that $\langle k, \omega \rangle = 0$. The resonance module of $\omega$,

$$Z(\omega) = \{k \in \mathbb{Z}^d / \langle k, \omega \rangle = 0\}$$

is a subgroup $\mathbb{Z}^d$; we denote by $R(\omega)$ the vector space generated by $Z(\omega)$ in $\mathbb{R}^d$. The order of resonance $r(\omega)$ is the dimension of $R(\omega)$. The main examples of resonances of order $r$ are the

frequencies $\omega = (\omega_1, 0)$, where $\omega_1 \in \mathbb{R}^{d-r}$ is nonresonant. This example is universal. Indeed, if $\omega$ is a resonant frequency, then there exists a matrix $A \in \mathrm{Gl}_d(\mathbb{Z})$ such that $A\omega = (\omega_1, 0)$, where $\omega_1 \in \mathbb{R}^{d-r}$ is not resonant. The matrix $A$ can be seen as a diffeomorphism of $\mathbb{T}^d$, which transports the constant vector field $\omega$ to the constant vector field $A\omega = (\omega_1, 0)$. It is useful to distinguish, among nonresonant frequencies, some which are sufficiently nonresonant. A frequency $\omega \in \mathbb{R}^d$ is called Diophantine if there exist real constants $\gamma > 0$ and $\tau \geq d$ such that

$$|\langle \omega, k \rangle| \geq \gamma \|k\|^{1-\tau}$$

for each $k \in \mathbb{Z}^d_*$. Finally, a frequency is called resonant Diophantine if there exists a matrix $A \in \mathrm{Gl}_n(\mathbb{Z})$ such that $\omega = A(\omega_1, 0)$, where $\omega_1 \in \mathbb{R}^{d_1}$ is a Diophantine frequency.

### Symplectic Diffeomorphisms and Normal Forms

An efficient mathematical method to take averaging effects into account is the use of normal forms. Normal form theory consists in finding new coordinates in which the fast angles have been eliminated from the equations up to a small remainder. This is done exploiting the existence of a large group of diffeomorphisms preserving the Hamiltonian structure of equations, called symplectic diffeomorphisms or canonical transformations. We refer the reader to standard textbooks for these notions, for example to Arnol'd (1964). An important point is that a symplectic diffeomorphism $\phi$ sends the trajectories of the Hamiltonian $H \circ \phi$ to the trajectories of the Hamiltonian $H$. A Hamiltonian $N(q, p)$ is said to be in $R$-normal form, where $R$ is a linear subspace of $\mathbb{R}^n$, if $\partial_q N \in R$ for each $(q, p)$. Let us give an illustrative result, taken from Lochak *et al.* (2003). Note that this result is not sufficient to obtain uniform stability estimates, as in Nekhoroshev theorem below. More precise normal form results are given in Nekhoroshev (1977) and Pöschel (1993).

### Normal Form Theorem

*Let $\omega_0 = \omega(p_0)$ be a given Diophantine or resonant-Diophantine frequency. Let us denote $B_r(p_0)$ the open ball of radius $r$ in $\mathbb{R}^d$ centered at $p_0$. There exists a constant $a$ which depends only on $\omega$, and constants $\epsilon_0 > 0$ and $C > 0$ such that the following holds: for each $\epsilon < \epsilon_0$, there exists an analytic symplectic embedding $\phi_\epsilon : \mathbb{T}^d \times B_{r(\epsilon)} \longrightarrow \mathbb{T}^d \times U$, which is $\epsilon$-close to identity and such that*

$$H_\epsilon \circ \phi_\epsilon(q, p) = h(p) + \epsilon N_\epsilon(q, p) + \mu(\epsilon) F_\epsilon(q, p)$$

*where $N$ is in $R(\omega_0)$-normal form, $r(\epsilon) \geq \sqrt{\epsilon}$, and $\mu(\epsilon) \leq e^{-C\epsilon^{-a}}$.*

This means that the motions with resonant initial conditions are confined, up to small oscillations, in the associated affine plane $p(0) + R(\omega(p(0))$ until they live in the domain of the normal form, or until time $\mu^{-1}(\epsilon)$.

### Geometry of Resonances

In view of the normal form theorem, we are led to consider the curves $P(\theta) : \mathbb{R} \longrightarrow \mathbb{R}^d$ which satisfy

$$P(\theta') - P(\theta) \in R(\omega(P(\theta)))$$

for each $\theta$ and $\theta'$. Indeed, it appears that these curves are the ones the action variables can follow on timescales not involving the remainders of the normal forms. Note that here the parameter $\theta$ is not the physical time. Assuming that $P(\theta)$ is such a curve, we can define the affine space

$$R := P(0) + \cap_{\theta \in \mathbb{R}} R(\omega(P(\theta)))$$

We then have $P(\theta) \in R$ for each $\theta$. In addition, each point $P(\theta), \theta \in \mathbb{R}$, is a critical point of the restriction $h_{|R}$ of the unperturbed Hamiltonian $h$ to the affine space $R$. It follows that the curve $P(\theta)$ has to be constant if the unperturbed Hamiltonian satisfies the following hypothesis.

### Nekhoroshev Steepness

*We say that the unperturbed Hamiltonian $h$ is steep if, for each affine subspace $\Lambda$ in $\mathbb{R}^d$, the restriction $h_{|\Lambda}$ has only isolated critical points.*

This formulation, due to Niederman, is much simpler than the equivalent one first given by Nekhoroshev. It turns out that this condition, which was made natural by our heuristic explanation, implies stability over exponential timescales for all initial conditions (see Nekhoroshev (1977)). We first need another condition.

### Kolmogorov Nondegeneracy

*We say that the unperturbed Hamiltonian $h$ is nondegenerate in the sense of Kolmogorov if it has nondegenerate Hessian at each point, or equivalently if the frequency map $p \longmapsto \omega(p)$ is an immersion.*

### Nekhoroshev Stability Theorem

*Assume that the unperturbed Hamiltonian does not have critical points ($\omega(p)$ does not vanish), satisfies Nekhoroshev steepness and Kolmogorov nondegeneracy conditions. Then there exists constants $a > 0$ and $b > 0$, which depend only on $h$, and constants $\epsilon_0 > 0$ and $C > 0$ such that the following holds: for $\epsilon < \epsilon_0$, each trajectory $(q_\epsilon(t), p_\epsilon(t))$ satisfies the estimate*

$$\|p_\epsilon(t) - p_\epsilon(0)\| \leq C\epsilon^b$$

*for all t such that* $|t| \leq e^{C\epsilon^{-a}}$.

### Herman's Example

In order to illustrate the necessity of the condition of steepness, let us consider the Hamiltonian

$$H_\epsilon(q_1, q_2, p_1, p_2) = p_1 p_2 + \epsilon V(q_1)$$

with $V : \mathbb{T} \longrightarrow \mathbb{R}$. The associated equations are

$$\dot{p}_2 = 0, \quad \dot{p}_1 = -V', \quad \dot{q}_1 = p_2, \quad \dot{q}_2 = p_1$$

The trajectories whose initial conditions are subjected to $p_2(0) = 0$ and $V'(q_1(0)) \neq 0$ satisfy

$$p_1(t) = p_1(0) - t\epsilon V'(q_1(0))$$
$$p_2(t) = 0, \qquad q_1(t) = q_1(0)$$

We see an evolution at speed $\epsilon$ of the action variable $p_1$ contradicting the conclusion of Nekhoroshev theorem. In this example, we have $R(\omega(p(t))) = \mathbb{R} \times \{0\}$, and $h_{|\mathbb{R} \times \{0\}} \equiv 0$, so that the curve

$$P(\theta) = (\theta, 0)$$

is indeed a curve of critical points of $h_{|\mathbb{R} \times \{0\}}$.

### Genericity of Steepness

The condition of steepness is frequently satisfied. In order to be more precise, we mention that, for $N \in \mathbb{N}$ large enough (how large depends on the dimension $d$), steepness is a generic condition in the finite-dimensional space of polynomials of degree less than $N$. Note in contrast that a quadratic Hamiltonian is steep if and only if it is positive definite. Finally, it is important to mention that convex Hamiltonians $h$ with positive-definite Hessian are steep. More generally, quasiconvex Hamiltonians are steep. A function $h : U \longrightarrow \mathbb{R}$ is said to be quasiconvex if, at each point, the restriction of its Hessian to the kernel of its differential is positive definite.

### The Quasiconvex Case

It is interesting to be more precise about the values of $a$ and $b$ in Nekhoroshev theorem. We shall do so in the quasiconvex case, which is the most stable case, and where much more is known. If $h$ is quasiconvex, one can take

$$a = b = \frac{1}{2d}$$

as was proved by Lochak (1992). It is a question of active present research whether these exponents are optimal. It now appears that this is almost so, and that the optimal exponent $a$ should not be larger than $1/2(d-3)$. That this exponent deteriorates as the dimension increases is of course very natural in the perspective of statistical mechanics. As a matter of fact, not only the exponent $a$ but also the threshold $\epsilon_0$ of validity of Nekhoroshev theorem deteriorates with the dimension, as was noticed in Bourgain and Kaloshin.

Another important fact was proved in Lochak (1992): in these expressions, the important value of $d$ is not the total number of degrees of freedom, but the number of active degrees of freedom. More precisely, resonant initial conditions are more stable than generic ones. If $r$ is the order of resonance of a given initial condition, then the number $d - r$ of fast angles can be substituted to the total number of degrees of freedom for the computation of the stability exponent. This phenomenon may account for the surprising stability obtained numerically by Fermi, Pasta, and Ulam.

## Permanent Stability

Many initial conditions satisfy more than exponential stability: they are permanently stable.

### Kolmogorov Theorem

*Assume that h satisfies Kolmogorov nondegeneracy condition* ("Kolmogorov nondegeneracy"). *Then for each open subset* $V \subset \mathbb{R}^d$ such that $\bar{V} \subset U$, *there exists* $\epsilon_0 > 0$ *such that, for each* $\epsilon < \epsilon_0$, *there exists*

- *a smooth symplectic embedding* $\phi_\epsilon : \mathbb{T}^d \times V \longrightarrow \mathbb{T}^d \times U$, *which is* $\epsilon$*-close to the identity*,
- *a compact subset* $F_\epsilon$ *of* $V$, *whose relative measure in* $V$ *is converging to 1 as* $\epsilon \longrightarrow 0$,

*such that the Hamiltonian system* $H_\epsilon \circ \phi_\epsilon$ *preserves the torus* $\mathbb{T}^d \times \{p\}$ *for each* $p \in F_\epsilon$.

The union

$$\mathcal{F}_\epsilon = \phi_\epsilon(\mathbb{T}^d \times F_\epsilon)$$

of all the invariant tori has positive measure. Its complement is usually an open dense subset of $\mathbb{T}^d \times U$. All the orbits starting in this invariant set obviously undergo oscillations of amplitude of the order of $\epsilon$ for all times. It is worth mentioning that some energy surfaces may not intersect the invariant set $\mathcal{F}_\epsilon$. This is illustrated in example, i.e., "Herman's example," where the surface of zero energy does not contain invariant tori. The following condition guarantees the existence of invariant tori on each energy surface.

#### Arnol'd Nondegeneracy

*The Hamiltonian $h$ is said to be nondegenerate in the sense of Arnol'd if it does not have critical points and if the map*

$$p \longmapsto \frac{\omega(p)}{\|\omega(p)\|}$$

*is a local diffeomorphism between each level set of $h$ and $S^{d-1}$. This is equivalent to say that the function $(\lambda, p) \in \mathbb{R} \times U \longmapsto \lambda h(p)$ has nondegenerate Hessian at each point of the form $(1, p)$.*

#### Arnol'd Theorem

If $h$ satisfies Arnol'd nondegeneracy condition, then the relative measure of the set $\mathcal{F}_\epsilon$ of invariant tori is converging to 1 in each energy surface.

This theorem prevents ergodicity of the perturbed systems for the canonical invariant measure on its energy surface. This may be considered as a very disappointing result for statistical mechanics, whose mathematical foundation has often been considered to be the Boltzmann hypothesis of ergodicity. However, statistical mechanics is first of all a question of letting $d$ go to infinity, and ergodicity might not be such a crucial hypothesis (see Khinchin).

When $d = 2$, the Arnol'd theorem has particularly strong consequences. Indeed, in this case, the invariant tori cut the energy surfaces in small connected components. The motion is then confined in these connected components. As a consequence, we obtain permanent stability for all initial conditions.

In higher dimensions however, the complement of $\mathcal{F}_\epsilon$ in each energy shell is usually a dense, connected open set. There may exist orbits wandering in this large connected set, although the speed of evolution of these orbits is limited by Nekhoroshev theory. Understanding the dynamics in this open set is a very important and difficult question. It is the subject of the next section.

#### Relaxed Assumption

For many applications, such as celestial mechanics, the nondegeneracy conditions of Arnol'd or Kolmogorov are not satisfied, or difficult to check. However, the existence of invariant tori has been proved under much milder assumptions. As a rule, invariant tori exist in the perturbed systems if the frequency map $p \longmapsto \omega(p)$ stably contains Diophantine vectors in its image.

## The Mechanism of Arnol'd

Understanding instability is the subject of intense present research. General methods of construction of interesting orbits as well as clever classes of examples are being developed. These methods are exploring the limits of stability theory. Here we shall only describe the fundamental ideas of Arnol'd (see Arnol'd 1964), where most of the present activity finds its roots. Although these ideas have some ambition of universality, they are best presented, like in Arnol'd (1964), on an example. We consider the quasiconvex Hamiltonian

$$\begin{aligned} H(q_1, q_2, q_3, p_1, p_2, p_3) \\ = (p_1^2 + p_2^2)/2 - p_3 + \epsilon \cos 2\pi q_2 \\ + \mu(\cos 2\pi q_2)(\cos 2\pi q_1 + \cos 2\pi q_3) \end{aligned}$$

As we have seen, this system is typical of the kind of Hamiltonians one gets after reduction to resonant normal form. However, it is illuminating to consider $\mu$ not as a function of $\epsilon$ but as an independent parameter. This is an idea of Poincaré then followed by Arnol'd. We shall expose the main steps of the proof of the following result.

#### Theorem

*Let us fix numbers $0 < A < B$. For each $\epsilon > 0$, there exists a number $\mu_0(\epsilon)$ such that, when $0 < \mu < \mu_0(\epsilon)$, there exists a trajectory*

$$(q_1(t), q_2(t), p_1(t), p_2(t))$$

*and a time $T > 0$ (which depends on $\epsilon$ and $\mu$) such that*

$$p_1(0) \leq A, \quad p_1(T) \geq B$$

#### The Truncated System

Let us begin with some remarks about the truncated Hamiltonian obtained when $\mu = 0$:

$$\begin{aligned} H_0(q, p) &= H_1(q_1, q_3, p_1, p_3) + H_2(q_2, p_2) \\ &= p_1^2/2 - p_3 + p_2^2/2 + \epsilon \cos 2\pi q_2 \end{aligned}$$

This system is the uncoupled product of $H_1$ and of the pendulum described by $H_2$. The variable $p_1$ is constant along motion; hence, the theorem can not hold for $\mu = 0$.

Recall that the point $q_2 = 0, p_2 = 0$ is a hyperbolic fixed point of the pendulum $H_2(q_2, p_2) = p_2^2/2 + \epsilon \cos 2\pi q_2$. The stable and unstable manifolds of this integrable system coincide; they form the energy level $H_2 = \epsilon$. As a consequence, in the product system of Hamiltonian $H_0 = H_1 + H_2$, there exists,

in the zero energy level, a one-parameter family $T_\omega$ of invariant tori of dimension 2:

$$T_\omega = \{p_1 = \omega, p_3 = \omega^2/2 + \epsilon, q_2 = 0, p_2 = 0\} \subset \mathbb{T}^3 \times \mathbb{R}^3$$

Each of these tori is hyperbolic in the sense that it has a stable manifold of dimension 3 and an unstable manifold of dimension 3, which are nothing but the liftings of the stable and unstable manifolds of the hyperbolic fixed point of $H_2$. Notice that these manifolds do not intersect transversally along $T_\omega$.

When $\mu \neq 0$, the perturbation is chosen in such a way that the tori $T_\omega$ are left invariant by the Hamiltonian flow.

### Splitting

*For* $0 < \mu < \mu_0(\epsilon)$, *the invariant tori* $T_\omega$ *still have stable and unstable manifolds of dimension 3. These stable and unstable manifolds intersect transversally in the energy surface*, *along an orbit which is homoclinic to the torus.*

The first point is that the tori remain hyperbolic, and that the stable and unstable manifolds are deformed, but not destroyed by the additional term. This results from the observation that the manifold $M$ formed by the union of the invariant tori is normally hyperbolic in its energy surface. Note that this step does not require exponential smallness of $\mu$.

It is then a very general result that the stable and unstable manifolds have nonempty intersection. It is a global property, which can be established by variational methods, and which still does not rest on exponential smallness of $\mu$.

The key point, where exponential smallness is required, is transversality. Since transversality is a generic phenomenon, one may think that this step is not so crucial. And indeed, it is very likely that the statement remains true for most values of $\mu \in ]0, \epsilon]$ (and not only for $\mu \leq \mu_0(\epsilon)$). However, there are two important issues here. First, transversality is difficult to establish on explicit examples. Second, it is useful for many further discussions to obtain some quantitative estimates.

Indeed, we can associate to the intersection between the stable and unstable manifolds a quantity, the splitting, which in a sense measures transversality. Discussions on such a definition are available in Lochak *et al.* (2003). Using methods of Poincaré and Melnikov, Arnol'd showed that this splitting can be estimated, for sufficiently small $\epsilon$, by

$$\alpha \geq \mu e^{-C/\sqrt{\epsilon}} + O(\mu^2) \qquad [3]$$

This implies non-nullity of the splitting, hence transversality, for small $\mu$.

### Transition Chain

We have established the existence, when $\mu > 0$ is small enough, of a family $T_\omega$ of hyperbolic invariant tori such that the stable manifold $W_\omega^+$ and the unstable manifold $W_\omega^-$ intersect transversally along a homoclinic orbit (but not along $T_\omega$!) for each $\omega$.

A stability argument shows that the stable manifold $W_\omega^+$ of the torus $T_\omega$ intersects transversally the stable manifold $W_{\omega_0}^-$ of the torus $T_{\omega_0}$ when $\omega$ is close enough to $\omega_0$. How close directly depends on the size of the splitting. We obtain heteroclinic orbits between tori close to each other.

Given two values $\omega$ and $\omega'$, we can find a sequence $\omega_i, 1 \leq i \leq N$, such that $\omega_0 = \omega, \omega_N = \omega'$, and $W_i^-$ intersects transversally $W_{i+1}^+$ for all $i$. The associated family $T_{\omega_i}$ of tori is called a transition chain.

The left step consists in proving that some orbits shadow the transition chain. Arnol'd solved this step by a very simple topological argument which, however, does not provide any estimate on the time $T$. He proves the existence of an orbit joining any neighborhood of $T_\omega$ to any neighborhood of $T_{\omega'}$. This ends the proof of the main theorem, since we can chose $\omega$ and $\omega'$ such that $\omega < A < B < \omega'$.

The dynamics associated to hyperbolic tori and transition chains have later been studied more carefully. It particular, a $\lambda$-lemma can be proved in this context, which allows us to conclude that, in a transition chain, the unstable manifold $W_0^-$ of the first torus intersects transversally the stable manifold of the last torus $W_N^+$. These detailed studies also allow us to relate the speed of diffusion to the splitting of the invariant manifolds.

### Diffusion Speed

It is interesting to estimate the speed of evolution of the variable $p_1$, or in other words the time $T$ in the statement. It follows from Nekhoroshev theory that this time $T$ has to be exponentially large as a function of $\epsilon$. In fact, it is possible to prove, either by recent developments on the ideas of Arnol'd exposed above, or more easily by variational methods, (Bessi 1996) that

$$T \leq \frac{e^{C/\sqrt{\epsilon}}}{-\mu \log \mu}$$

for $\mu \leq \mu_0(\epsilon)$. This time is of course highly related to the estimate [3] of the splitting. In addition, Ugo Bessi proved that one can take $\mu_0(\epsilon) = e^{-C/\sqrt{\epsilon}}$. Plugging this value of $\mu$ in the estimate of $T$, we get the estimate $T \leq e^{C/\sqrt{\epsilon}}$ as a function of the only parameter $\epsilon$.

Considering the fact that the orbit we have described goes close to double resonances, this is the best estimate one may hope for in view of the improved Nekhoroshev stability estimates at resonances.

The idea is now well spread that the time of diffusion is exponentially large. However, we point out that, if it is indeed exponentially small as a function of the parameter $\epsilon$, it is only polynomially small as a function of the second parameter $\mu$, as was first understood by P Lochak and proved in Bernard (1996) using the variational method of U Bessi.

## Conclusion

The theories of instability are developing in several directions. One of them is to try to understand the limits of stability, and to test to what extent the stability results obtained so far are optimal. This aspect has quickly developed recently, for example, the optimal stability exponent $a$ for convex systems is almost known. Another direction is to try to give a description of unstable orbits in typical systems. This remains a widely open question.

Let us finally mention that the application of the theories we have presented to concrete systems is very difficult. One of the reasons is that the estimates of the threshold $\epsilon_0$ of validity of Nekhoroshev and KAM theorems that can (painfully) be obtained by inspection in the proofs are very bad, and it is much too bad, for example, to think about applications to the solar systems with the physical values of the parameters.

# Hamilton–Jacobi Equations and Dynamical Systems: Variational Aspects

**A Siconolfi**, Università di Roma "La Sapienza", Rome, Italy

## Overview

Given a continuous Hamiltonian $H(x,p)$ defined on the cotangent bundle of a compact boundaryless manifold, where $x$ and $p$ are the state and the momentum variable, respectively, and satisfying suitable convexity and coercivity assumptions, we consider the family of Hamilton–Jacobi equations

$$H(x, D\phi) = a \qquad [1]$$

with $a$ a real parameter. If, in addition, $H$ is assumed to be smooth, we also consider the Hamilton's equations

$$\dot{\xi} = H_p(\xi, \eta), \qquad \dot{\eta} = -H_x(\xi, \eta) \qquad [2]$$

whose analysis is related to the variational problem of minimizing the action functional

$$\int_I L(\xi, \dot{\xi})\, dt \qquad [3]$$

among all Lipschitz–continuous or, equivalently, continuous piecewise $C^1$ curves defined on $I$ with fixed end points. Here $I$ is a compact interval and $L$, the Lagrangian, is the Fenchel transform of $H$. A "conjugate" flow, named after Euler–Lagrange, is

also defined on the tangent bundle of the underlying manifold.

A connection between [1] and [2] is provided by the classical Hamilton–Jacobi method, which shows that the graph of the differential of any regular, say $C^1$, global solution to [1] is an invariant subset for the Hamiltonian flow. The drawback of this approach is that such regular solutions do not exist in general, even for very regular Hamiltonians.

However, for any continuous Hamiltonian a distinguished value of the parameter $a$ can be detected, denoted by $c$ and qualified, from now on, as critical, for which there are a.e. subsolutions of the corresponding Hamilton–Jacobi equations enjoying some extremality properties. Note that such functions can be equivalently defined as weak solutions, in the viscosity sense, of [1] with $a = c$, or as fixed points of the associated Lax–Oleinik semigroup (see Fathi (to appear)). We do not give these interpretations here to avoid any technicalities.

Even if they are just Lipschitz–continuous on the whole underlying manifold, these extremal subsolutions become of class $C^1$, when restricted on a special compact subset, the same for any of them, say $\mathcal{A}$, and the corresponding differentials coincide on $\mathcal{A}$. More generally, all critical subsolutions, that is, the a.e. subsolutions to [1] with $a = c$, are continuously differentiable on $\mathcal{A}$. This regularity property holds if $H$ is at least locally Lipschitz–continuous in both variables. When, in addition, the Hamiltonian is smooth, so that the Hamiltonian flow is defined, the graph of this common differential defined in $\mathcal{A}$, denoted by $\tilde{\mathcal{A}}$, is an invariant set for the flow, and is foliated by integral curves of [1] possessing some global minimizing properties with respect to the action functional.

The aim of this presentation is to give an explanation of the previously described phenomena occurring at the critical level, and of some related facts, using tools and arguments as simply as possible. We propose a metric approach to the subject and consider as central in our analysis a family of distances, denoted by $S_a$, for any $a \geq c$. We emphasize that such distances can be defined for only continuous Hamiltonians, and the qualitative analysis of the critical subsolutions has an interest independent from the dynamical applications. Indeed, it can be used in other contexts such as in homogenization problems, and the large-time behavior of the viscosity solutions to the time-dependent equation $u_t + H(x, Du) = 0$.

The discovery of the critical value has a history that reflects the dual character of the topics, which has a dynamical as well as a partial differential equation (PDE) interest.

It was probably Ricardo Mañé who first focused his attention on it, at the beginning of the 1980s, in connection with the analysis of integral curves of the Euler–Lagrange flow with some global minimizing properties. The set, previously denoted by $\tilde{A}$, has been found and analyzed by Serge Aubry, in a purely dynamical way, as the union of the supports of such minimizing curves. On the other hand, John Mather (1986) independently defined, in a more general framework, a set, contained in the Aubry set, through a weak approach that utilizes minimal probability measures invariant with respect to the Euler–Lagrange flow. The Mather set is actually the closure of the union of the supports of such measures. We will follow the approach of Aubry (see Fathi (2005b)), and will not introduce the Mather's measures.

In the viscosity solution theory, the critical value has instead been introduced in a famous unpublished paper of P L Lions, S R S Varadhan, and G Papanicolaou (1987), in connection with some periodic homogenization problems for Hamilton–Jacobi equations. It is worth noticing that they consider continuous Hamiltonian, defined on the flat $N$-dimensional torus, without any convexity assumption.

They define the critical value, and show the existence of viscosity solutions to the critical equation by means of an ergodic approximation, that is, by considering the equation $\varepsilon u + H(x, Du) = 0$ and then passing to the limit for $\varepsilon \to 0$. The critical viscosity solutions are used as correctors in the homogenization. They do not perform any qualitative analysis, and if such analysis can be done, and something similar to the Aubry–Mather sets exists for nonconvex Hamiltonian this is still an important open problem.

The two pieces of the picture were pasted together by Fathi (1996) with his weak KAM theory (see Contreras and Iturriaga (1999) and Fathi (2005a) for a general treatment, where the relevance of the extremal critical subsolutions has first been recognized for the analysis of the dynamics, and the Aubry–Mather sets have been characterized as a regularity set for such subsolutions, as described above). Evans and co-workers have been presently using more general PDE methods in weak KAM theory to address some integrability issues and to find a quantum analog (see Evans and Gomes (2001, 2002) and Evans (2004)).

## Critical Value and Extremal Subsolutions

We consider the family of Hamilton–Jacobi equations [1] defined, for simplicity, on the flat torus $\mathbb{T}^N = \mathbb{R}^N/\mathbb{Z}^N$, endowed with the flat Riemannian

metric induced by the Euclidean metric on $\mathbb{R}^N$. The tangent, as well as the cotangent bundle of $\mathbb{T}^N$ will be identified with $\mathbb{T}^N \times \mathbb{R}^N$. All the results discussed in the remainder of the paper are still true in any compact boundaryless manifold, and some of them also hold in noncompact manifolds. We require $H$ to be continuous in both variables, to satisfy the coercivity assumption,

$$\{(y,p)\colon H(y,p) \le a\} \text{ is compact for any } a$$

and the following (strict) quasiconvexity conditions for any $x \in \mathbb{T}^N$, $a \in \mathbb{R}$:

$$\{p\colon H(y,p) \le a\} \text{ is strictly convex}$$
$$\partial\{p\colon H(y,p) \le a\} = \{p\colon H(y,p) = a\}$$

where $\partial$, in the above formula, indicates the boundary. We denote by $\mathcal{S}_a$ the (possibly empty) set of the Lipschitz–continuous a.e. subsolutions to [1]. They will be called in the sequel, for short, just subsolutions. Due to the convex character of the Hamiltonian and its continuity, the property of being a subsolution, for some function $u$, can be equivalently expressed by requiring the inequality $H(x,p) \le a$ to hold for any $x \in \mathbb{T}^N$ and any $p$ in the (Clarke) generalized gradient $\partial u(x)$, defined by

$$\partial u(x) = \mathrm{co}\{p = \lim_i Du(x_i)\colon x_i \text{ differentiability point of } u, \lim_i x_i = x\}$$

where co indicates the convex hull. Note that if this set of weak derivatives reduces to a singleton at some $x$, then the function $u$ is strictly differentiable at $x$, i.e., it is differentiable and $Du$ is continuous at $x$.

By a strict subsolution to [1] we mean a Lipschitz–continuous function $w$ with $\mathrm{ess\,sup}_{\mathbb{T}^N} H \times (x, Dw(x)) < a$. The property of being a (strict) subsolution is not affected by addition of constants. Moreover, the pointwise supremum (resp. infimum) of any class of equibounded subsolution to [1] is itself a subsolution, and $\mathcal{S}_a$ is stable with respect to the uniform convergence in $\mathbb{T}^N$.

The purpose of this section is to show that there is a unique value $c$ (the critical value) for which the corresponding equation

$$H(x, Du) = c \qquad [4]$$

possesses subsolutions enjoying some extremality properties. We, more precisely, call a subsolution $u \in \mathcal{S}_a$ maximal (resp. minimal) if for any open subset $\Omega$ of $\mathbb{T}^N$ and any Lipschitz–continuous function $\phi$ with

$$u = \phi \quad \text{on } \partial\Omega \quad \text{and} \quad \mathrm{ess\,sup}_\Omega H(x, D\phi(x)) < a \qquad [5]$$

one has $u \ge \phi$ (resp. $u \le \phi$) in $\Omega$.

Any maximal (resp. minimal) subsolution $u$ is actually an a.e. solution of [1]. If, in fact, $H(x_0, Du(x_0)) < a$ for some differentiability point $x_0$ of $u$, then the function $\phi(x) = u(x_0) + Du(x_0)(x - x_0) - \varepsilon|x - x_0| + \varepsilon$ (resp. $\phi(x) = u(x_0) + Du(x_0)(x - x_0) + \varepsilon|x - x_0| - \varepsilon$) should satisfy [5] for a suitable choice of $\varepsilon > 0$ and of a neighborhood $\Omega$ of $x_0$, and so should violate the maximality (resp. minimality) condition for $u$.

The previous argument can be easily adapted to show something more general: if $u$ is a maximal (resp. minimal) subsolution then no subtangents (resp. supertangents) to $u$ at any $y \in \mathbb{T}^N$ can be local strict subsolutions at $y$, that is, strict subsolutions in some neighborhood of $y$.

The subtangency (resp. supertangency) condition of a function $\phi$ to $u$ at a point $x_0$ means that $x_0$ is a local minimizer (resp. maximizer) of $u - \phi$. We denote by $D^-u(x_0)$ (resp. $D^+u(x_0)$) the sets made up by the differentials of the $C^1$-subtangent (resp. supertangent) to $u$ at $x_0$. They are (possibly empty) closed convex subsets of $\partial u(x_0)$. It is apparent that if $D^+u(x_0) \ne \emptyset \ne D^-u(x_0)$ then $u$ is differentiable at $x_0$ and $D^+u(x_0) = D^-u(x_0) = \{Du(x_0)\}$.

It is an immediate consequence of the previous fact that no extremal subsolutions can exist in $\mathcal{S}_a$, whenever [1] admits a strict subsolution, say $\phi$, since there are global minimizers and maximizers of $u - \phi$, for any $u \in \mathcal{S}_a$, because of the compactness of $\mathbb{T}^N$. The function $\phi$ is then subtangent and supertangent, respectively, to $u$ at such points.

The unique value we can look at for finding extremal subsolutions is therefore

$$c = \inf\{a \in \mathbb{R}\colon \mathcal{S}_a \ne \emptyset\} \qquad [6]$$

The set on the right-hand side of [6] is nonempty since the null function belongs to $\mathcal{S}_a$ when $a > \max_{\mathbb{T}^N} H(x,0)$, and bounded from below by $\min_{\mathbb{T}^N} H(x,0)$. The value $c$ is consequently well defined by [6].

Moreover, any sequence $u_n \in \mathcal{S}_{a_n}$, with $a_n$ decreasing and convergent to $c$, is equi-Lipschitz–continuous because of the coercivity of $H$, and equibounded, up to addition of suitable constants. It is therefore uniformly convergent, up to a subsequence, to some $u$, which belongs to $\mathcal{S}_{a_n}$, for any $n$, since these classes are stable for the uniform convergence. This implies that $u$ is a subsolution to [4], so that $\mathcal{S}_c \ne \emptyset$. The critical value $c$ is then characterized by the property that the corresponding eqn [4] admits subsolutions but not strict subsolutions. Our aim is to show that extremal subsolutions do exist for the critical eqn [4].

For any supercritical value $a$, that is, $a \geq c$, we can define the functional nonsymmetric semidistance:

$$S_a(y,x) = \sup\{u(x) - u(y)\colon u \in \mathcal{S}_a\} \\ = \sup\{u(x)\colon u \in \mathcal{S}_a, u(y) = 0\}$$

for any $x$, $y$ in $\mathbb{T}^N$. It is immediate that $S_a$ satisfies the triangle inequality and $S_a(y,y) = 0$ for any $y$. But it fails, in general, to be symmetric and positive if $x \neq y$. We will nevertheless call it a distance, in the sequel, to ease terminology. The function $x \mapsto S_a(y,x)$ is itself a subsolution to [1], for any $y$, being the pointwise supremum of a family of equibounded subsolutions. Taking into account the inequality

$$u(x) - u(y) \geq -S_a(x,y)$$

which holds for any $u \in \mathcal{S}_a$, and the fact that it becomes an equality by setting $u = S_a(x,\cdot)$, we also get

$$-S_a(x,y) = \inf\{u(x) - u(y)\colon u \in \mathcal{S}_a\} \\ = \inf\{u(x)\colon u \in \mathcal{S}_a, u(y) = 0\}$$

and $-S_a(\cdot,y)$ is, as well, a subsolution to [1]. Note that

$$S_a(x,y) + S_a(y,x) \geq 0 \quad \text{for any } y, x \qquad [7]$$

The interest of introducing the distance $S_a$ in the present context is that, for any $a \geq c$ and $y \in \mathbb{T}^N$, the function $x \mapsto S_a(y,x)$ (resp. $x \mapsto -S_a(x,y)$) satisfies the maximality (resp. minimality) condition for subsolutions of [1] in any open set not containing $y$. If, by contradiction, the maximality property of $S_a(y,\cdot)$ were violated in some open set $\Omega$ with $y \notin \Omega$ by a $\phi$ satisfying [5] then one could make the set $\{x\colon \phi(x) > S_a(y,x)\}$ nonempty and compactly contained in $\Omega$, by adding a suitable constant. Hence, the formula

$$u = \begin{cases} \max\{\phi, S_a(y,\cdot)\} & \text{in } \Omega \\ S_a(y,\cdot) & \text{otherwise} \end{cases} \qquad [8]$$

could provide a subsolution to [1] with $u(y) = S_a(y,y) = 0$ and $u > S_a(y,\cdot)$ at some point of $\Omega$, which is in contrast with the very definition of $S_a$. One can similarly prove the minimality condition for $-S_a(\cdot,y)$.

We now focus our attention on the critical case. We derive from the previous considerations that if a maximal subsolution to [4] does not exist then, for any $y$, we can find a neighborhood $\Omega'_y$ of $y$ where $S_c(y,\cdot)$ fails to be maximal. We can thus construct, through a formula like [8], a $u_y \in \mathcal{S}_c$ with

$$\text{ess sup}_{\Omega_y} H(\cdot, Du_y(\cdot)) < c \qquad [9]$$

in some neighborhood $\Omega_y$ of $y$ contained in $\Omega'_y$. Thanks to the compactness of $\mathbb{T}^N$, we can extract from $\{\Omega_y\}$ a finite subcover $\{\Omega_{y_i}\}, i = 1, \ldots, m$, for some $m \in \mathbb{N}$, and define

$$u = \sum_i \lambda_i u_{y_i}$$

where $\lambda_i$ are positive constants with $\sum_1^m \lambda_i = 1$. The convex character of the Hamiltonian and [9] imply that $u$ is a strict critical subsolution, which cannot be. We therefore conclude that there is a nonempty subset of $y$, denoted henceforth by $\mathcal{A}$, for which $S_c(y,\cdot)$ is indeed a maximal critical subsolution. It can also be proved, by exploiting some stability properties of the maximal subsolutions, that $\mathcal{A}$ is closed. Similarly, $-S_a(\cdot,y)$ must be a minimal critical subsolution for some $y$. We denote by $\bar{\mathcal{A}}$ the closed set made up by such points.

The previous covering argument shows that if $y \notin \mathcal{A}$ (resp. $y \notin \bar{\mathcal{A}}$) then there is a local strict critical subsolution at $y$. The converse is also true: let in fact $\phi$ be such a strict subsolution satisfying $\phi(y) = S_c(y,y) = 0$; then $\phi$ is subtangent to $S_c(y,\cdot)$ (resp. supertangent to $-S_c(\cdot,y)$) at $y$, by the very definition of the distance $S_c$. This shows that $S_c(y,\cdot)$ (resp. $-S_c(\cdot,y)$) is not a maximal (resp. minimal) critical subsolution, and so $y \notin \mathcal{A}$ (resp. $y \notin \bar{\mathcal{A}}$). Since the previous characterization holds for both $\mathcal{A}$ and $\bar{\mathcal{A}}$, it follows that $\mathcal{A} = \bar{\mathcal{A}}$. This set is a generalization of the (projected) Aubry set. We will come back on this point later on.

We also see from the covering argument that there is a critical subsolution $\phi$, which is strict outside $\mathcal{A}$, that is, such that $\text{ess sup}_\Omega H(x, D\phi(x)) < c$ for any open set $\Omega$ compactly contained in $\mathbb{T}^N \backslash \mathcal{A}$.

This implies that any $y$ such that $\{p\colon H(y,p) \leq c\}$ has empty interior, belongs to $\mathcal{A}$. The empty interior condition in fact implies, thanks to the strict quasiconvexity of $H$, that the sublevel set reduces to a singleton, say $\{p_0\}$. We know that $\partial u(y) \subset \{p\colon H(y,p) \leq c\}$, for any $u \in \mathcal{S}_c$; therefore, $\partial u(y)$ is a singleton and so any critical subsolution $u$ is strictly differentiable at $y$ with $H(y, Du(y)) = H(y, p_0) = c$. Hence, there cannot be critical subsolutions which are strict around $y$.

The previously described points will be called, in the sequel, equilibria, and the (possibly empty) closed set made up by them will be denoted by $\mathcal{E}$. The reason of this terminology will be explained later. The differentiability property of the critical subsolutions at equilibria, can be extended, quite surprisingly, to any point of $\mathcal{A}$, under more stringent assumptions on $H$. We will discuss this issue in the next section.

## Qualitative Properties of Generalized Aubry Set

We introduce some dynamical aspects in the picture by showing that the distances $S_a$, defined in the previous section for any $a \geq c$, are actually of length type, in the sense that $S_a(y,x)$ equals, for any pair $y$, $x$, the infimum of the intrinsic length of absolutely continuous, or equivalently Lipschitz-continuous, curves joining $y$ to $x$. By intrinsic length, we mean the total variation of $S_a$ on the curve. It will be denoted by $\ell_a$, while $\ell$ will indicate the natural (i.e., Euclidean) length.

For this purpose, we proceed to give a line-integral representation formula of $S_a$. To start with, we consider a $C^1$ subsolution $u$ to [1], some $x$, $y$ $\mathbb{T}^N$ and a (Lipschitz-continuous) curve $\xi$, defined in some compact interval $I$, joining $y$ to $x$. We have

$$u(x) - u(y) = \int_I Du\,\dot{\xi}\,\mathrm{d}t \leq \int_I \sigma_a(\xi,\dot{\xi})\,\mathrm{d}t \qquad [10]$$

where, for any $(x,v) \in \mathbb{T}^N \times \mathbb{R}^N, \sigma_a(x,v) := \max_{p\in Z_a(x)} pv$ and

$$Z_a(x) := \{p\colon H(x,p) \leq a\}$$

Inequality [10] also holds for a Lipschitz-continuous subsolution to [1] through suitable replacement of the differential by the generalized gradient. The set-valued map $Z_a$ is compact convex valued, by the coercivity and quasiconvexity assumptions on $H$, and continuous with respect to the Hausdorff metric. The function $\sigma_a$ is accordingly continuous in the first variable, and convex and positively homogeneous in the second, being a support function. This implies in particular that the integral on the right-hand side of [10] is invariant under change of parameter preserving the orientation. We derive, from [10],

$$S_a(y,x) \leq \inf\left\{ \int_0^1 \sigma_a(\xi,\dot{\xi})\,\mathrm{d}t\colon \xi \text{ defined in } [0,1] \text{ and joining } y \text{ to } x \right\} \qquad [11]$$

for any $y, x$. We denote by $\overline{S}_a(y,x)$ the quantity on the right-hand side of [11]. It is immediate that the triangle inequality holds for $\overline{S}_a$. The function $u := \overline{S}_a(y,\cdot)$ is, moreover, Lipschitz-continuous since $\sigma_a(x,v)/|v|$ is bounded from above in $\mathbb{T}^N \times (\mathbb{R}^N \backslash \{0\})$ because of the coercivity of $H$. Given $v \in \mathbb{R}^N$, we exploit the definition of $\overline{S}_a$, the continuity of $\sigma_a$, and the triangle inequality for $\overline{S}_a$, to get at any differentiability point $x_0$ of $u$,

$$\begin{aligned} Du(x_0)v &= \lim_{h\to 0^+} \frac{u(x_0 - hv) - u(x_0)}{h} \\ &\leq \limsup_{h\to 0^+} \frac{\overline{S}_a(x_0 - hv, x_0)}{h} \\ &\leq \lim_{h\to 0^+} \frac{1}{h}\int_0^1 \sigma_a(x_0 - hvt, hv)\,\mathrm{d}t \\ &= \lim_{h\to 0^+} \int_0^1 \sigma_a(x_0 - hvt, v)\,\mathrm{d}t \\ &= \sigma_a(x_0, v) \end{aligned}$$

This implies by Hahn–Banach theorem that $Du(x_0) \in Z_a(x)$ or, in other terms, that $u = \overline{S}_a(y,\cdot) \in \mathcal{S}_a$. We then derive, from [11] and the very definition of $S_a$,

$$S_a(y,x) = \inf\left\{ \int_0^1 \sigma(\xi,\dot{\xi})\,\mathrm{d}t\colon \xi \text{ defined in } [0,1] \text{ with } \xi(0) = y,\ \xi(1) = x \right\}$$

Taking into account that the integral functional appearing in the previous formula is lower semicontinuous for the uniform convergence of equi-Lipschitz-continuous sequence of curves, by standard variational results, we in turn infer that it equals the intrinsic length $\ell_a$. Mathematically,

$$\ell_a(\xi) = \int_I \sigma_a(\xi,\dot{\xi})\,\mathrm{d}t$$

for any compact interval $I$ and any curve $\xi$ defined in $I$.

Since $S_a$ is just a semidistance, we do not have any *a priori* information on the sign of $\ell_a$; however, by [10], the intrinsic length of any cycle must be nonnegative. Furthermore, while $|\ell_a(\xi)|$ must be small for any curve $\xi$ with small natural length, by the coercivity condition on $H$, no converse estimates hold, in general. If $a > c$, some information in this direction can be gathered by taking a strict subsolution $\phi$ to [1], that it can be assumed smooth, up to regularization by mollification, then $D\phi(x)v \leq \sigma_a(x,v) - \rho|v|$ for any $(x,v) \in \mathbb{T}^N \times \mathbb{R}^N$, and some $\rho > 0$, and consequently

$$\ell_a(\xi) \geq \int_I (\sigma_a(\xi,\dot{\xi}) - D\phi(\xi)\dot{\xi})\,\mathrm{d}t + \phi(x) - \phi(y) \geq \rho\ell(\xi) - S_a(x,y) \qquad [12]$$

for any pair $y$, $x$ and any curve $\xi$, defined in some interval $I$, joining $y$ to $x$. The previous formula says, in particular, that when $|x-y|$ is small then any curve whose intrinsic length approximates $S_a(y,x)$ must have small natural length. The previous

argument cannot be extended to the critical case. This gap suggests the next definition. The main purpose for introducing it is to get a metric characterization of the Aubry set $\mathcal{A}$.

We say that $S_c$ is localizable at some $y$ if for every $\varepsilon > 0$ there is $0 < \delta_\varepsilon < \varepsilon$ such that

$$S_c(y,x) = \inf\{\ell_c(\xi)\colon \xi \text{ joins } y \text{ to } x \text{ and } \ell(\xi) < \varepsilon\} \quad [13]$$

whenever $|x-y| < \delta_\varepsilon$. If $y \notin \mathcal{A}$, we adapt the argument previously used in the strict subcritical case to get that $S_c$ is indeed localizable at $y$. In this case we have, in fact, at our disposal a critical subsolution, say $\phi$, which is strict in some neighborhood $\Omega$ of $y$, thanks to the characterization of the Aubry set given in the previous section.

We assume, to simplify, $\phi$ to be $C^1$; under the natural condition of Lipschitz-continuity, generalized gradients should be used in place of differentials. We have $D\phi(x)v \le \sigma(x,v) - \rho|v|$ for any $x \in \Omega$, any $v \in \mathbb{R}^N$, and some $\rho > 0$, and $D\phi(x)v \le \sigma(x,v)$, for any $x$, $v$. Exploiting these inequalities, we obtain an estimate analogous to [12] for curves starting from $y$, which allows us to prove [13].

Conversely, let $y \notin \mathcal{E}$ be a point where $S_c$ is localizable. We claim that $Z_c(y) \subset D^- u(y)$, where $u := S_c(y,\cdot)$. It is enough to show that any $p_0$ in the interior of $Z_c(y)$ belongs to $D^-u(y)$, since $D^-u(y)$ is closed. Note that the interior of $Z_c(y)$ is nonempty since we are assuming that $y$ is not an equilibrium. Such a $p_0$ belongs to the interior of $Z_c(x)$ for $x$ sufficiently close to $y$, thanks to the continuity of $Z_c$; consequently, $p(x-y) < \ell_c(\xi)$ for any $x$ close to $y$ and any curve $\xi$ joining $y$ to $x$ with $\ell(\xi)$ sufficiently small. Taking into account [13], we then deduce

$$p(x-y) \le S_c(y,x) \quad \text{for } x \text{ close to } y$$

and so the linear function $\phi(x) := p_0(x-y)$ is subtangent to $u$ at $y$. This in turn implies that $y$ is out of $\mathcal{A}$ since $\phi$ is a local strict critical subsolution at $y$, and so $S_c(y,\cdot)$ cannot be a maximal subsolution by the characterization given in the previous section.

The fact that $S_c$ is not localizable at any point of $y \in \mathcal{A}\backslash\mathcal{E}$ leads to the announced metric characterization of $\mathcal{A}$. If $y$ is such a point, there is an $\varepsilon > 0$, a point $x$, with $|x-y|$, and so $|S_c(y,x)|$, as small as desired, and a curve $\xi$ joining $y$ to $x$ with $\ell_c(\xi) \sim S_c(y,x)$ and $\ell(\xi) > \varepsilon$. We construct a cycle $\gamma$, passing through $y$, by juxtaposition of $\xi$ and the Euclidean segment joining $x$ to $y$. We obtain, in this way, a sequence of cycles $\gamma_n$, passing through $y$, with length $\ell_c(\gamma_n) \to 0$ and $\ell(\gamma_n) \ge \varepsilon$, for any $n$.

The same result can also be obtained for $y \in \mathcal{E}$. In this case we select $\varepsilon > 0$ and $v_0 \in \mathbb{R}^N$ with $\sigma_c(y, v_0) = 0$, and denote by $B_n$ a sequence of Euclidean balls, centered at $y$, satisfying $\sigma_c(\cdot, v_0) < 1/n$ in $B_n$. We construct a sequence of cycles, passing through $y$, by going up and down on the line $\{y + sv\}$ in such a way that $\gamma_n(t) \in B_n$, for every $t$, and $\varepsilon < \ell(\gamma_n) < 2\varepsilon$; therefore $0 \le \ell_c(\gamma_n) < 2\varepsilon/n$.

Conversely, such a sequence of cycles cannot exist at any $y \notin \mathcal{A}$ because $S_c$ is localizable at $y$.

We emphasize that the previous definition of $\mathcal{A}$ through cycles and the fact that $S_c$ is not localizable at any point $y \in \mathcal{A}$ with $\mathrm{int} Z_c(y) \neq \emptyset$ shows that, apart for the special case of equilibria, the property of being a point of $\mathcal{A}$ is definitively not of local nature.

As pointed out already, if $y \notin \mathcal{A}$, and so $S_c$ is localizable at $y$, then $Z_c(y) \subset D^-u(y)$, where $u := S_c(y,\cdot)$; on the other hand, we know that $D^-u(y) \subset \partial u(y)$ and $\partial u(y) \subset Z_c(y)$, where the latter inclusion holds since $u$ is a critical subsolution. We then derive

$$D^-u(y) = \partial u(y) = Z_c(y)$$

We interpret these inequalities as a convexity–type property, or, to use a more appropriate terminology, a semiconvexity property of the distance function $S_c(y,\cdot)$ at $y$. The same property holds for the Euclidean distance function $|x|$ at 0.

A contrasting phenomenon takes place if $y \in \mathcal{A}$, namely $S_c(y,\cdot)$ is semiconcave at $y$, which means that $D^+u(y) = \partial u(y)$. This is more complicated to prove (see Fathi 2005b), and requires, in addition, $H$ to be strictly convex in $p$ and locally Lipschitz-continuous in $(x,p)$. Under these assumptions one can, more generally, show that $S_c(y,\cdot)$ is semiconcave in $\mathbb{T}^N$, if $y \in \mathcal{A}$, while it is semiconcave in $\mathbb{T}^N\backslash\{y\}$ and semiconvex in $y$, if $y \notin \mathcal{A}$. Some important consequences can be deduced.

First, thanks to the semiconcavity property there are $C^1$ supertangents to $u := S_c(y,\cdot)$ at $y$, whenever $y \in \mathcal{A}$. Such a function, say $\phi$, is also supertangent to $-S_c(\cdot,y)$, which is a minimal critical subsolution, at the same point. We know from the previous section that no supertangents to $-S_c(\cdot,y)$ at $y$ can be strict critical subsolution locally at $y$, and so $H(y, D\phi(y)) = c$. This implies that $D^+u(y)$ is contained in the boundary of $Z_c(y)$. We then see, taking into account that $D^+u(y)$ is convex and $Z_c(y)$ strictly convex, that $D^+u(y)$ reduces to a singleton, and so, by the semiconcavity property, $\partial u(y)$ reduces to a singleton. Therefore, $S_c(y,\cdot)$ is strictly differentiable at $y$, for any $y \in \mathcal{A}$. One can similarly show that $-S_c(\cdot,y)$ is strictly differentiable at $y$.

Second, given $y \in \mathcal{A}$ and a critical subsolution $w$, which can be assumed, up to addition of a constant, to vanish at $y$, we see that $S_c(y,\cdot)$ (resp. $-S_c(\cdot,y)$) is supertangent (resp. subtangent) at $y$ because of its extremality properties. Since both these

super(sub)-tangents are differentiable, by the previous point, we deduce that $w$ itself is differentiable at $y$. Moreover, the differentials at $y$ of all three functions under consideration, namely $S_c(y,\cdot)$, $-S_c(\cdot,y)$, and $w$, coincide. In particular, $H(y,Dw(y))=c$, and $y\mapsto Dw(y)$ is continuous on $\mathcal{A}$, since $S_c(y,\cdot)$ has been proved to be strictly differentiable at $y$, whenever $y\in\mathcal{A}$. Any critical subsolution, restricted to $\mathcal{A}$, is consequently a continuously differentiable solution to [4].

Summing up, we have discovered (under the assumption of strict convexity and Lipschitz-continuity for $H$) that every critical subsolution is differentiable on $\mathcal{A}$, and the differential on $\mathcal{A}$ is the same for every critical subsolution. A continuous map $G:\mathcal{A}\to\mathbb{R}^N$ is then defined by taking $G(y)$ equal to the common differential of any critical subsolution at $y$. We denote by $\tilde{\mathcal{A}}$ the graph of $G$, which is a subset of the cotangent bundle of $\mathbb{T}^N$, identified with $\mathbb{T}^N\times\mathbb{R}^N$.

As we have already pointed out, the existence of a $C^\infty$ subsolution to [1] is obvious when $a>c$, and such a subsolution can be obtained through a suitable regularization by mollification of any strict subsolution. The same construction cannot be performed at the critical level, since no strict critical subsolutions are available to start the regularization procedure. We can nevertheless show the existence of $C^1$ critical subsolutions by exploiting the information gathered on the Aubry set. We start by considering a countable locally finite open cover of $\mathbb{T}^N\backslash\mathcal{A},\{\Omega_i\}$; we know from the previous section that there is a critical subsolution, say $w_i$, which is strict on $\Omega_i$, for any $i$. Loosely speaking, we have some space, also in this case, for regularizing $w_i$ in such a way that the regularized function is still a critical subsolution, at least on $\Omega_i$.

We can glue together, with some precautions, these regularized local critical subsolutions through a $C^\infty$ partition of the unity, to produce a critical subsolution which is $C^\infty$ outside $\mathcal{A}$. Using the fact that any critical subsolution is differentiable on $\mathcal{A}$, we can further adjust the previous construction so that the critical subsolution is $C^1$ on the whole $\mathbb{T}^N$. We state this result in the following way: if the equation [1] has a subsolution then it also has a $C^1$ subsolution. It is worth noticing that it holds even if the underlying manifold is noncompact (see Fathi (2004, 2005b)).

## The Intrinsic Lengths and the Action Functional

Here we assume $H$ to satisfy all the usual assumptions in order to define the Hamilton's equations [2] and to have the completeness of the associated Hamiltonian flow. Namely, we require $H$ to be $C^2$ in both variables, $C^2$-strictly convex, that is, $H_{pp}>0$ in $\mathbb{T}^N\times\mathbb{R}^N$ and superlinear, in the sense that

$$\lim_{|p|\to+\infty}\frac{H(x,p)}{|p|}=+\infty\quad\text{uniformly in } x$$

We define the Lagrangian $L$ as the Fenchel transform of $H$. It takes finite values thanks to the superlinearity condition, and, in addition, inherits, from $H, C^2$ regularity, $C^2$-strict convexity and superlinearity. In our setting, the Fenchel transform is involutive.

We call a vector $v_0$ and a covector $p_0$ conjugate at a point $x$ if $v_0=H_p(x,p_0)$, and so $L(x,v_0)=p_0v_0-H(x,p_0)$. This also implies the relations $p_0=L_v(x,v_0)$ and $H(x,p_0)=p_0v_0-L(x,v_0)$. If $H(x,p_0)=a$, for some $a$, then $p_0v_0=\sigma_a(x,v_0)$, and $p_0$ is the unique element of $Z_a(x_0)$ for which such a relation holds. Since the function $y\mapsto p_0v_0-H(y,p_0)$ is subtangent to $L(\cdot,v_0)$ at $x$, we see that $L_x(x,v_0)=-H_x(x,p_0)$.

We introduce, for any (Lipschitz-continuous) curve $\xi$ defined in $[a,b]$, for some $a<b$, the action functional $A(\xi)$ through

$$A(\xi)=\int_I L(\xi,\dot\xi)\,\mathrm{d}t$$

We say that the curve $\xi$ is a minimizer of the action if $A(\xi)\le A(\gamma)$ for any $\gamma$ defined $[a,b]$ and with the same end points of $\xi$. It is a classical result in calculus of variations that any of such minimizers $\xi$ is of class $C^2$ and satisfies the Euler–Lagrange equation

$$\frac{\mathrm{d}}{\mathrm{d}t}L_v(\xi,\dot\xi)=L_x(\xi,\dot\xi)\quad\text{in } ]a,b[$$

Consequently, $\xi$ and the conjugate curve $\eta=L_v(\xi,\dot\xi)$ satisfy the Hamilton's equations [2]. Note that all the integral curves of [2] lie in a fixed level of the Hamiltonian, which is compact by the superlinearity condition. The corresponding Hamiltonian flow is consequently complete.

We show that if $x_0\in\mathcal{E}$, and $Z_c(x_0)=\{G(x_0)\}$, then $(x_0,G(x_0))$ is a steady state of the Hamiltonian flow. In this case, in fact, $c=\min_p H(x_0,p)$ and so $L(x_0,0)=-c$ and $H_p(x_0,G(x_0))=0$, or equivalently $G(x_0)$ and 0 are conjugate at $x_0$. Taking into account that $c$ is the critical value, we have that

$$L(x,0)=-\min_p H(x,p)\ge -c\quad\text{for any } x\in\mathbb{T}^N$$

so that $x_0$ is a minimizer of $x\mapsto L(x,0)$ and $L_x(x_0,0)=-H_p(x_0,G(x_0)=0$. It is easy to see that,

conversely, if $(x_0, p_0)$ is a steady state of the Hamiltonian flow and $H(x_0, p_0) = c$ then $x_0 \in \mathcal{E}$ and $p_0 = G(x_0)$.

We want to establish a relation between $A(\cdot)$ and the length functionals $\ell_a$ defined in the previous section for $a \geq c$. This will allow, among other things, to show that the Aubry set $\tilde{\mathcal{A}}$ is invariant for the Hamiltonian flow and to analyze the properties of the integral curves lying on it. To this aim, we consider the minimal geodesics for $S_a, a \geq c$, that is, the curves, defined on compact intervals, whose intrinsic lengths $\ell_a$ equal the distance $S_a$ between their end points.

If $a > c$, we claim that, given any pair of points in $\mathbb{T}^N$, there is a minimal geodesics joining them. Recalling the formula [12], whose validity depends on the fact that in the strict supercritical case there is a smooth strict subsolution to [1], we have

$$\ell_a(\xi) \to +\infty \quad \text{whenever} \quad \ell(\xi) \to +\infty$$

The claim is then proved by using the Ascoli theorem and the lower-semicontinuity property of $\ell_a$. In the critical case, given $y \notin \mathcal{A}$, we can use the same argument to deduce the existence of minimizing geodesics for $S_c$ between $y$ and any point $x$ sufficiently close to $y$ (in the Euclidean sense). This comes from the fact that $S_c$ is localizable at $y$, and so any sequence of curves $\xi_n$ with $\ell_c(\xi_n) \to S_c(y, x)$ has bounded natural length. For a general pair of points, we will show, on the contrary, that existence of a minimal geodesic is not guaranteed in the critical case.

We consider a minimizing geodesics $\xi$ for $S_a$ between a pair of points $y$ and $x$. We assume $a > c$ or $a = c$ and $\xi \cap \mathcal{E} = \emptyset$. We want to show that $\xi$ is a minimizing curve for the action, up to a change of parameter. We choose the new parameter in such a way that

$$L(\tilde{\xi}, \dot{\tilde{\xi}}) + a = \sigma_a(\tilde{\xi}, \dot{\tilde{\xi}}) \qquad [14]$$

where we have denoted by $\tilde{\xi}$ the reparametrized curve. Since $\tilde{\xi}$ stays away from $\mathcal{E}$, the velocities $|\dot{\tilde{\xi}}|$ are bounded from below by a positive constant and so the domain of definition of $\tilde{\xi}$, denoted by $[0, T]$, is a compact interval. Note that $\ell_a(\xi) = \ell_a(\tilde{\xi})$, since the intrinsic length is invariant under change of parameter. We take into account that $\xi$ is a minimal geodesic and the inequality $L(x, v) + a \geq \sigma_a(x, v)$, which holds for any $x$, $v$, to get

$$A(\tilde{\xi}) = \ell_a(\xi) - aT \leq \ell_a(\gamma) - aT \leq A(\gamma)$$

for any $\gamma$ defined in $[0, T]$ with $\gamma(0) = y, \gamma(T) = x$. This proves the announced minimality property of $\tilde{\xi}$.

Furthermore, we show that the function $u := S_a(y, \cdot)$ is strictly differentiable at $\tilde{\xi}(s)$, for $s \in ]0, T[$, and

$$Du(\tilde{\xi}) = L_v(\tilde{\xi}, \dot{\tilde{\xi}}) =: \eta \qquad [15]$$

in $[0, T]$. Hence, $(\tilde{\xi}, Du(\tilde{\xi}))$ is a solution of the Hamilton's equations in $]0, T[$. To see this, we start from the relations

$$\int_0^t \frac{\mathrm{d}}{\mathrm{d}s} u(\tilde{\xi}(s))\, \mathrm{d}s = u(\tilde{\xi}(t)) = \int_0^t \sigma_c(\tilde{\xi}, \dot{\tilde{\xi}})\, \mathrm{d}s = \int_0^t \eta \dot{\tilde{\xi}}\, \mathrm{d}s \qquad [16]$$

which hold in $[0, T]$ because $u$ is Lipschitz-continuous, $\tilde{\xi}$ is a minimizing geodesic, and $\eta(s)$ is conjugate to $\dot{\tilde{\xi}}(s)$ at $\tilde{\xi}(s)$ for any $s \in [0, T]$. We know that

$$\frac{\mathrm{d}}{\mathrm{d}s} u(\tilde{\xi}(s)) = p\dot{\tilde{\xi}}(s)$$
$$\text{for a.e. } s \text{ and some } p \in \partial u(\tilde{\xi}(s))$$

We have that $p \in Z_c(\tilde{\xi}(s))$, since $u$ is a critical subsolution, and so

$$p\dot{\tilde{\xi}}(s) \leq \sigma_c(\tilde{\xi}(s), \dot{\tilde{\xi}}(s)) = \eta(s)\dot{\tilde{\xi}}(s))$$

We see, in the light of [16], that equality must hold in the previous formula, for a.e. $s$. Therefore,

$$\frac{\mathrm{d}}{\mathrm{d}s} u(\tilde{\xi}(s)) = \eta(s)\, \dot{\tilde{\xi}}(s) \quad \text{for a.e. } s \qquad [17]$$

we derive from the fact that the function $\eta(\cdot)\dot{\tilde{\xi}}(\cdot)$ is continuous that $(u(\tilde{\xi}(\cdot))$ is actually continuously differentiable in $]0, T[$ and that [17] holds for any $s$. We finally exploit that $u$ is semiconcave in $\mathbb{T}^N \backslash \{y\}$, as pointed out in the previous section, and so $D^+u(\tilde{\xi}(s)) = \partial u(\tilde{\xi}(s))$, for any $s$. If $\phi$ is a $C^1$-supertangent to $u$ at $\tilde{\xi}(s)$ then

$$D\phi(\tilde{\xi}(s))\dot{\tilde{\xi}}(s)) = \frac{\mathrm{d}}{\mathrm{d}s} u(\tilde{\xi}(s))$$

accordingly,

$$p\dot{\tilde{\xi}}(s) = \eta(s)\tilde{\xi}(s) \quad \text{for any } s \text{ and } p \in \partial u(\tilde{\xi}(s))$$

Since $\partial u(\tilde{\xi}(s)) \subset Z_c(\tilde{\xi}(s))$, this implies that $\partial u(\tilde{\xi}(s)) = \{\eta(s)\}$. This actually gives the strict differentiability function $u$ at $\tilde{\xi}(s)$, and $Du(\tilde{\xi}(s)) = \eta(s)$ for any $s$.

The same argument works, with some adjustment, also when $a = c$ and $\xi \cap \mathcal{E} \neq \emptyset$. If, for instance, $y \notin \mathcal{E}, t_0 = \min\{t\colon \xi(t) \in \mathcal{E}\}$, then by reparametrizing $\xi$ in $[0, t_0]$, as indicated in [14], we get a curve $\tilde{\xi}$ defined in $[0, +\infty[$ which is a minimizer of the action functional in any compact interval contained in $[0, +\infty[$. Moreover, $u := S_c(y, \cdot)$ is strictly

differentiable in $]0,+\infty[$ and $(\tilde{\xi}, Du(\tilde{\xi}))$ is a solution of the Hamilton's equations.

We proceed to investigate the properties of the Hamiltonian flow on $\mathcal{A}$. We take a $y_0$ in $\mathcal{A}\backslash\mathcal{E}$, and consider a sequence $\xi_n$ of cycles passing through $y_0$ with $\ell_c(\xi_n)) \to 0, \ell(\xi_n) \geq 2\delta$, for some positive $\delta$. Such a sequence does exist in view of the characterization of $\mathcal{A}$ through cycles given in the previous section. Moreover, we assume that the $\xi_n$ are parametrized by the natural arc length in $[-T_n, T_n]$, for some $T_n \geq \delta$, and satisfy $\xi_n(0) = y_0$ for any $n$. There is then defined a uniform limit curve $\gamma$ in $[-\delta, \delta]$, up to a subsequence, thanks to the Ascoli theorem.

The idea is to construct a new sequence of cycles $\gamma_n$ by replacing the portion of the $\xi_n$ between $-\delta$ and $\delta$ by $\gamma$, and pasting this new piece with the remainder of $\xi_n$ through Euclidean segments at the end points. The $\gamma_n$ are still of infinitesimal intrinsic length $\ell_c$, which shows, in particular, that $\gamma$ is contained in $\mathcal{A}$. By exploiting that $S_c$ is a length distance, that the $\gamma_n$ are cycles, and the formula [7], with $a = c$, we get

$$\begin{aligned}\ell_c(\gamma_n) &\geq S_c(\gamma(-\delta), \gamma(\delta)) + S_c(\gamma(\delta), \gamma(-\delta)) \\ &\geq 0\end{aligned}$$

for any $n$, and we at last derive

$$\ell_c(\gamma) = S_c(\gamma(\delta), \gamma(-\delta)) = -\,S_c(\gamma(-\delta), \gamma(\delta))$$

Note that the second equality is actually redundant. By reparametrizing $\gamma$, as in [14], with $a = c$, in some open interval containing 0 as interior point and contained in $[-\delta, \delta]$, we get a curve contained in $\mathcal{A}\backslash\mathcal{E}$, denoted by $\xi$, defined on some open interval $I$ and satisfying

$$\begin{aligned}A(\xi|_{[s,t]}) + c(t-s)) &= \ell_c(\xi|_{[s,t]}) \\ &= -S_c(\xi(t), \xi(s)) \quad \text{for any } t > s \qquad [18]\end{aligned}$$

This, in particular, shows that $\xi$ is a minimizer of the action functional in any $[s,t] \subset I$. If we denote, as usual, by $\eta$ the curve conjugate to $\dot{\xi}$, we have, arguing as above, that $\eta(t)$ is the differential of the function $S_c(\xi(s), \cdot)$ at $\xi(t)$, but, since the differentials of all critical subsolutions coincide on $\mathcal{A}$, we finally get that $\eta(t) = G(\xi(t)$ for every $t \in I$. Therefore, $(\xi, G(\xi))$ is a solution of the Hamilton's equation in $I$ and is contained in $\tilde{\mathcal{A}}$. The same properties can be extended on the whole $\mathbb{R}$.

Taking into account that if $y \in \mathcal{E}$ then $(y, G(y))$ is a steady state of the Hamiltonian flow, we in the end see that $\tilde{\mathcal{A}}$ is foliated by integral curves of the Hamiltonian flow $(\xi, G(\xi))$, with $\xi$ enjoying the variational property [18]. This is indeed a characterization since if, conversely, a curve $\xi$ satisfies [18] then it must be contained in $\mathcal{A}$.

As an application, we finally show that there cannot be minimal geodesics, for the critical metric $S_c$, joining a point of $\mathcal{A}$, say $y$, to some $x \notin \mathcal{A}$, at least when $\mathcal{E} = \emptyset$. If such a geodesic, say $\xi$, exists, and is defined in $[0, T]$, for some $T > 0$, then $(\xi, Du(\xi))$ is a solution of the Hamilton's equations, up to a change of parameter, where $u := S(y, \cdot)$, satisfying the initial conditions $\xi(0) = y_0, \eta(0) = \lim_{t\to 0^+} Du(\xi(t))$.

The last relation tells us that $\eta(0) \in \partial u(y)$ and, since $u$ is differentiable at $y \in \mathcal{A}$ with $Du(y) = G(y)$, we conclude that $\eta(0) = G(y)$. Therefore, $(\xi, Du(\xi))$ is a part of the integral curve of the Hamiltonian flow starting at $(y, G(y))$ that we know, by the above reasoning, to be contained in $\tilde{\mathcal{A}}$, which is in contradiction with $\xi(T) = x \notin \mathcal{A}$.

## Introduction

The phenomenon of superconductivity is one of the most profound manifestations of quantum mechanics in the macroscopic world. The celebrated Bardeen–Cooper–Schrieffer (BCS) theory (Bardeen *et al.* 1957) of superconductivity (SC) provides a basic theoretical framework to understand this remarkable phenomenon in terms of the pairing of electrons with opposite spin and momenta to form a collective condensate state. This theory does not only quantitatively explain the experimental data of conventional superconductors, the basic concepts developed from this theory, including the concept of spontaneous broken symmetry, the Nambu–Goldstone modes and the Anderson–Higgs mechanism provide the essential building blocks for the unified theory of fundamental forces. The discovery of high-temperature superconductivity (HTSC) in the copper oxide material poses a profound challenge to theoretically understand the phenomenon of superconductivity in the extreme limit of strong correlations. While the basic idea of electron pairing in the BCS theory carries over to the HTSC, other aspects like the weak coupling mean field approximation and the phonon mediated pairing mechanism may not apply without modifications. Therefore, HTSC system provides an exciting opportunity to develop new theoretical frameworks and concepts for strongly correlated electronic systems.

To date, a number of different HTSC materials have been discovered. The most studied ones include the hole-doped $La_{2-x}Sr_xCuO_{4+\delta}$ (LSCO), $YBa_2Cu_3O_{6+\delta}$ (YBCO), $Bi_2Sr_2CaCu_2O_{8+\delta}$ (BSCO), $Tl_2Ba_2CuO_{6+\delta}$ (TBCO) materials and the electron-doped $Nd_{2-x}Ce_xCuO_4$ (NCCO) material. All these materials have a two-dimensional (2D) $CuO_2$ plane, and have an antiferromagnetic (AF) insulating phase at half-filling. The magnetic properties of this insulating phase is well approximated by the antiferromagnetic Heisenberg model with spin $S = 1/2$ and an AF exchange constant $J \sim 100\,\text{meV}$. The Neel temperature for the 3D AF ordering is approximately given by $T_N \sim 300 \sim 500\,\text{K}$. The HTSC material can be doped either by holes or by electrons. In the doping range of $5\% \lesssim x \lesssim 15\%$, there is an SC phase with a dom-like shape in the temperature versus doping plane. The maximal SC transition temperature $T_c$ is of the order of 100 K. The generic phase diagram of HTSC is shown in Figure 1.

One of the main questions concerning the HTSC phase diagram is the transition region between the AF and the SC phases. Partly because of the complicated material chemistry in this regime, there is no universal agreement among different experiments. Different experiments indicate several different possibilities, including phase separation with an inhomogeneous density distribution, uniform coexistence phase between AF and SC and periodically ordered spin and charge distributions in the form of stripes or checkerboards.

The phase diagram of the HTSC cuprates also contains a regime with anomalous behaviors conventionally called the pseudogap phase. This region of the phase diagram is indicated by the dashed lines in Figure 1. In conventional superconductors, a pairing gap opens up at $T_c$. In a large class of HTSC cuprates, however, an electronic gap starts to open up at a temperature much higher than $T_c$. Many experiments indicate that the pseudogap "phase" is

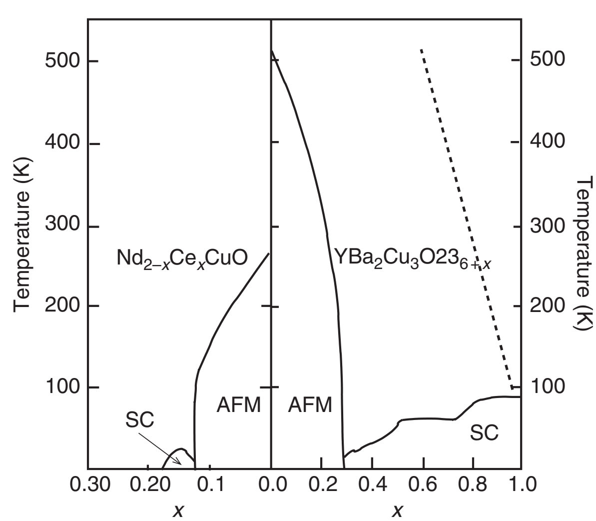

**Figure 1** Phase diagram of the of the NCCO and the YBCO superconductors.

not a true thermodynamical phase, but rather the precursor towards a crossover behavior.

The SC phase of the HTSC has a number of striking properties not shared by conventional superconductors. First of all, phase-sensitive experiments indicate that the SC phase for most of the cuprates has *d* wave like pairing symmetry. This is also supported by the photoemission experiments which show the existence of the nodal points in the quasiparticle gap. Neutron scattering experiments find a new type of collective mode, carrying spin 1, lattice momentum close to $(\pi, \pi)$, and a resolution-limited sharp resonance energy around 20–40 meV. Most remarkably, this resonance mode appears only below $T_c$ of the optimally doped cuprates. Another property uniquely different from the conventional superconductors is the vortex state. Most HTSCs are type II superconductors where the magnetic field can penetrate into the SC state in the form of a vortex lattice, where the SC order is destroyed at the center of the vortex core. In conventional superconductors, the vortex core is filled by the normal metallic electrons. However, a number of different experimental probes, including neutron scattering, muon spin resonance ($\mu$sR), and nuclear magnetic resonance (NMR), have shown that the vortex cores in the HTSC cuprates are antiferromagnetic, rather than normal metallic. This phenomenon has been observed in almost all HTSC materials, including LSCO, YBCO, TBCO, and NSCO, making it one of the most universal properties of the HTSC cuprates.

The HTSC materials also have highly unusual transport properties. While conventional metals have a $T^2$ dependence of resistivity, in accordance with the predictions of the Fermi liquid theory, the HTSC materials have a linear $T$ dependence of resistivity near optimal doping. This linear $T$ dependence extends over a wide temperature window, and seems to be universal among most of the cuprates. When the underdoped or sometimes optimally doped SC state is destroyed by applying a high magnetic field, the "normal state" is not a conventional conducting state, but exhibits insulator-like behavior, at least along the *c*-axis. This phenomenon may be related to the insulating AF vortices mentioned in the previous paragraph.

The discovery of HTSC has greatly stimulated the theoretical understanding of superconductivity in strongly correlated systems. There are a number of promising approaches, partially reviewed in Dagotto (1994), Imada *et al.* (1998), and Orenstein and Millis (2000), but an universally accepted theory has not yet emerged. This article focuses on a particular theory, which unifies the AF and the SC phases of the HTSC cuprates based on an approximate SO(5) symmetry (Zhang 1997). The SO(5) theory draws its inspirations from the successful application of symmetry concepts in theoretical physics. All fundamental laws of Nature are statements about symmetry. Conservation of energy, momentum, and charge are direct consequences of global symmetries. The form of fundamental interactions is dictated by local gauge symmetries. Symmetry unifies apparently different physical phenomena into a common framework. For example, electricity and magnetism were discovered independently, and viewed as completely different phenomena before the nineteenth century. Maxwell's theory, and the underlying relativistic symmetry between space and time, unify the electric field $\boldsymbol{E}$ and the magnetic field $\boldsymbol{B}$ into a common electromagnetic field tensor $F_{\mu\nu}$. This unification shows that electricity and magnetism share a common microscopic origin, and can be transformed into each other by going to different inertial frames. As discussed previously, the two robust and universal ordered phases of the HTSC are the AF and the SC phases. The central question of HTSC concerns the transition from one phase to the other as the doping level is varied. The SO(5) theory unifies the 3D AF order parameter $(N_x, N_y, N_z)$ and the 2D SC order parameter $(\mathrm{Re}\Delta, \mathrm{Im}\Delta)$ into a single, 5D order parameter called "superspin," in a way similar to the unification of electricity and magnetism in Maxwell's theory:

$$F_{\mu\nu} = \begin{pmatrix} 0 & & & \\ E_x & 0 & & \\ E_y & B_z & 0 & \\ E_z & -B_y & B_x & 0 \end{pmatrix} \Leftrightarrow n_a = \begin{pmatrix} \mathrm{Re}\,\Delta \\ N_x \\ N_y \\ N_z \\ \mathrm{Im}\,\Delta \end{pmatrix} \qquad [1]$$

This unification relies on the postulate that a common microscopic interaction is responsible for both AF and SC in the HTSC cuprates and related materials. A well-defined SO(5) transformation rotates one form of the order into another. Within this framework, the mysterious transition from the AF and the SC as a function of doping is explained in terms of a rotation in the 5D order parameters space. Symmetry principles are not only fundamental and beautiful, they are also practically useful in extracting information from a strongly interacting system, which can be tested quantitatively. The approximate SO(5) symmetry between the AF and the SC phases has many direct consequences, which can be, and some of them have been, tested both numerically and experimentally.

The commonly used microscopic model of the HTSC materials is the repulsive Hubbard model, which describes the electronic degrees of freedom in

the $CuO_2$ plane. Its low-energy limit, the $t-J$ model is defined by

$$H = -t \sum_{\langle x,x' \rangle} (c_\sigma^\dagger(x) c_\sigma(x') + \text{h.c.}) + J \sum_{\langle x,x' \rangle} S(x) \cdot S(x') \qquad [2]$$

where the term $t$ describes the hopping of an electron with spin $\sigma$ from a site $x$ to its nearest neighbor $x'$, with double occupancy removed, and the $J$ terms describe the nearest-neighbor exchange of its spin $S$. The main merit of these models does not lie in the microscopic accuracy and realism, but rather in the conceptual simplicity. However, despite their simplicity, these models are still very difficult to solve, and their phase diagrams cannot be compared directly with experiments. The idea of the SO(5) theory is to derive an effective quantum Hamiltonian on a coarse-grained lattice, which contains only the superspin degrees of freedom. The resulting SO(5) quantum nonlinear $\sigma$-model is much simpler to solve using the standard field theoretical techniques, and the resulting phase diagram can be compared directly with experiments.

## SO(4) Symmetry of the Hubbard Model

Before presenting the full SO(5) theory, let us first discuss a much simpler toy model, namely the negative $U$ Hubbard model, which has an SC ground state with $s$-wave pairing. However, it also has a charge-density-wave (CDW) ground state at half-filling. The competition between CDW and the SC states is similar to the competition between AF and SC states in the HTSC cuprates. In the negative $U$ Hubbard model, the CDW/SC competition can be accurately described by a hidden symmetry, namely the SO(4) symmetry of the Hubbard model.

The Hubbard model is defined by the Hamiltonian

$$H = -t \sum_{\langle x,x' \rangle} (c_\sigma^\dagger(x) c_\sigma(x') + \text{h.c.}) + U \sum_x \left(n_\uparrow(x) - \frac{1}{2}\right)\left(n_\downarrow(x) - \frac{1}{2}\right) - \mu \sum_x n_\sigma(x) \qquad [3]$$

where $c_\sigma(x)$ is the fermion operator and $n_\sigma(x) = c_\sigma^\dagger(x) c_\sigma(x)$ is the electron density operator at site $x$ with spin $\sigma$, $t$, $U$, and $\mu$ are the hopping, interaction, and the chemical potential parameters, respectively. The Hubbard model has a pseudospin SU(2) symmetry generated by the operators

$$\eta^- = \sum_x (-)^x c_\uparrow(x) c_\downarrow(x), \qquad \eta^+ = (\eta^-)^\dagger$$
$$\eta^z = \frac{1}{2} \sum_\sigma \left(n_\sigma(x) - \frac{1}{2}\right), \qquad [\eta^\alpha, \eta^\beta] = \mathrm{i}\epsilon_{\alpha\beta\gamma}\eta^\gamma \qquad [4]$$

where $\eta^\pm = \eta^x \pm \mathrm{i}\eta^y$ and $\alpha = x, y, z$. The model is defined on any bipartite lattice, and the lattice function $(-)^x$ takes the value 1 on even sublattice and $-1$ on odd sublattice. These operators commute with the Hubbard Hamiltonian at half-filling when $\mu = 0$, that is, $[H, \eta^\alpha] = 0$; therefore, they form the symmetry generators of the model (Yang and Zhang 1990). Combined with the standard SU(2) spin rotational symmetry, the Hubbard model enjoys an $SO(4) = SU(2) \otimes SU(2)/Z_2$ symmetry. This symmetry has important consequences in the phase diagram and the collective modes in the system. In particular, it implies that the SC and CDW orders are degenerate at half-filling. The SC and the CDW order parameters are defined by

$$\Delta^- = \sum_x c_\uparrow(x) c_\downarrow(x), \qquad \Delta^+ = (\Delta^-)^\dagger$$
$$\Delta^z = \frac{1}{2} \sum_{x\sigma} (-1)^x n_\sigma(x), \qquad [\eta^\alpha, \Delta^\beta] = \mathrm{i}\epsilon_{\alpha\beta\gamma}\Delta^\gamma \qquad [5]$$

where $\Delta^\pm = \Delta^x \pm \mathrm{i}\Delta^y$. The last equation of [5] shows that the $\eta$ operators perform the rotation between the SC and CDW order parameters. Thus, $\eta^\alpha$ is the pseudospin generator and $\Delta^\alpha$ is the pseudospin order parameter. Just like the total spin and the Neel order parameter in the AF Heisenberg model, they are canonically conjugate variables. Since $[H, \eta^\alpha] = 0$ at $\mu = 0$, this exact pseudospin symmetry implies the degeneracy of SC and CDW orders at half-filling.

The phase diagram of the $U < 0$ Hubbard model is identical to the phase diagram of the AF Heisenberg model in a uniform magnetic field. If the AF order parameter originally points along the $z$-direction, a magnetic field applied along the $z$-direction causes the AF order parameter to flop into the $xy$-plane. This transition is called the spin-flop transition, and is depicted in Figures 2a and 2c. The chemical potential $\mu$ in the negative $U$ Hubbard model plays a role similar to the magnetic field in the AF Heisenberg model. It transforms a CDW state at half-filling to an SC state away from half-filling, as depicted in Figures 2a and 2c.

In the low-energy sector, both the AF Heisenberg model in a magnetic field and the negative-$U$ Hubbard model with a chemical potential can be described by the SO(3) nonlinear $\sigma$-model, which is defined by the following Lagrangian density (in

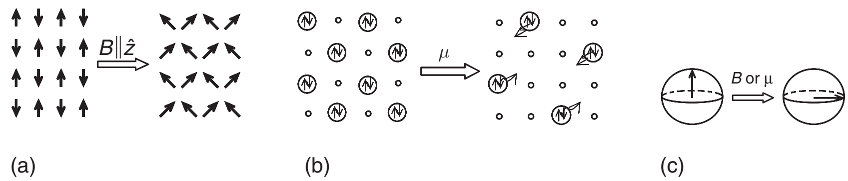

**Figure 2** The spin-flop transition. (a) The spin-flop transition of the AF Heisenberg model. When a uniform magnetic field is applied along the direction of the AF moments, there is no net gain of the Zeeman energy. Therefore, after a critical value of the magnetic field, the AF spin component flops into the *xy*-plane, while a uniform spin component aligns in the direction of applied magnetic field. (b) The Mott insulator to superfluid transition of the hardcore boson model or the $U < 0$ Hubbard model. At half-filling, one possible state is the CDW state of ordered boson pairs. Upon doping, the pairs become mobile and form the superfluid state. (c) Both transitions can be described by the spin or the pseudospin flop in the SO(3) nonlinear $\sigma$-model, induced either by the magnetic field or by the chemical potential.

imaginary time coordinates) for a unit vector field $n_\alpha$ with $n_\alpha^2 = 1$:

$$\mathcal{L} = \frac{\chi}{2}\omega_{\alpha\beta}^2 + \frac{\rho}{2}(\partial_i n_\alpha)^2 + V(n)$$
$$\omega_{\alpha\beta} = n_\alpha(\partial_t n_\beta - \mathrm{i}B_{\beta\gamma}n_\gamma) - (\alpha \to \beta) \qquad [6]$$

where the magnetic field, or equivalently the chemical potential, is given by $B_\alpha = (1/2)\epsilon_{\alpha\beta\gamma}B_{\beta\gamma}$. $\chi$ and $\rho$ are the susceptibility and stiffness parameters, and $V(n)$ is the anisotropy potential, which can be taken as $V(n) = -(g/2)n_z^2$. Exact SO(3) symmetry is obtained when $g = B_\alpha = 0$. $g > 0$ corresponds to easy axis anisotropy, while $g < 0$ corresponds to easy plane anisotropy. In the case of $g > 0$, there is a phase transition as a function of $B_z$ with $B_x = B_y = 0$. To see this, let us expand out the first term in [6]. The time-independent part contributes to an effective potential

$$V_{\text{eff}} = V(n) - \frac{\chi B^2}{2}(n_x^2 + n_y^2)$$

from which we see that there is a phase transition at $B_{c1} = \sqrt{g/\chi}$. For $B < B_{c1}$, the system is in the Ising phase, while for $B > B_{c1}$, the system is in the XY phase. Therefore, tuning $B$ for a fixed $g > 0$ leads to the spin-flop transition. In $D = 2$, both the XY and the Ising phase can have a finite-temperature phase transition into the disordered state. However, because of the Mermin–Wagner theorem, a finite-temperature phase transition is forbidden at the point $B = g = 0$, where the system has an enhanced SO(3) symmetry. This SO(3) symmetric point leads to a large regime below the mean field transition temperature where the fluctuation dominates. This large fluctuation regime can be identified as the pseudogap behavior.

The pseudospin SU(2) symmetry of the negative-$U$ Hubbard model has another important consequence. Away from half-filling, the $\eta$ operators no longer commute with the Hamiltonian, but they are eigenoperators of the Hamiltonian, in the sense that

$$[H, \eta^\pm] = \mp 2\mu\eta^\pm \qquad [7]$$

This means that the $\eta$ operators create well-defined collective modes with energy $2\mu$. Since they carry charge $\pm 2$, they usually do not couple to any physical probes. However, in an SC state, the SC order parameter mixes the $\eta$ operators with the CDW operator $\Delta^z$, via eqn [5]. From this reasoning, a pseudo-Goldstone mode was predicted to exist in the density response function at wave vector $(\pi, \pi)$ and energy $2\mu$, which appears only below the SC transition temperature $T_c$.

## Unification of Antiferromagnetism and Superconductivity through the SO(5) Theory

### Order Parameters and SO(5) Group Properties

The negative $U$ Hubbard model and the SO(3) nonlinear $\sigma$-models discussed in the previous section give a nice description of the quantum phase transition from the Mott insulating phase with CDW order to the SC phase. On the other hand, these simple models do not have enough complexity to describe the AF insulator at half-filling and the SC order away from half-filling. Therefore, a natural step is to generalize these models so that the Mott insulating phase with the scalar CDW order parameter is replaced by a Mott insulating phase with the vector AF order parameter. The pseudospin SO(3) symmetry group considered previously arises from the combination of one real scalar component of the CDW order parameter with one complex, or two real components of the SC order parameter. After replacing the scalar CDW order parameter by the three components of the AF order parameter, and combining with the two components of the SC order parameters, we are naturally led to consider a five-component order parameter vector, and the SO(5) symmetry group which transforms it.

It is simplest to define the concept of the SO(5) symmetry generator and order parameter on two sites with fermion operators $c_\sigma$ and $d_\sigma$, respectively,

where $\sigma = 1, 2$ is the usual spin index. The AF order parameter operator can be naturally defined in terms of the difference between the spins of the $c$ and $d$ fermions as follows:

$$N^\alpha = \tfrac{1}{2}(c^\dagger \tau^\alpha c - d^\dagger \tau^\alpha d), \qquad n_2 \equiv N_1$$
$$n_3 \equiv N_2, \qquad n_4 \equiv N_3 \qquad [8]$$

where $\tau^\alpha$ are the Pauli matrices. In view of the strong on-site repulsion in the cuprate problem, the SC order parameter should be naturally defined on a bond connecting the $c$ and $d$ fermions, explicitly given by

$$\Delta^\dagger = \frac{-\mathrm{i}}{2} c^\dagger \tau^y d^\dagger = \frac{1}{2}(-c_\uparrow^\dagger d_\downarrow^\dagger + c_\downarrow^\dagger d_\uparrow^\dagger),$$
$$n_1 \equiv \frac{(\Delta^\dagger + \Delta)}{2}, \qquad n_5 \equiv \frac{(\Delta^\dagger - \Delta)}{2i} \qquad [9]$$

We can group these five components together to form a single vector $n_a = (n_1, n_2, n_3, n_4, n_5)$ called the superspin, since it contains both superconducting and antiferromagnetic spin components. The individual components of the superspin are explicitly defined in the last parts of eqns [8] and [9].

The concept of the superspin is only useful if there is a natural symmetry group acting on it. In this case, since the order parameter is 5D, it is natural to consider the most general rotation in the 5D order parameter space spanned by $n_a$. In 3D, three Euler angles specify a general rotation. In higher dimensions, a rotation is specified by selecting a plane and the angle of rotation within this plane. Since there are $n(n-1)/2$ independent planes in $n$ dimensions, the group SO($n$) is generated by $n(n-1)/2$ elements, specified in general by antisymmetric matrices $L_{ab} = -L_{ba}$, with $a = 1, \ldots, n$. In particular, the SO(5) group has ten generators. The total spin and the total charge operator

$$S_\alpha = \tfrac{1}{2}(c^\dagger \tau_\alpha c + d^\dagger \tau_\alpha d)$$
$$Q = \tfrac{1}{2}(c^\dagger c + d^\dagger d - 2) \qquad [10]$$

perform the function of rotating the AF and SC order parameters within each subspace. In addition, there are six so-called $\pi$ operators, defined by

$$\pi_\alpha^\dagger = -\tfrac{1}{2} c^\dagger \tau_\alpha \tau_y d^\dagger, \quad \pi_\alpha = (\pi_\alpha^\dagger)^\dagger \qquad [11]$$

which perform the rotation from AF to SC and vice versa. These infinitesimal rotations are defined by the commutation relations

$$[\pi_\alpha^\dagger, N_\beta] = \mathrm{i}\delta_{\alpha\beta}\Delta^\dagger, \qquad [\pi_\alpha^\dagger, \Delta] = \mathrm{i}N_\alpha \qquad [12]$$

The ten operators, the total spin $S_\alpha$, the total charge $Q$, and the six $\pi$ operators form the ten generators of the SO(5) group.

The superspin order parameter $n_a$, the associated SO(5) generators $L_{ab}$, and their commutation relations can be expressed compactly and elegantly in terms of the SO(5) spinor and the five Dirac $\Gamma$ matrices. The four-component SO(5) spinor is defined by

$$\Psi_\mu = \begin{pmatrix} c_\sigma \\ d_\sigma^\dagger \end{pmatrix} \qquad [13]$$

They satisfy the usual anticommutation relations

$$\{\Psi_\mu^\dagger, \Psi_\nu\} = \delta_{\mu\nu}, \qquad \{\Psi_\mu, \Psi_\nu\} = \{\Psi_\mu^\dagger, \Psi_\nu^\dagger\} = 0 \qquad [14]$$

Using the $\Psi$ spinor and the five Dirac $\Gamma$ matrices, we can express $n_a$ and $L_{ab}$ as

$$n_a = \tfrac{1}{2}\Psi_\mu^\dagger \Gamma_{\mu\nu}^a \Psi_\nu, \qquad L_{ab} = -\tfrac{1}{2}\Psi_\mu^\dagger \Gamma_{\mu\nu}^{ab}\Psi_\nu \qquad [15]$$

The $L_{ab}$ operators satisfy the commutation relation

$$[L_{ab}, L_{cd}] = -\mathrm{i}(\delta_{ac}L_{bd} + \delta_{bd}L_{ac} - \delta_{ad}L_{bc} - \delta_{cc}L_{ad}) \qquad [16]$$

The $n_a$ and the $\Psi_\mu$ operators form the vector and the spinor representations of the SO(5) group, satisfying the following equations:

$$[L_{ab}, n_c] = -\mathrm{i}(\delta_{ac}n_b - \delta_{bc}n_a) \qquad [17]$$

and

$$\left[L_{ab}, \Psi_\mu\right] = -\tfrac{1}{2}\Gamma_{\mu\nu}^{ab}\Psi_\nu \qquad [18]$$

If we arrange the ten operators $S_\alpha, Q$, and $\pi_\alpha$ into $L_{ab}$'s by the following matrix form:

$$L_{ab} = \begin{pmatrix} 0 & & & & \\ \pi_x^\dagger + \pi_x & 0 & & & \\ \pi_y^\dagger + \pi_y & -S_z & 0 & & \\ \pi_z^\dagger + \pi_z & S_y & -S_x & 0 & \\ Q & \frac{1}{i}(\pi_x^\dagger - \pi_x) & \frac{1}{i}(\pi_y^\dagger - \pi_y) & \frac{1}{i}(\pi_z^\dagger - \pi_z) & 0 \end{pmatrix} \qquad [19]$$

and group $n_a$ as in eqns [8] and [9], we see that eqns [16] and [17] compactly reproduce all the commutation relations worked out previously. These equations show that $L_{ab}$ and $n_a$ are the symmetry generators and the order parameter vectors of the SO(5) theory.

Having introduced the concept of local symmetry generators and order-parameter-based sites in real space, we now proceed to discuss definitions of these operators in momentum space. The AF and dSC order parameters can be naturally expressed in terms of the microscopic fermion operators as

$$N^\alpha = \sum_p c_{p+\Pi}^\dagger \tau^\alpha c_p, \quad \Delta^\dagger = \frac{-\mathrm{i}}{2}\sum_p d(p) c_p^\dagger \tau^y c_{-p}^\dagger$$
$$d(p) \equiv \cos p_x - \cos p_y \qquad [20]$$

where $\Pi \equiv (\pi, \pi)$ and $d(p)$ is the form factor for $d$-wave pairing in 2D. They can be combined into the five-component superspin vector $n_a$ by using the

**Table 1** Quantum number of the AF and the dSC order parameters, and the $\pi$ operator, which rotates the AF and the dSC order parameters into each other

| | *Charge* | *Spin* | *Momentum* | *Internal angular momentum* |
|---|---|---|---|---|
| $\Delta, \Delta^\dagger$ or $n_1, n_5$ | $\pm 2$ | 0 | 0 | d-Wave |
| $N^\alpha$ or $n_{2,3,4}$ | 0 | 1 | $(\pi, \pi)$ | s-Wave |
| $\pi_\alpha, \pi_\alpha^\dagger$ | $\pm 2$ | 1 | $(\pi, \pi)$ | d-Wave |

same convention as before. The total spin and total charge operator are defined microscopically as

$$S_\alpha = \sum_p c_p^\dagger \tau^\alpha c_p, \qquad Q = \frac{1}{2}\sum_p (c_p^\dagger c_p - 1) \qquad [21]$$

and the $\pi$-operators can be defined as

$$\pi_\alpha^\dagger = \sum_p g(p) c_{p+\Pi}^\dagger \tau^\alpha \tau^y c_{-p}^\dagger \qquad [22]$$

The form factor $g(p)$ needs to be chosen appropriately to satisfy the SO(5) commutation relation [16], and this requirement determines $g(p) = \mathrm{sgn}(d(p))$.

The SO(5) symmetry generators perform the most general rotation among the five-order parameters. It is easy to see that the quantum number of the $\pi$ operators exactly patches up the difference in quantum numbers between the AF and the dSC order parameters, according to Table 1.

### The SO(5) quantum nonlinear $\sigma$-model

In the previous section we presented the concept of the local SO(5) order parameters and symmetry generators. These relationships are purely kinematic, and do not refer to any particular Hamiltonian. One can in fact construct microscopic models with exact SO(5) symmetry out of these operators. A large class of models, however, may not have SO(5) symmetry at the microscopic level, but their long-distance, low-energy properties may be described in terms of an effective SO(5) model. In the previous section, we have seen that many different microscopic models indeed all have the SO(3) nonlinear $\sigma$-model as their universal low-energy description. Similarly, we present the SO(5) quantum nonlinear $\sigma$-model as a general theory of AF and dSC in the HTSC.

From eqn [17] and the discussions in the previous subsection, we see that $L_{ab}$ and $n_a$ are conjugate degrees of freedom, very much similar to $[q, p] = i\hbar$ in quantum mechanics. This suggests that we can construct a Hamiltonian from these conjugate degrees of freedom. The Hamiltonian of the SO(5) quantum nonlinear $\sigma$-model takes the following form:

$$H = \frac{1}{2\chi}\sum_x L_{ab}^2(x) + \frac{\rho}{2}\sum_{<x,x'>} n_a(x) n_a(x') + \sum_x B_{ab}(x) L_{ab}(x) + \sum_x V(n(x)) \qquad [23]$$

where the $n_a$ vector field is subjected to the constraint

$$n_a^2 = 1 \qquad [24]$$

This Hamiltonian is quantized by the canonical commutation relations [16] and [17]. Here, the first term is the kinetic energy of the SO(5) rotors, where $\chi$ has the physical interpretation of the moment of inertia of the SO(5) rotors. The second term describes the coupling of the SO(5) rotors on different sites, through the generalized stiffness $\rho$. The third term introduces the coupling of external fields to the symmetry generators, while the $V(n)$ can include anisotropic terms to break the SO(5) symmetry to the SO(3) × U(1) symmetry. The SO(5) quantum nonlinear $\sigma$-model is a natural combination of the SO(3) nonlinear $\sigma$-model describing the AF Heisenberg model and the quantum XY model describing the SC to insulator transition. If we restrict to the values $a = 2, 3, 4$, then the first two terms describe the symmetric Heisenberg model, the third term describes easy plane or easy axis anisotropy of the Neel vector, while the last term represents the coupling to the uniform external magnetic field. On the other hand, for $a = 1, 5$, the first term describes Coulomb or capacitance energy, the second term is the Josephson coupling energy, while the last term describes coupling to external chemical potential.

The first two terms of the SO(5) model describe the competition between the quantum disorder and classical order. In the ordered state, the last two terms describe the competition between the AF and the SC order. Let us first consider the quantum competition. The first term prefers sharp eigenstates of the angular momentum. At an isolated site, $C \equiv \sum L_{ab}^2$ is the Casimir operator of the SO(5) group, in the sense that it commutes with all the SO(5) generators. The eigenvalues of this operator can be determined completely from group theory; they are 0, 4, 6, and 10, respectively, for the 1D SO(5) singlet, 5D SO(5) vector, 10D antisymmetric tensor, and 14D symmetric, traceless tensors. Therefore, we see that this term always prefers a quantum-disordered SO(5) singlet ground state, which is a total spin singlet. This ground state is separated from the first excited state, the fivefold

SO(5) vector state with an energy gap of $2/\chi$. This gap will be reduced, when the different SO(5) rotors are coupled to each other by the second term. This term represents the effect of stiffness, which prefers a fixed direction of the $n_a$ vector, rather than a fixed angular momentum. This competition is an appropriate generalization of the competition between the number sharp and phase sharp states in a superconductor and the competition between the classical Neel state and the bond or plaquette singlet state in the Heisenberg AF. The quantum phase transition occurs near $\chi\rho \simeq 1$.

In the classically ordered state, the last two anisotropy terms compete to select a ground state. To simplify the discussion, we can first consider the following simple form of the static anisotropy potential:

$$V(n) = -g(n_2^2 + n_3^2 + n_4^2) \qquad [25]$$

At the particle-hole symmetric point with vanishing chemical potential $B_{15} = \mu = 0$, the AF ground state is selected by $g > 0$, while the SC ground state is selected by $g < 0$ coupled with the constraint $n_a^2 = 1$. $g = 0$ is the quantum phase transition point separating the two ordered phases.

However, it is unlikely that the HTSC cuprates can be close to this quantum phase transition point. In fact, we expect the anisotropy term $g$ to be large and positive, so that the AF phase is strongly favored over the SC phase at half-filling. However, the chemical potential term has the opposite, competing effect favoring SC. To see this, we transform the Hamiltonian into the Lagrangian density (in imaginary time coordinates) in the continuum limit:

$$\mathcal{L} = \frac{\chi}{2}\omega_{ab}(x,t)^2 + \frac{\rho}{2}(\partial_k n^a(x,t))^2 + V(n(x,t)) \qquad [26]$$

where

$$\omega_{ab} = n_a(\partial_t n_b - \mathrm{i}B_{bc}n_c) - (a \to b) \qquad [27]$$

is the angular velocity. We see that the chemical potential enters the Lagrangian as a gauge coupling in the time direction. Expanding the time derivative term, we obtain an effective potential

$$V_{\text{eff}}(n) = V(n) - \frac{(2\mu)^2\chi}{2}(n_1^2 + n_5^2) \qquad [28]$$

from which we see that the $V$ term competes with the chemical potential term. For $\mu < \mu_c = \sqrt{g/\chi}$, the AF ground state is selected, while for $\mu > \mu_c$, the SC ground state is realized. At the transition point, even though each term strongly breaks SO(5) symmetry, the combined term gives an effective static potential which is SO(5) symmetric, as we can see from [28]. Even though the static potential is SO(5) symmetric, the full quantum dynamics is not. This can be most easily seen from the time-dependent term in the Lagrangian. When we expand out the square, the term quadratic in $\mu$ enters the effective static potential in eqn [28]. However, there is also a time-dependent term linear in $\mu$. This term breaks the particle-hole symmetry, and it dominates over the second-order time derivative term in the $n_1$ and $n_5$ variables. In the absence of an external magnetic field, only second-order time derivative terms of $n_{2,3,4}$ enter the Lagrangian. Therefore, while the chemical potential term compensates the anisotropy potential in eqn [28] to arrive at an SO(5) symmetric static potential, its time-dependent part breaks the full quantum SO(5) symmetry. This observation leads to the concept of the projected, or static SO(5) symmetry (Zhang *et al.* 1999). A model with projected or static SO(5) symmetry is described by a quantum effective Lagrangian of the form

$$\mathcal{L} = \frac{\chi}{2}\sum_{a=2,3,4}(\partial_t n_a)^2 - \chi\mu(n_1\partial_t n_5 - n_5\partial_t n_1) - V_{\text{eff}}(n) \qquad [29]$$

where the static potential $V_{\text{eff}}$ is SO(5) symmetric, but the time-dependent part contains a first-order time derivative term in $n_1$ and $n_5$.

The SO(5) quantum nonlinear $\sigma$-model is constructed from two canonically conjugate field operators $L_{ab}$ and $n_a$. In fact, there is a kinematic constraint among these field operators:

$$L_{ab}n_c + L_{bc}n_a + L_{ca}n_b = 0 \qquad [30]$$

This identity is valid for any triples $a$, $b$, and $c$, and can be easily proved by expressing $L_{ab} = n_a p_b - n_b p_a$, where $p_a$ is the conjugate momentum of $n_a$. Geometrically, this identity expresses the fact that $L_{ab}$ generates a rotation of the $n_a$ vector. The infinitesimal rotation vector lies on the tangent plane of the four sphere $S^4$, and is therefore orthogonal to the $n_a$ vector itself.

In a large class of materials, including the high-$T_c$ cuprates, the organic superconductors, and the heavy fermion compounds, the AF and SC phases occur in close proximity to each other. The SO(5) theory is developed based on the assumption that these two phases share a common microscopic origin and should be treated on an equal footing. The SO(5) theory gives a coherent description of the rich global phase diagram of the high-$T_c$ cuprates and its low-energy dynamics through a simple symmetry principle and a unified effective model based on a single quantum Hamiltonian. A number of theoretical predictions, including the intensity dependence of the neutron resonance

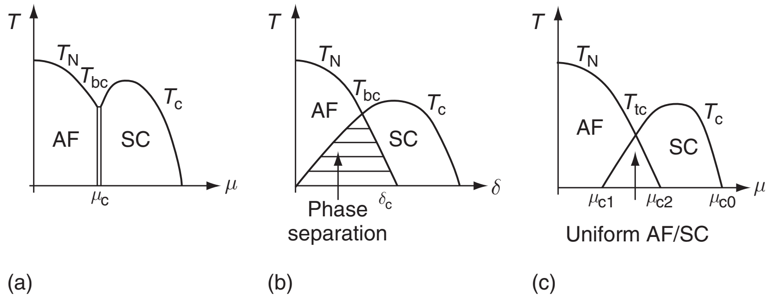

**Figure 3** The finite-temperature phase diagram of the SO(5) model in the temperature ($T$) versus chemical potential ($\mu$) plane. (a) and (b) are two different representations of the same phase diagram, corresponding to a direct first-order phase transition between AF and SC, as a function of the chemical potential and doping, respectively. (c) corresponds to two second-order phase transitions with a uniform AF/SC mix phase in between. The AF and the SC transition temperatures $T_N$ and $T_c$ merge into a bicritical $T_{bc}$ or a tetra-critical point $T_{tc}$. Both possibilities are allowed theoretically; it is up to experiments to determine which one is actually realized in the high-$T_c$ cuprates.

mode, the AF vortex state, and the mixed phase of AF and SC, have been verified experimentally (Figure 3). The theory also sheds light on the microscopic mechanism of superconductivity and quantitatively correlates the AF exchange energy with the condensation energy of superconductivity. However, the theory is still incomplete in many ways and lacks full quantitative predictive power. While the role of fermions is well understood within the exact SO(5) models, their roles in the effective SO(5) models are still not fully worked out. As a result, the theory has not made many predictions concerning the transport properties of these materials.

# Holomorphic Dynamics

**M Lyubich**, University of Toronto, Toronto, ON, Canada and Stony Brook University, NY, USA

## Introduction

### Subject

*Holomorphic dynamics* (in a narrow sense) is a theory of iterates of rational endomorphisms of the Riemann sphere $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$. The goal is to understand the *phase portrait* of this dynamical system, that is, the structure of its trajectories, and the dependence of the phase portrait on *parameters* (coefficients of $f$).

Holomorphic dynamics in a broader sense would include the theory of analytic transformations, local and global, in dimension 1 and higher, as well as the theory of groups and pseudogroups of analytic transformations, which would cover theory of Kleinian groups and holomorphic foliations. However, we will mostly focus on holomorphic dynamics in the narrow sense.

### Brief History

Local dynamical theory of analytic maps was laid down in the late nineteenth and early twentieth century by Königs, Schröder, Böttcher, and Leau. Global theory of iterates of rational maps was founded by Fatou and Julia in comprehensive memoires of 1918–19. The theory had been

developed very little since then until early 1980s when it exploded with new methods, ideas, and computer images. Particularly influential were the works of D Sullivan who introduced ideas of *quasiconformal deformations* into the field, of A Douady and J Hubbard who gave a comprehensive combinatorial description of the Mandelbrot set, and W Thurston who linked holomorphic dynamics to three-dimensional hyperbolic geometry bringing to the field ideas of geometrization and rigidity. As a result, profound rigidity conjectures were formulated. Renormalization ideas introduced to the theory later on led to a significant progress towards these conjectures (*see* Universality and Renormalization).

Another source of ideas came from ergodic theory and the general theory of dynamical systems, particularly hyperbolic dynamics and thermodynamical formalism. They led to constructions of natural geometric measures on the Julia sets that helped to penetrate into their fractal nature.

### General Terminology and Notations

$\mathbb{N} = \{1, 2, \ldots\}$ is the set of natural numbers; $\mathbb{D}$ is the unit disk; $\mathbb{Z}_+ = \mathbb{N} \cup \{0\}; \mathbb{T} = \partial\mathbb{D}$.

A *topological disk* is a simply connected domain in $\mathbb{C}$. A *topological annulus* is a doubly connected domain in $\mathbb{C}$ (i.e., a domain homeomorphic to a round annulus). A *Cantor set* is a totally disconnect compact subset of $\mathbb{R}^n$ without isolated points.

Given a map $f: X \to X, f^n$ will stand for its $n$-fold iterate. The semigroup of iterates form a *dynamical system with discrete time*. An *orbit* or *trajectory* of a point $z$ is $\mathrm{orb}_f(z) = (f^n z)_{n=0}^{\infty}$.

A subset $Y \subset \hat{\mathbb{C}}$ is called *invariant* if $f(Y) \subset Y$ and *completely invariant* if also $f^{-1}(Y) \subset Y$.

A point $\alpha \in \hat{\mathbb{C}}$ is called *periodic* if $f^p \alpha = \alpha$ for some natural $p$. The smallest such $p$ is called the *period* of $\alpha$. If $p = 1$, then $\alpha$ is called a *fixed point*. The orbit of a periodic point is also called a *cycle*.

Two maps $f: X \to X$ and $g: Y \to Y$ on topological spaces $X$ and $Y$ are called *topologically conjugate* if there exists a homeomorphism $h: X \to Y$ such that $h \circ f = g \circ h$. If $h$ has better regularity properties, for example, it is quasiconformal/conformal/affine, then $f$ and $g$ are called *quasiconformally/conformally/affinely conjugate*.

Let $f(z) = P(z)/Q(z)$ be a rational function viewed as a map $\hat{\mathbb{C}} \to \hat{\mathbb{C}}$. Its *topological degree* $\deg f = \# f^{-1}(z)$, $z \in \hat{\mathbb{C}}$, (where the preimages of $z$ are counted with multiplicity), is equal to the *algebraic degree* $\max(\deg P, \deg Q)$. The dynamics of $f$ is very simple in degree 1, so in what follows we assume that $\deg f \geq 2$.

Let $C_f = \{c : Df(c) = 0\}$ stand for the set of *critical points* of $f$, and $V_f = f(C_f)$ be the set of *critical values*. A rational function of degree $d$ has $2d - 2$ critical points counted with multiplicity. Moreover,

$$C_{f^n} = \bigcup_{k=0}^{n-1} f^{-k}(C_f), \qquad V_{f^n} = \bigcup_{k=1}^{n} f^k(C_f)$$

The latter formula explains why the behavior of the critical orbits crucially influences the global dynamics of $f$. The set $O_f = \cup V_{f^n}$ is called *postcritical*.

## Basic Dynamical Theory

### Local Theory

The local theory describes the dynamics of an analytic map $f: z \mapsto \lambda z + \sum_{n=2} a_n z^n$ near its fixed point 0. The derivative $\lambda = f'(0)$ is called the multiplier of 0. The fixed point is called *attracting*, *repelling*, or *neutral*, depending on whether $|\lambda| < 1$, $|\lambda| > 1$, or $|\lambda| = 1$. It is called *superattracting* if $\lambda = 0$.

In case when 0 is an attracting (but not superattracting) or repelling fixed point, the map is *linearizable*, that is, it is conformally conjugate to its linear part $z \mapsto \lambda z$; thus, there is a local conformal solution of the *Schröder equation* $\phi(fz) = \lambda\phi(z)$. This solution is also called the *linearizing coordinate* near 0.

In the superattracting case, the map is conformally conjugate to the map $z \mapsto z^d$, where $a_d z^d$ is the first nonvanishing term in the local expansion of $f$. Thus, in this case there is a local conformal solution of the *Böttcher equation* $\phi(fz) = \phi(z)^d$. It is also called the *Böttcher coordinate* near 0.

The situation in the neutral case (when $\lambda = e^{2\pi i\theta}$, $\theta \in \mathbb{R}/\mathbb{Z}$) depends in a delicate way on the arithmetic properties of the *rotation number* $\theta$. If $\theta = q/p$ is rational, the fixed point 0 is called *parabolic*. The local dynamics is then described in terms of the *Leau–Fatou flower* consisting of attracting petals alternating with repelling petals. In each petal, the map is conformally conjugate to the translation $z \mapsto z + 1$. The quotients of the petals by dynamics are conformally equivalent to the cylinder $\mathbb{C}/\langle z \mapsto z + 1 \rangle$. They are called (*attracting/repelling*) *Ecalle–Voronin cylinders*.

In the *irrational* case, when $\theta \in \mathbb{R} \backslash \mathbb{Q}$, the map can be either linearizable or not. Accordingly, 0 is called a *Siegel* or a *Cremer* fixed point. If the multiplier is *Diophantine* (i.e., there exist $C > 0$ and $\alpha > 2$ such that for all rational numbers $q/p$, we have: $|\theta - q/p| \geq Cp^{\alpha}$), then 0 is linearizable (Siegel 1942).

Notice that almost all numbers are Diophantine. A sharper arithmetic condition for linearizability in terms of the continuous fraction expansion for $\theta$ was given by Bruno (1965). In the quadratic case, $z \mapsto e^{2\pi i\theta} z + z^2$, this condition was proved to be sharp (Yoccoz 1988).

### Fatou and Julia Sets

From now on, $f : \hat{\mathbb{C}} \to \hat{\mathbb{C}}$ is a rational endomorphism of the Riemann sphere. The theory starts with the splitting of the sphere into two subsets now called Fatou and Julia sets based on the notion of a normal family in the sense of Montel. A family $(\phi_\alpha : S \to \hat{\mathbb{C}})$ of meromorphic functions on some Riemann surface $S$ is called *normal* if it is precompact in the open–closed topology. The *Fatou set* $F(f)$ is the maximal open subset of $\hat{\mathbb{C}}$ on which the family of iterates $(f^n)_{n=0}^{\infty}$ is normal. The *Julia set* $J(f)$ is the complement of the Fatou set. Both sets are completely invariant. The Julia set is always nonempty, and is either nowhere dense or coincides with the whole sphere. The trajectories on the Fatou set are *Lyapunov stable* (if $z$ is close to $z_0 \in F(f)$, then $\mathrm{orb}_f(z)$ is uniformly close to $\mathrm{orb}_f(z_0)$), while the dynamics on the Julia set is "chaotic."

If $f$ is a polynomial, then the Fatou and Julia sets can be defined in a more concrete way as follows. In this case, $\infty$ is a superattracting fixed point for $f$. Let us consider its *basin of attraction*,

$$D_f(\infty) = \{z : f^n z \to \infty \text{ as } z \to \infty\}$$

Its complement, $K(f)$, is called the *filled Julia set*. Then,

$$J(f) = \partial K(f) = \partial D_f(\infty)$$

### Periodic Points

Let $\alpha$ be a periodic point of $f$ of period $p$. As a fixed point of $f^p$, it is subject of the local theory. Thus, it (and its cycle) is classified as *attracting*, *repelling*, etc., according to the properties of the *multiplier* $\lambda = (f^p)'(\alpha)$ (that can be calculated in *any* local chart near $\alpha$).

The *basin of attraction* $D_f(\boldsymbol{\alpha})$ of an attracting cycle $\boldsymbol{\alpha} = (f^n \alpha)_{n=0}^{p-1}$ is the set $\{z : f^n z \to \boldsymbol{\alpha} \text{ as } n \to \infty\}$. The *immediate basin of attraction* $D_f^*(\boldsymbol{\alpha})$ is the union of components of $D_f(\boldsymbol{\alpha})$ containing the points of $\boldsymbol{\alpha}$.

**Theorem 1** (Fatou–Julia). *The immediate basin of any attracting cycle contains a critical point.* (*Note that a superattracting cycle actually contains some critical point.*)

It follows that *a rational function of degree d has at most* $2d-2$ *attracting cycles. A polynomial of degree d has at most* $d-1$ *attracting cycles in* $\mathbb{C}$.

Attracting cycles belong to the Fatou set, while repelling cycles lie on the Julia set. Parabolic and Cremer points lie on the Julia set, while Siegel points belong to the Fatou set. The *basin of attraction* of a parabolic cycle $\boldsymbol{\alpha}$ is defined as

$$D_f(\boldsymbol{\alpha}) = \{z : f^n z \to \boldsymbol{\alpha} \text{ as } n \to \infty\} \setminus \bigcup_{n=0}^{\infty} f^{-n}(\boldsymbol{\alpha})$$

It is the union of some components of the Fatou set. The union of the components of $D_f(\boldsymbol{\alpha})$ containing the petals of the Leau–Fatou flower is called the *immediate basin of attraction* $D_f^*(\boldsymbol{\alpha})$ of $\boldsymbol{\alpha}$. As in the attracting case, *the immediate basin* $D_f^*(\boldsymbol{\alpha})$ *of a parabolic cycle contains a critical point of f*.

Components of the Fatou set containing Siegel periodic points are called *Siegel disks*. If $D$ is a Siegel disk of period $p$, then $f^p|D$ is conformally conjugate to the irrational rotation $z \mapsto e^{2\pi i\theta} z$ of the unit disk.

**Theorem 2** (Shishikura 1987). *A rational function of degree d has at most* $2d-2$ *nonrepelling cycles.*

The proof of this result uses the methods of *quasiconformal surgery*.

### Examples

For $f : z \mapsto z^d, d \geq 2$, the Julia set $J(f)$ is the unit circle. Moreover, $D_f(\infty) = \hat{\mathbb{C}} \setminus \bar{\mathbb{D}}$, while $\mathbb{D}$ is the basin of attraction of the superattracting fixed point 0.

For maps $f_\varepsilon : z \mapsto z^2 + \varepsilon$ with sufficiently small $\varepsilon \neq 0$, the Julia set $J(f)$ is a *nowhere-differentiable* Jordan curve (see Figure 1). The domain bounded by this curve is the basin of attraction of an attracting fixed point $\alpha_\varepsilon$.

The filled Julia set of the map $f : z \mapsto z^2 - 1$ called the *basilica* is depicted in black in Figure 2. The

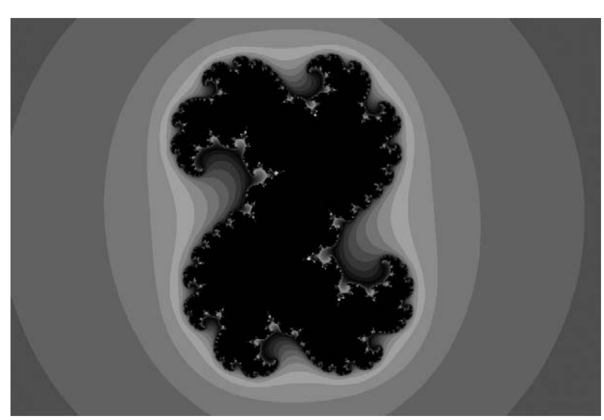

**Figure 1** Nowhere-differentiable Jordan curve.

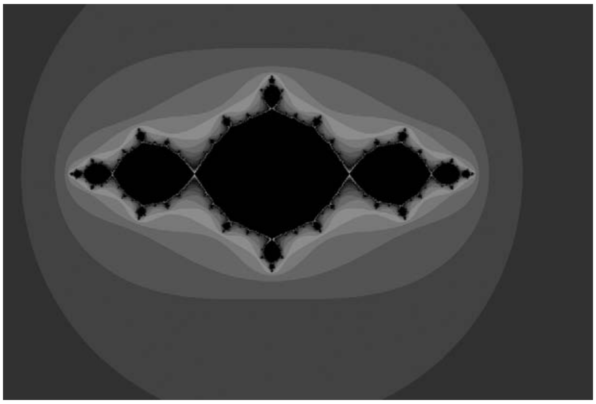

**Figure 2** Basilica.

interior of the basilica is the basin of the super-attracting cycle $\alpha = (0, 1)$ of period 2.

For the map $f: z \mapsto z^2 - 2$, the Julia set is the interval $[-2, 2]$. It is affinely conjugate to the Chebyshev quadratic polynomial $\mathrm{Ch}_2 : z \mapsto 2z^2 - 1$. More generally, for a Chebyshev polynomial $\mathrm{Ch}_d$ of any degree $d$, the Julia set is the interval. (By definition, the *Chebyshev polynomial* $\mathrm{Ch}_d$ is the solution of the functional equation $\cos dz = \mathrm{Ch}_d(\cos z)$.)

For quadratic maps $f_c : z \mapsto z^2 + c$ with $c < -2$, the Julia set is a *Cantor set* on $\mathbb{R}$. For maps $f_c$ with $c > 1/4$, the Julia set is a Cantor set that does not meet $\mathbb{R}$. For $c \in (-2, 1/4]$, the Julia set contains an invariant interval on $\mathbb{R}$, but is not contained in $\mathbb{R}$.

For $f: z \mapsto z^2 + i$, the Julia set is a "dendrite" (see Figure 3).

For $c \approx 0.12 + 0.74i$, the map $f: z \mapsto z^2 + c$ has an attracting cycle of period 3. Its Julia set in known as the *Douady rabbit* (Figure 4).

## No Wandering Domains Theorem and Dynamics on the Fatou Set

A component $D$ of the Fatou set is called *wandering* if $f^n(D) \cap f^m(D) = \emptyset$ for all natural $n > m$.

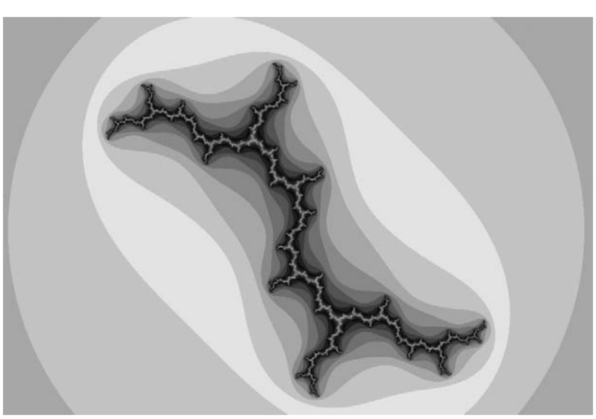

**Figure 3** Dendrite.

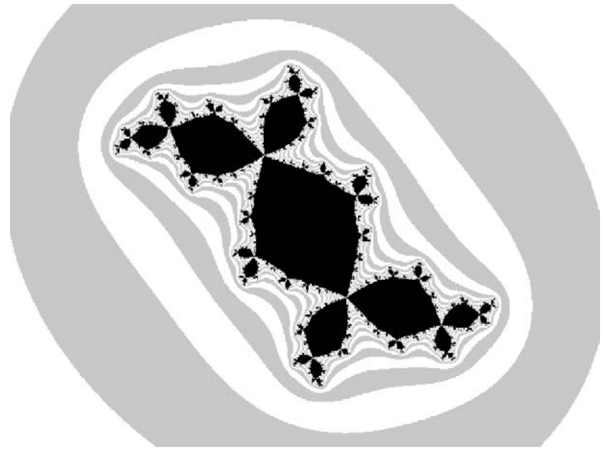

**Figure 4** Douady rabbit.

**Theorem 3** (Sullivan 1982). *Rational functions do not have wandering domains.*

This theorem is analogous to Ahlfors theorem in the theory of Kleinian groups. Its proof introduced to holomorphic dynamics the methods of *quasiconformal deformations* that has become the basic tool of the subject.

The "no wandering domains theorem" has completed the picture of dynamics on the Fatou set. Namely, for any $z \in F(f)$, one of the following three events may happen:

- $z$ belongs to the basin of attraction of some attracting cycle;
- $z$ belongs to the basin of attraction of some parabolic cycle; and
- for some $n$, $f^n z$ belongs to a rotation domain.

Here a *rotation domain* is either a Siegel disk, or a *Herman ring*, that is, a topological annulus $A$ such that $f^p(A) = A$ for some $p \in \mathbb{N}$ and $f^p \,|\, A$ is conformally equivalent to an irrational rotation $z \mapsto e^{2\pi i} z$ of a round annulus $\{z : 1 < |z| < R\}$. Note that Herman rings cannot occur for polynomial maps.

## More Properties of the Julia Set

There are two more useful characterizations of the Julia set:

- If $z$ is not an attracting periodic point and does not belong to a rotation domain, then *the set of accumulation points of the full preimages $f^{-n}z$ is equal to $J(f)$.*
- *The Julia set is the closure of the set of repelling periodic points.*

In the polynomial case, the Julia set $J(f)$ (and the filled Julia set $K(f)$) *is connected if and only if the critical points do not escape to* $\infty$ (in other words,

$C_f \subset K(f)$). In the quadratic case, the *Basic Dichotomy* holds: *the Julia set (and the filled Julia set) is either connected or a Cantor set*.

### Böttcher Coordinate

Let $f = z^d + a_1 z^{d-1} + \cdots + a_d$ be a monic polynomial of degree $d \geq 2$. Then $\infty$ is a superattracting fixed point, and hence there is a univalent function $B(z) = B_f(z)$ near $\infty$ satisfying the Böttcher equation $B(fz) = B(z)^d$ (the *Böttcher coordinate* near $\infty$). Moreover, $B(z) \sim z$ as $z \to \infty$ since $f$ is monic.

If $J(f)$ is connected, $B(z)$ can be analytically extended to the whole basin of $\infty$, and provides us with the Riemann map $\mathbb{C} \setminus K(f) \to \mathbb{C} \setminus \bar{\mathbb{D}}$. Otherwise, $B(z)$ extends to a conformal map from some invariant domain $\Omega_f$ whose boundary contains a critical point onto $\mathbb{C} \setminus \bar{\mathbb{D}}_R$, where $R = R_f > 1$.

The $B$-preimage of a straight ray $\{re^{2\pi i\theta}: 0 < r < \infty\}$ is called the *external ray* $\mathcal{R}_\theta$ of angle $\theta$. The $B$-preimage of a round circle $\{re^{2\pi i\theta}: 0 \leq \theta < 1\}$ is called the *equipotential* $\mathcal{E}_t$ *of level* $t = \log r$. External rays and equipotentials form two orthogonal $f$-invariant foliations. We let $\mathcal{R}_\theta(t) = \mathcal{R}_\theta \cap \mathcal{E}_t$.

### Combinatorial Equivalence

Assume now that $J(f)$ is connected. One says that an external ray $\mathcal{R}_\theta$ *lands* at some point $z \in J(f)$ if $\mathcal{R}_\theta(t) \to z$ as $t \to 0$. *Any external ray of rational angle* $\theta = q/p$ *with odd* $p$ *lands at some repelling or parabolic periodic point of period dividing* $p$ (Douady and Hubbard 1982). Vice versa, *any repelling or parabolic point is a landing point of at least one rational ray as above* (Douady 1990s).

Let us consider the following equivalence relation on the set of rational numbers with odd denominators: two such numbers $\theta$ and $\theta'$ are equivalent if the corresponding rays $\mathcal{R}_\theta$ and $\mathcal{R}_{\theta'}$ land at the *same* point $z \in J(f)$. Two polynomials $f$ and $\tilde{f}$ with connected Julia set are called *combinatorially equivalent* if the corresponding equivalence relations coincide. Notice that topologically equivalent polynomials are combinatorially equivalent.

## Parameter Phenomena

### Spaces of Rational Functions

Let $\mathrm{Rat}_d$ stand for the space of rational functions of degree $d$. As an open subset of the complex projective space $\mathbb{CP}^{2d+1}$, it is endowed with the natural topology and complex structure.

### Hyperbolic Maps and Fatou's Conjecture

Hyperbolic maps form an important and best-understood class of rational maps (compare with Hyperbolic Dynamical Systems). A rational map $f$ is called *hyperbolic* if one of the following equivalent conditions holds:

- All critical points of $f$ converge to attracting cycles;
- The map is expanding on the Julia set:

$$|Df^n(z)| \geq C\lambda^n, \quad z \in J(f)$$

where $C > 0$, $\lambda > 1$.

For instance, the maps $z \mapsto z^2 + \varepsilon$ for small $\varepsilon$, $z \mapsto z^2 - 1$, and $z \mapsto z^2 + c$ for $c \in \mathbb{R} \setminus [-2, 1/4]$ are hyperbolic. It is easy to see from the first definition that hyperbolicity is a *stable* property, that is, the set of hyperbolic maps is open in the space $\mathrm{Rat}_d$ of rational maps of degree $d$. One of the central open problems in holomorphic dynamics is to prove that this set is also dense. This problem is known as *Fatou's conjecture*.

### Postcritically Finite Maps and Thurston's Theory

A rational map is called *postcritically finite* if the orbits of all critical points are finite. In this case, any critical point $c$ is either a superattracting periodic point, or a repelling *preperiodic* point (i.e., $f^n c$ is a repelling periodic point for some $n$). *If all critical points of f are preperiodic, then* $J(f) = \hat{\mathbb{C}}$.

Important examples of postcritically finite maps with $J(f) = \hat{\mathbb{C}}$ come from the theory of elliptic functions. Namely, let $\mathcal{P}_\tau : \mathbb{C}/\Gamma_\tau \to \hat{\mathbb{C}}$ be the Weierstrass $\mathcal{P}$-function, where $\Gamma_\tau$ is the lattice in $\mathbb{C}$ generated by 1 and $\tau$, $\mathrm{Im}\,\tau > 0$. It satisfies the functional equation $\mathcal{P}_\tau(nz) = f_{\tau,n}(\mathcal{P}(z))$, where $f_{\tau,n}$ is a rational function. These functions called *Lattés examples* possess the desired properties. (For some special lattices, $n$ can be selected complex: the corresponding maps are also called Lattés.)

More generally, one can consider postcritically finite topological branched coverings $f : S^2 \to S^2$. Two such maps, $f$ and $g$, are called *Thurston combinatorially equivalent* if there exist homeomorphisms $h, h' : (S^2, O_f) \to (S^2, O_g)$ homotopic $\mathrm{rel}\, O_f$ (and hence coinciding on $O_f$) such that $h' \circ f = h \circ g$.

A combinatorial class is called *realizable* if it contains a rational function. Thurston (1982) gave a combinatorial criterion for a combinatorial class to be realizable. If it is realizable, then *the realization is unique*, except for Lattés examples (*Thurston's Rigidity Theorem*).

## Structural Stability and Holomorphic Motions

A map $f \in \mathrm{Rat}_d$ is called *J-stable* if for any maps $g \in \mathrm{Rat}_d$ sufficiently close to $f$, the maps $f \,|\, J(f)$ and $g \,|\, J(g)$ are topologically conjugate, and moreover, the conjugacy $h_g : J(f) \to J(g)$ is close to id. Thus, the Julia set $J(f)$ *moves continuously* over the set of $J$-stable maps. The following result proves a weak version of Fatou's conjecture:

**Theorem 4** (Lyubich and Mañé-Sad-Sullivan 1983). *The set of J-stable maps is open and dense in* $\mathrm{Rat}_d$. *Moreover, the set of unstable maps is the closure of maps that have a parabolic periodic point.*

A map $f \in \mathrm{Rat}_d$ is called *structurally stable* if for any maps $g \in \mathrm{Rat}_d$ sufficiently close to $f$, the maps $f$ and $g$ are topologically conjugate on the whole sphere, and moreover, the conjugacy $h_g : \hat{\mathbb{C}} \to \hat{\mathbb{C}}$ is close to id. *The set of structurally stable maps is also open and dense in* $\mathrm{Rat}_d$ (Mañé-Sad-Sullivan).

The proofs make use of the theory of holomorphic motions developed for this purpose but having much broader range of applications in dynamics and analysis. Let $X$ be a subset of $\hat{\mathbb{C}}$, and let $h_\lambda : X \to \hat{\mathbb{C}}$ be a family of injections depending on parameter $\lambda \in \Lambda$ in some complex manifold with a marked point $\lambda_*$. Assume that $h_{\lambda_*} = \mathrm{id}$ and that the functions $\lambda \mapsto h_\lambda(z)$ are holomorphic in $\lambda$ for any $z \in X$. Such a family of injections is called a *holomorphic motion*.

A holomorphic motion of any set $X$ over $\Lambda$ *extends to a holomorphic motion of the whole sphere* $\hat{\mathbb{C}}$ over some smaller manifold $\Lambda' \subset \Lambda$ (Bers–Royden, Sullivan–Thurston 1986). If $h_\lambda$ is a holomorphic motion of an open subset of the sphere, then *the maps* $h_\lambda$ *are quasiconformal* (Mañè-Sad-Sullivan). These statements are usually referred to as the *λ-lemma*.

If $\Lambda = \mathbb{D}$, then the holomorphic motion of a set $X \subset \hat{\mathbb{C}}$ extends to a holomorphic motion of $\hat{\mathbb{C}}$ over the *whole disk* $\mathbb{D}$ (Slodkowsky 1991).

## Fundamental Conjectures

The above rigidity and stability results led to the following profound conjectures:

**QC Rigidity Conjecture** *If two rational maps are topologically conjugate, then they are quasiconformally conjugate.*

Let us consider the real projective tangent bundle PT over $\hat{\mathbb{C}}$, with a natural action of the map $f$. *A measurable invariant line field on the Julia set* is an invariant measurable section $X \to \mathrm{PT}$ over an invariant set $X \subset J(f)$ of positive Lebesgue measure. In other words, it is a family of tangent lines $L_z \subset T_z$, $z \in X$, such that $Df(L_z) = L_{fz}$. Note that such a field can exist only if $J(f)$ has positive Lebesgue measure.

**No Invariant Line Fields Conjecture** *Let us consider two rational maps, $f$ and $\tilde{f}$, that are not Lattés examples. If they are quasiconformally conjugate and the conjugacy is conformal on the Fatou set, then they are conjugate by a Möbius transformation. Equivalently, if $f$ is not Lattés, then there are no measurable invariant line fields on $J(f)$.*

This conjecture would imply Fatou's conjecture.

## Mandelbrot Set

Let us consider the quadratic family $f_c : z \mapsto z^2 + c$. (Note that any quadratic polynomial is affinely conjugate to a unique map $f_c$.) The *Mandelbrot set* classifies parameters $c$ according to the Basic Dichotomy of the subsection "More properties of the Julia set":

$$M = \{c : J(f_c) \text{ is connected}\} = \{c : f_c^n(0) \mapsto \infty\}$$

Note that $\phi_n(c) \equiv f_c^n(0)$ is a polynomial in $c$ of degree $2^{n-1}$, and these polynomials satisfy a recursive relation $\phi_{n+1} = \phi_n^2 + c$. Moreover, $M = \{c : |\phi_n(c)| \le 2,\ n \in \mathbb{Z}_+\}$, which gives an easy way to make a computer image of $M$ (see Figure 5).

A distinguished curve seen at the picture of $M$ is the *main cardioid* $\mathcal{C} = \{c = \mathrm{e}^{2\pi i\theta} - \mathrm{e}^{4\pi i\theta}/4\}$, $\theta \in \mathbb{R}/\mathbb{Z}$. For such a $c = c(\theta) \in \mathcal{C}$, the map $f_c$ has a neutral fixed point $\alpha_c$ with rotation number $\theta$. For $c$ inside the domain $H_0$ bounded by $\mathcal{C}, f_c$ has an attracting fixed point $\alpha_c$, and the Julia set $J(f_c)$ is a Jordan curve (see Figure 1).

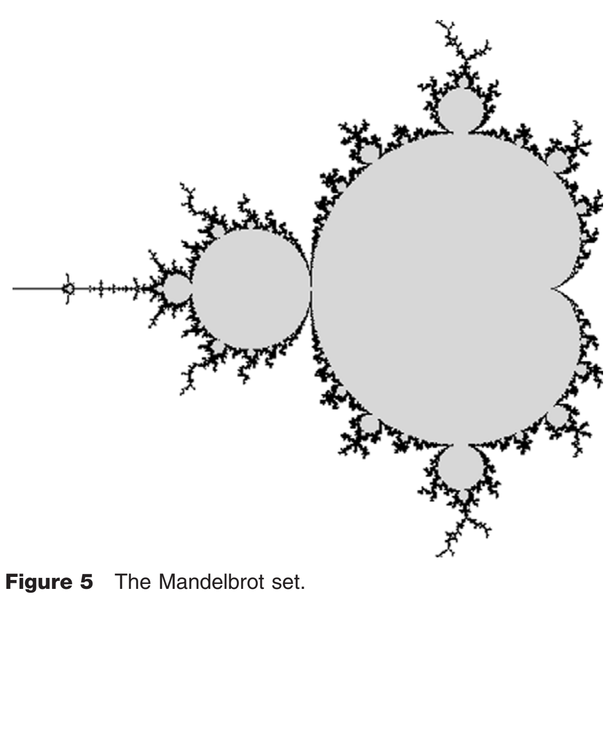

**Figure 5** The Mandelbrot set.

At the cusp $c = 1/4 = c(0)$ of the main cardioid, the map $f_c$ has a parabolic point with multiplier 1. This point is also called the *root* of $\mathcal{C}$. Other parabolic points $c = c(q/p)$ on $\mathcal{C}$ are *bifurcation points*: if one crosses $\mathcal{C}$ transversally at $c$, then the fixed point $\alpha_c$ "gives birth" to an attracting cycle of period $p$. This cycle preserves its "attractiveness" within some component $H_{q/p}$ of int $M$ attached to $\mathcal{C}$.

On the boundary of $H_{q/p}$, the above attracting cycle becomes neutral, and similar bifurcations happen as one crosses this boundary transversally, etc. In this way we obtain *cascades* of bifurcations and associated necklaces of components of int $M$. The most famous one is the cascade of *doubling bifurcations* that occur along the real slice of $M$.

Components of int $M$ that occur in these bifurcation cascades give examples of hyperbolic components of int $M$. More generally, a component $H$ of int $M$ is called *hyperbolic of period p* if the maps $f_c, c \in H$, have an attracting cycle of period $p$. Many other hyperbolic components become visible if one begins to zoom-in into the Mandelbrot set. Some of them are *satellite*, that is, they are born as above by bifurcation from other hyperbolic components. Others are *primitive*. They can be easily distinguished geometrically: primitive components have a cusp at their root, while satellite components are bounded by smooth curves.

Given a hyperbolic component $H$, let us consider the multiplier $\lambda(c), c \in H$, of the corresponding attracting cycle, as a function of $c \in H$. *The function $\lambda$ univalently maps H onto the unit disk $\mathbb{D}$* (Douady and Hubbard 1982). Thus, there is a single parameter $c_0 \in H$ for which $\lambda(c_0) = 0$, so that $f_{c_0}$ has a *superattracting cycle*. This parameter is called the *center* of $H$.

Nonhyperbolic components of int $M$ are called *queer*. *Conjecturally, there are no queer components*. This conjecture is equivalent to Fatou's conjecture for the quadratic family.

*The boundary of M coincides with the set of J-unstable quadratic maps* (see the subsection "Structural stability and holomorphic motions").

### Connectivity and Local Connectivity

**Theorem 5** (Douady and Hubbard 1982). *The Mandelbrot set is connected.*

The proof provides an explicit uniformization $R_M : \mathbb{C} \setminus M \to \mathbb{C} \setminus \bar{\mathbb{D}}$. Namely, let $B_c : \Omega_c \to \mathbb{C} \setminus \mathbb{D}_{R_c}$, $c \in \mathbb{C} \setminus M$, be the Böttcher coordinate near $\infty$. Then $R_M(c) = B_c(c)$. This remarkable formula explains the *phase-parameter similarity* between the Mandelbrot set near a *parameter* $c \in M$ and the corresponding Julia set $J(f_c)$ near the *critical value c*.

The following is the most prominent open problem in holomorphic dynamics:

**MLC Conjecture** *The Mandelbrot set is locally connected.*

If this is the case, then the inverse map $R_M^{-1}$ extends to the unit circle $\mathbb{T}$, and the Mandelbrot set can be represented as the quotient of $\mathbb{T}$ modulo certain equivalence relation that can be explicitly described. Thus, we would have *an explicit topological model for the Mandelbrot set* (Douady and Hubbard, Thurston).

The MLC conjecture is equivalent to the following conjecture:

**Combinatorial Rigidity Conjecture** *If two quadratic maps $f_c$ and $f_{c'}$ with all periodic points repelling are combinatorially equivalent, then $c = c'$.*

In turn, this conjecture would imply, in the quadratic case, the above fundamental conjectures. For a progress towards the MLC conjecture (*see* Universality in Mathematical Physics).

### Parabolic Implosion

Parabolic maps $f_{c_0} : z \mapsto z^2 + c_0$ are unstable in a dramatic way. In particular, the Julia set $J(f_c)$ *does not depend continuously on c* near $c_0$. Instead, $J(f_c)$ tends to fill in a good part of int $J(f_{c_0})$. This phenomenon called *parabolic implosion* has been explored by Douady, Lavaurs, Shishikura, and many others.

## Geometric Aspects

### Area

One of the basic problems in holomorphic dynamics is *whether a Julia set that does not coincide with $\hat{\mathbb{C}}$ can have positive area*. It would give an example of "observable chaos" that occurs on a topologically small set. It is also related to the No Invariant Line Fields Conjecture.

Maps with strong hyperbolic properties have zero area Julia set. A rational map $f$ is called *Collet–Eckmann* if there exist constants $C > 0$ and $\lambda > 1$ such that:

$$|Df^n(fc)| \geq C\lambda^n, \quad n \in \mathbb{N}$$

for all critical points $c$. *If f is a Collet–Eckmann map with $J(f) \neq \hat{\mathbb{C}}$, then* area $J(f) = 0$ (Przytycki and Rohde 1998) (*see* Universality and Renormalization for more examples). On the other hand, A Douady has set up a compelling program of constructing a Cremer quadratic polynomial $f : z \mapsto e^{2\pi i\theta} z + z^2$ whose Julia set would have *positive area*. Buff and

Cheritat have recently announced that they have completed the program, thus constructing the first example of a Julia set of positive area. (It makes use of a renormalization theorem for parabolic implosion recently announced by Shishikura.)

In the parameter plane, it would be interesting to know *whether the boundary of the Mandelbrot set has zero area*.

#### Hausdorff Dimension

Hausdorff dimension (HD) gives us a further refinement of fractal sets of zero area. Any Julia set has positive HD. *If $f$ is a polynomial with connected Julia set, then* $\mathrm{HD}(J(f)) > 1$ *unless $f$ is affinely conjugate to $z \mapsto z^d$ or a Chebyshev polynomial* (Zdunik 1990). If $f$ is a Collet–Eckmann map with $J(f) \neq \hat{\mathbb{C}}$, then $\mathrm{HD}\, J(f) < 2$ (Przytycki–Rohde 1998). On the other hand, in the quadratic case $f_c : z \mapsto z^2 + c, \mathrm{HD}(J(f_c)) = 2$ *for a generic parameter* $c \in \partial M$. The corresponding parameter result is that $\mathrm{HD}(\partial M) = 2$ (Shishikura 1998). It is based on the parabolic implosion phenomenon.

#### Conformal Measure

Let $\delta \geq 0$. A Borel measure $\mu$ on $\hat{\mathbb{C}}$ is called *$\delta$-conformal* if

$$\mu(f\,X) = \int_X |Df|^\delta \, \mathrm{d}\mu$$

for any measurable set $X$ such that $f \,|\, X$ is injective.

**Theorem 6** (Sullivan 1983). *Any rational map $f$ has a $\delta$-conformal measure with $\delta \in (0, 2]$ supported on $J(f)$.*

This is a dynamical measure that captures well geometric properties of $J(f)$. For instance, for Collet–Eckmann maps, $\delta = \mathrm{HD}(J(f))$, and $\mu$ is equivalent to the Hausdorff measure on $J(f)$ in dimension $\delta$.

The *hyperbolic dimension*, $\mathrm{HD}_{\mathrm{hyp}}$ of $J(f)$ is the supremum of $\mathrm{HD}(X)$ over all compact invariant hyperbolic subsets of $J(f)$. Denker and Urbanski (1991) proved that $\mathrm{HD}_{\mathrm{hyp}}(J(f))$ *is equal to the smallest exponent $\delta$ of all $\delta$-conformal measures supported on $J(f)$* (*see* Universality and Renormalization).

#### Measure of Maximal Entropy

An $f$-invariant measure $\mu$ is called *balanced* if $\mu(f\,X) = d\mu(X)$ for any measurable set $X$ such that $f \,|\, X$ is injective (where $d = \deg f$).

**Theorem 7** (Brolin 1965, Lyubich 1982). *Any rational map $f$ has a unique balanced measure $\mu$. Moreover, preimages of any point $z$ except at most two are equidistributed with respect to $\mu$ (meaning that the probability measures $\mu_{n,z}$ that assign mass 1 to every $f^n$-preimage of $z$ converge weakly to $\mu$ as $n \to \infty$).*

For polynomials, the balanced measure coincides with the *harmonic measure* on $J(f)$ (Brolin). (The latter is the charge distribution on the conductor $J(f)$ generated by the unit charge placed at $\infty$.) In general, the balanced measure is the *unique measure of maximal entropy* of $f$, and moreover, *periodic points are equidistributed with respect to $\mu$* (Lyubich).

Measure of maximal entropy is supported on a relatively small measurable set: *its HD is strictly less than* $\mathrm{HD}(J(f))$, unless $f$ is conformally equivalent to $z \mapsto z^d$, a Chebyshev polynomial, or a Lattés example (Zdunik 1990). In the polynomial case, it is supported on a set of HD at most 1 (Manning 1984).

In complex analysis, there has been an extensive study of fractal properties of harmonic measures, providing insights at the balanced measure $\mu$ and the other way around (Carleson, Makarov, Jones, Binder, Smirnov, ...)

# Holonomic Quantum Fields

**J Palmer**, University of Arizona, Tucson, AZ, USA

## Introduction

The term, holonomic field, was coined by Sato, Miwa, and Jimbo (SMJ) in 1978 and the subject was investigated by them in a series of five long papers and many shorter notes in the period from 1978–81 (Sato *et al.* 1979a, 1979b, 1979c, 1980, Tracy and Widom 1994). The term refers to a special class of two-dimensional interacting quantum field theories whose $n$ point correlations can be expressed in terms of the solution to a holonomic system of differential equations. A holonomic system is an overdetermined system of differential equations with only a finite-dimensional family of solutions. There is a sense in which these interacting systems with infinitely many degrees of freedom have a finite-dimensional substrate (at the level of $n$ point functions for fixed $n$). After developing their theory, SMJ realized that such quantum fields made an earlier appearance in work of Thirring and Federbush. The models considered by Thirring and Federbush are self-interacting fermionic systems whose nonlinear classical field equations have solutions that are an explicit nonlinear transformation of solutions to the free field equations. This inspired the idea of trying to study these models by "quantizing" the nonlinear transformation. Expressions were obtained for the correlations and S-matrix but the connection with deformation theory was not understood until the SMJ work.

In what follows we will sketch the SMJ theory and discuss some of its offshoots. There is one circumstance that it might help the reader to be aware of even though it will be mostly glossed over. Quantum fields in one space and one time dimension have correlations which transform under the symmetries of spacetime with metric signature (1,1). Since the work of Osterwalder and Schrader, it is customary to pass back and forth between this Minkowski regime and the Schwinger functions obtained by analytically continuing the $n$ point functions to pure imaginary values for the time variable where they possess the rotational symmetries associated with a positive-definite metric. The Ising model, which we take up next, is naturally considered in the Euclidean domain where the correlations have an interpretation in statistical mechanics as the expected value of a product of random variables. Ultimately, the SMJ deformation analysis is done in the Euclidean domain.

## The Two-Dimensional Ising Model

The SMJ theory was inspired by, and provides an attractive setting for, an earlier result of Wu, McCoy, Tracy, and Baruch (WMTB), concerning the spin–spin scaling functions of the two-dimensional Ising model (Wu *et al.* 1976). Since the Ising model is the example with the most direct significance for physics, we will take some time to explain the WMTB result and to sketch the way in which it fits into the SMJ theory.

The Ising model is a statistical model of magnetism on a lattice that incorporates ferromagnetic interactions of nearest-neighbor spins. In the 1920s, Ising solved the model for the one-dimensional lattice and showed that there was no phase transition in the infinite volume limit. Interest in the two-dimensional model intensified dramatically following Onsager's calculation of the specific heat in the infinite volume limit (see Palmer and Tracy (1981) and references within). His formula for the specific heat was the first instance of a thermodynamic quantity in a nearest-neighbor model which exhibits the sort of discontinuity in temperature dependence expected at a phase transition. For many years, the Ising model served as a testbed for the now accepted notion that the infinite volume limit of Gibbsian statistical mechanics provides a suitable setting for the study of phase transitions.

A configuration for the Ising model on a finite subset, $\Lambda$, of the integer lattice, $\mathbf{Z}^2$, is a map $\mathcal{C}: \Lambda \to \{+1, -1\}$, which assigns to each site on the lattice either an up spin $(+1)$ or a down spin $(-1)$. The energy function of the Ising model, $E_\Lambda(\sigma)$, is defined by

$$E_\Lambda(\sigma) = -J \sum_{\langle i,j \rangle \in \Lambda} \sigma(i)\sigma(j)$$

for $J > 0$ and a spin configuration $\sigma$ is a sum over pairs of nearest-neighbor sites $i, j$ in $\Lambda$ (boundary terms require special consideration). This energy function tends to favor spin configurations, $\sigma$, in which the nearest-neighbor spins are aligned in the sense that the Boltzmann weight, $e^{-E_\Lambda(\sigma)/kT}$, is larger for such configurations. In the Gibbs ensemble, which is expected to describe systems in equilibrium at temperature $T$, the configuration $\sigma$ occurs with a probability proportional to the Boltzmann weight. The factor $k$ which appears is a conversion factor between thermal and kinetic energy called the Boltzmann constant. It is clear from the formula for the Boltzmann weight that small temperatures (near 0) tend to accentuate the difference in

statistical weights assigned to configurations with different energies, and large temperatures tend to wash out the difference in statistical weights associated to configurations with different energies.

Remarkably, there is a sharp critical temperature $0 < T_c < \infty$ so that for $T < T_c$ the propensity for order built into the energy triumphs in the infinite volume limit $\Lambda \uparrow \boldsymbol{Z}^2$, and for $T > T_c$ the randomness or disorder associated with high temperatures governs the infinite volume behavior. More specifically, if $T < T_c$ and the infinite volume limit is taken with plus spins assigned to the boundary of $\Lambda$, the system exhibits a residual magnetism (there is a positive expected value, $\langle\sigma\rangle$, for the spin per site). This infinite volume plus state is the quintessential example of symmetry breaking – the spin flip symmetry possessed by the bulk energy is broken below $T_c$ in the thermodynamic limit. For $T > T_c$, the spin per site is 0 no matter what boundary conditions are imposed on the infinite volume limit.

Pure equilibrium states both above and below $T_c$ exhibit clustering in the thermodynamic limit (uniqueness for the ground state in field theory). This is the tendency of spin variables $\sigma(a)$ and $\sigma(b)$ at sites $a, b \in \boldsymbol{Z}^2$ to become statistically independent as the distance $|a-b|$ tends to $\infty$. In such a pure state the two-point function, which is the expected value of the product of spin variables, $\langle\sigma(a)\sigma(b)\rangle$, will tend to the square $\langle\sigma\rangle^2$ both below $(\langle\sigma\rangle \neq 0)$ and above $(\langle\sigma\rangle = 0)$ the critical temperature $T_c$ as $|a-b| \to \infty$. To leading order, this clustering takes place at an exponential rate, $e^{-|a-b|/\xi(T)}$, for a function $\xi(T)$ called the correlation length. The correlation length $\xi(T) \to \infty$ as $T \to T_c$. The scaling limit (from below $T_c$) of the spin–spin correlation is the leading-order correction to the clustering behavior of the correlations when these correlations are examined at the scale of the correlation length. It is the limit

$$\langle\sigma(a)\sigma(b)\rangle = \lim_{T\uparrow T_c} \frac{\langle\sigma(\xi(T)a)\sigma(\xi(T)b)\rangle_T}{\langle\sigma\rangle_T^2}$$

where the correlations on the right-hand side are thermodynamic correlations on the lattice at temperature $T$. Since $\langle\sigma\rangle_T$ tends to 0 as $T \to T_c$, the normalization by $\langle\sigma\rangle_T^{-1}$ on the right produces an "infinite wave function renormalization" in the limit.

Equivalently, one may think of this continuum limit being achieved by letting the lattice spacing shrink to 0 as $T$ approaches $T_c$ so that the correlation length stays fixed on the new scale. The scaling limit from above $T_c$ turns out to be different from the scaling limit from below $T_c$ and since $\langle\sigma\rangle_T = 0$ for $T > T_c$, it is defined by a different wave function renormalization. The resulting asymptotics are expected to capture quite a lot about what is interesting in the behavior of the correlations near the phase transition. In the late 1970s, the scaling behavior in this model was also a prototype for the emerging connection between renormalization group ideas in quantum field theory and statistical mechanics.

Wu *et al.* (1976) showed that the two-point scaling function, $\langle\sigma(0)\sigma(x)\rangle$, is a function of $r = |x|$ and can be written as

$$\langle\sigma(0)\sigma(x)\rangle = \begin{cases} \cosh(\psi/2) \\ \quad \times \exp\dfrac{1}{4}\displaystyle\int_r^\infty \left(\sinh^2\psi - \left(\dfrac{d\psi}{dt}\right)^2\right) s\, ds \\ \quad \times (T \uparrow T_c) \\ \sinh(\psi/2) \\ \quad \times \exp\dfrac{1}{4}\displaystyle\int_r^\infty \left(\sinh^2\psi - \left(\dfrac{d\psi}{dt}\right)^2\right) s\, ds \\ \quad \times (T \downarrow T_c) \end{cases} \qquad [1]$$

where $\psi = \psi(r)$ satisfies the differential equation,

$$\frac{d}{dr}\left(r\frac{d\psi}{dr}\right) = \frac{r}{2}\sinh(2\psi)$$

The substitution $\eta = e^{-\psi}$ transforms this differential equation into a Painlevé equation of the third kind. This was used by McCoy, Tracy, and Wu (see Palmer and Tracy (1981) and references within) to study the short-distance behavior, $r \to 0$, of the scaling functions – behavior which is far from manifest in the infinite series expansions obtained for the scaling functions.

## Deformation Theory

Sato, Miwa, and Jimbo showed that there was a class of quantum field theories that included the scaling limits of the Ising model which have the property that the $n$-point correlations are "tau functions" for monodromy-preserving deformations of the Dirac equation in two dimensions. The two-dimensional (Euclidean) Dirac operator is

$$\mathcal{D} = \begin{bmatrix} m & -2\partial \\ -2\bar{\partial} & m \end{bmatrix}$$

with

$$\partial = \frac{1}{2}\left(\frac{\partial}{\partial x} - i\frac{\partial}{\partial y}\right), \qquad \bar{\partial} = \frac{1}{2}\left(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\right)$$

the usual complex derivatives acting on smooth functions on $\boldsymbol{R}^2$. The monodromy-preserving deformations mentioned above are families of (multivalued) solutions $w(x)$ to

$$\mathcal{D}w = 0 \qquad [2]$$

which are branched at points $a_j \in \boldsymbol{R}^2 (j = 1, 2, \ldots, n)$ and change by a factor $e^{2\pi i \ell_j}$ as $x$ makes a small circuit about $a_j$. SMJ (1979b) show that the $L^2(\boldsymbol{R}^2)$ (square-integrable) solutions $w(x)$ of the Dirac equation with this prescribed branching behavior comprise an $n$-dimensional subspace of $L^2(\boldsymbol{R}^2)$. The constants $e^{2\pi i \ell_j}$ are called the monodromy of the solutions and the term "deformation" in the description refers to the fact that the monodromy constants do not change as the branch points $a_j$ are varied. SMJ show that it is possible to choose a basis $w_j(x,a) = w_j(x, a_1, \ldots, a_n)$ $(j = 1, \ldots, n)$ so that the vector

$$W(x,a) := [w_1(x,a), w_2(x,a), \ldots, w_n(x,a)]$$

becomes a section for a flat (Dirac compatible) connection in the $(x, a)$ variables. That is,

$$d_{x,a} W = \Omega(x,a) W$$

where $d_{x,a}$ is the exterior derivative in the $x$ and $a$ variables and $\Omega$ is a matrix-valued 1-form that satisfies the zero curvature condition,

$$d_{x,a}\Omega = \Omega \wedge \Omega$$

They also introduced the notion of a tau function, $\tau(a)$, for such deformations. The logarithmic derivative $d_a \log \tau(a) = \omega$, where $\omega$ is a 1-form on $\boldsymbol{R}^2 \backslash \{a_1, a_2, \ldots, a_n\}$ expressed in terms of the matrix elements of $\Omega$. The 1-form $\omega$ introduced by SMJ is shown to be closed when $\Omega$ satisfies the zero curvature condition above. The scaling limit of the Ising model is related to the situation for monodromy multipliers –1 and when the scaling limits of correlations are identified as suitable $\tau$-functions in this case, the WMTB result emerges when the nonlinear zero curvature condition is identified with a Painlevé equation.

The connection between the deformation theory and quantum field theory is developed in the computationally intensive paper SMJ (1980). Extensive use is made of local operator product expansions, analytic continuation, and formal series expansions that are infinite-dimensional analogs of Wick-type theorems for finite-dimensional spin representations (developed by SMJ (1978)). One can get a feeling for the source of the connection by recalling that in one of the "exact solutions" of the two-dimensional Ising model the spin operators, $\sigma(a)$, are identified as elements of an infinite spin representation of the orthogonal group and are characterized by their linear action on Fermionic variables (Palmer and Tracy 1981). In the physics literature, the $\sigma(a)$ are referred to as Bogoliubov transformations. In the scaling limit the associated representation space is the home to a free Fermi field $\psi(x)$, an operator-valued solution to the Dirac equation. Of course, $\psi(x)$ has components $\psi_j(x)$ but for simplicity we will suppress such details in the mostly schematic discussion that follows. For coincident second coordinates $x_2 = a_2$ the Fermi field $\psi(x)$ and $\sigma(a)$ satisfy the commutation relation

$$\sigma(a)\psi(x) = -\mathrm{sgn}(x_1 - a_1)\psi(x)\sigma(a) \qquad [3]$$

which is a surviving remnant of the linear action of $\sigma(a)$ on lattice fermions. In the transfer matrix formalism, which is natural for statistical mechanics, translation in the "space" variable $x_1$ is unitary, but translation in the "time" variable, $x_2$, is governed by the transfer matrix, the generator of a contractive semigroup. Because of this, the quantities that are well behaved in this formalism are "time-ordered vacuum expectations"; these involve only "positive" powers of the transfer matrix. Let $\mathcal{T}$ denote the "time"-ordering operator; a sequence of operators depending on coordinates in $\boldsymbol{R}^2$ is reordered following $\mathcal{T}$ so that the second coordinates appear in increasing order from left to right. Sign changes are incorporated whenever it is necessary to exchange Fermi type operators like $\psi^*(x)$ and $\psi(y)$ to put them in the correct order. In the Euclidean setting (pure imaginary time) it is well known that

$$G(x,y) = \langle \mathcal{T}\psi^*(x)\psi(y)\rangle$$

is a Green function for the Dirac operator $\mathcal{D}$ (the distribution kernel for $\mathcal{D}^{-1}$).

This observation and [3] suggests that the hybrid vacuum expectation

$$G(x,y;a) = \frac{\langle \mathcal{T}\psi^*(x)\psi(y)\sigma(a_1)\cdots\sigma(a_n)\rangle}{\langle \mathcal{T}\sigma(a_1)\cdots\sigma(a_n)\rangle}$$

should be the Green function for a Dirac operator with a domain containing "functions" branched at the points $a_j$ having "monodromy" –1 there. It is possible to recast the SMJ analysis so that a Dirac operator, $\mathcal{D}(a)$, on a suitable vector bundle with base $\boldsymbol{R}^2 \backslash \{a_1, \ldots, a_n\}$ becomes the central player (see Palmer *et al.* (1994) and references therein). The data for the vector bundle includes the factors $e^{2\pi i \ell_j}$ incorporated in transition functions for the bundle. The $\tau$-function becomes an infinite determinant (or Pfaffian in the Ising case)

$$\tau(a) = \det \mathcal{D}(a) \qquad [4]$$

in the Segal–Wilson sense (see Palmer *et al.* (1994) and references therein). The Green function $G(x,y;a)$ has a finite-rank derivative,

$$d_a G(x,y;a) = \sum_j r_j(x,a)s_j(y,a)\,\mathrm{d}a_j + u_j(x,a)v_j(y,a)\,\mathrm{d}\bar{a}_j \qquad [5]$$

which is the key result in this version of the SMJ analysis (this observation appears in SMJ (1980) but does not have a central role there). The "wave functions" $r$, $s$, $u$, and $v$ are closely related to the $L^2$ wave functions $w_j$ described above. Equation [5] is both the source of the deformation equations for $r$, $s$, $u$, and $v$ which arise from $d_a^2 G = 0$ coupled with the rotational and translational symmetries of the Green function, and also of the expression for $d_a \log \tau(a)$ in terms of data associated with the deformation theory. A "transfer matrix" calculation of the determinant allows one to make the connection with the scaling limits of lattice fields including the Ising model (see Palmer *et al.* (1994) and references therein).

The short-distance behavior of the two-point function for the Ising model scaling functions has been rigorously calculated by Tracy and later by Tracy and Widom (see Harnad and Its (2002) and references therein). A less detailed analysis of the short-distance behavior of the $n$ point functions that uses the deformation analysis of the correlations in a crucial way can be found in Palmer (2000).

## The Riemann–Hilbert Problem

In SMJ (1979b), a "massless" version of holonomic fields is developed. This concerns monodromy-preserving deformations of the Cauchy–Riemann operator $\bar{\partial}$. The techniques used to study this lead back to the Riemann–Hilbert problem – the problem of determining a linear differential equation in the complex plane with rational coefficients and prescribed monodromy at the poles of the coefficients. More specifically, suppose one is given $n$ distinct points $\{a_1,\ldots,a_n\}$ in $\boldsymbol{P}^1$, the Riemann sphere, and a base point $a_0$ distinct from the $a_j, j \neq 0$. Let $\gamma_j$ denote a simple closed curve based at $a_0$ which winds counterclockwise once around $a_j$ but has winding number 0 for the other points $a_k, k \neq j$. Choose $n$ invertible $p \times p$ matrices $M_j$ which satisfy the single condition $M_1 M_2 \cdots M_n = I$. Then, the homotopy classes of the curves $\gamma_j$ are the generators for the fundamental group of the punctured sphere $\boldsymbol{P}^1 \backslash \{a_1,\ldots,a_n\}$ with base point $a_0$ and the map which sends $\gamma_j \to M_j$ determines a representation of the fundamental group. One version of the Riemann–Hilbert problem is to find $p \times p$ complex matrices $A_j$ for $j = 1,\ldots,n$ so that the linear differential equation

$$\frac{\mathrm{d}Y}{\mathrm{d}z} = \sum_j \frac{A_j}{z - a_j} Y \qquad [6]$$

has monodromy representation given by $\gamma_j \to M_j$. This means that the fundamental solution $Y(z)$ defined in a neighborhood of $z = a_0$ and normalized so the $Y(a_0) = I$ (the identity) will become the fundamental solution $Y(z)M_j^{-1}$ after analytic continuation around the curve $\gamma_j$. This form of the problem does not always have a solution but when it does, it is interesting to consider deformations $a \to A_j(a)$ that preserve the monodromy multipliers $M_j$. Such monodromy-preserving deformations were first considered by Schlesinger in 1912 (see Palmer and Tracy (1981) and references therein) and he discovered that the coefficients $A_j$ must satisfy nonlinear differential equations that, for $a_0 = \infty$, can be written as

$$d_a A_j = \sum_{k \neq j} \frac{A_k - A_j}{a_k - a_j} d(a_k - a_j)$$

SMJ introduced $\tau$-functions associated with these deformations and they gave these $\tau$-functions a quantum field theory interpretation as $n$ point functions. Eventually this theory was extended to include the Birkhoff generalization of the Riemann–Hilbert problem, a generalization which incorporates the additional information needed to fix local holomorphic equivalence at higher-order poles (formal asymptotics and Stokes' multipliers) (Jimbo and Miwa 1981, Sato *et al.* 1978). Roughly speaking, the problem is to reconstruct a global connection with specified singularities from its local holomorphic equivalence data and its global monodromy representation. Thinking of the differential equation [6] as a holomorphic connection proved very helpful in a geometric reworking of the SMJ analysis given by Malgrange (1983a, 1983b) who showed that the zeros of the $\tau$-function occurred at points where a suitably defined Riemann–Hilbert problem fails to have a solution (see also Palmer (1999) references within). The mathematical significance of massless holonomic quantum fields as (quantized) singular elements of a gauge group is apparent from the SMJ work and later work of Miwa but the possibility of interesting physics in these models does not seem to have been much investigated at this time. These quantum fields are also conformal fields; however, a comprehensive integration into the highly developed formalism of conformal field theory on compact Riemann surfaces has not currently been developed

(an analog of [5] should survive on compact Riemann surfaces but the deformation analysis of the correlations is likely limited to symmetric spaces).

## Further Developments

This work on massless holonomic fields and the connection with the Riemann–Hilbert problem is doubtless the aspect of holonomic fields with the most "spin offs" in the mathematics and physics literature. These include an analysis of the delta-function gas done by Jimbo, Miwa, Mori, and Sato in 1981, random matrix models first looked at by Jimbo, Miwa, Mori, and Sato and later systematically investigated by Tracy and Widom (1994), the deformations of line bundles on Riemann surfaces that led to KdV in the work of Segal and Wilson (1985), which emerged from work of Sato, Miwa, Jimbo and collaborators, the analysis of Painlevé equations starting with work of McCoy, Tracy and Wu (see Palmer and Tracy (1981) and references within) and more systematically developed by Its and Novokshenov (1986), and the revival of interest in monodromy-preserving deformations (Harnad and Its 2002).

Holonomic fields are related to free fields in a well-understood way and it is natural to study them in situations where free fields make sense. In particular, they are an interesting testbed for the nonperturbative investigation of the influence of geometry (or curvature) on quantum fields. In Palmer *et al.* (1994), the deformation analysis of $\tau$-functions for holonomic fields is carried out for the Poincaré disk. The two-point functions are shown to be expressible in terms of solutions to the family of Painlevé VI equations. A quantum field theory interpretation of these $\tau$-functions is given by Doyon and there are natural analogs of the scaling limit of the Ising model on the Poincaré disk as well. The role of "spacetime" symmetries in the deformation theory suggests that such analysis will be limited to symmetric spaces. In addition to the plane and the Poincaré disk, the cylinder, the sphere, and the torus round out the possibilities in two dimensions. Lisovyy has recently worked out the analysis for the cylinder, which is important for the study of thermodynamic correlations. It should be possible to recast the analysis of the continuum Ising model on the torus (Zuber and Itzykson 1977) in deformation theoretic terms. It does not appear that the holonomic fields associated with the Dirac operator for the constant curvature metric on the 2-sphere have been studied yet.

# Homeomorphisms and Diffeomorphisms of the Circle

**A Zumpano and A Sarmiento**, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

## Introduction

In this article we consider the following question: which homeomorphisms of the circle transport one given class of continuous functions into another? The allowed classes of functions are Banach spaces contained in $C(\mathbb{T})$, the space of continuous functions on the unit circle $\mathbb{T}$, and will be defined by the properties of the Fourier series of the functions. Next, we will develop the theory of Poincaré–Denjoy which describes some basic geometric properties about diffeomorphisms of the circle such as existence and properties of the rotation number, classifications of possible orbits of diffeomorphisms, and Denjoy counterexample.

A homeomorphism of the circle is regarded here as a change of variables for periodic functions. So, it will be our major concern to describe the changes of variables that do not affect "too much" the behavior of the Fourier series of the functions in the given class.

We say that a function $h:\mathbb{R}\to\mathbb{R}$ is a homeomorphism of the circle $\mathbb{T}=\{(x,y)\in\mathbb{R}^2 : x^2+y^2=1\}$, if $h$ itself is a homeomorphism such that $h(t+2\pi)=h(t)\pm 2\pi$ for all $t\in\mathbb{R}$. It is clear that such function $h$ induces a unique homeomorphism $\widetilde{h}:\mathbb{T}\to\mathbb{T}$ that makes the following diagram commutative:

$$\begin{array}{ccc} \mathbb{T} & \xrightarrow{\widetilde{h}} & \mathbb{T} \\ e^{it}\downarrow & & \downarrow e^{it}, \\ \mathbb{R} & \xrightarrow[h]{} & \mathbb{R} \end{array} \quad \text{i.e.,}\ \widetilde{h}(e^{it})=e^{ih(t)}$$

In the same way, we identify functions $\widetilde{\psi}:\mathbb{T}\mapsto\mathbb{C}$ with $2\pi$-periodic functions $\psi:\mathbb{R}\mapsto\mathbb{C}$.

Let $\mathcal{U}(\mathbb{T})$ be the space of all continuous functions on $\mathbb{T}$ that have uniformly convergent Fourier series, and let $\mathcal{A}(\mathbb{T})$ be the space of all continuous functions on $\mathbb{T}$ with absolute convergent Fourier series.

In 1953, Beurling and Helson proved an important result about the homeomorphisms that preserve the space $\mathcal{A}(\mathbb{T})$: they are rotations and symmetries, that is, if $f\circ h\in\mathcal{A}(\mathbb{T})$ for all $f\in\mathcal{A}(\mathbb{T})$, then the homeomorphism $h$ must have the form $h(t)=t+\alpha$ or $h(t)=-t+\alpha$. It is quite obvious that rotations and symmetries preserve $\mathcal{A}(\mathbb{T})$, since the Fourier coefficients of $f\circ h$ and $f$ have the same modulus, but to prove the converse is very hard. So, homeomorphisms that preserve $\mathcal{A}(\mathbb{T})$ are a very restrict class.

A wider class is obtained when we transport $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$, that is, $f\circ h\in\mathcal{U}(\mathbb{T})$ for all $f\in\mathcal{A}(\mathbb{T})$. The major object of this article is to study such changes of variables.

We say that a homeomorphism of the circle $h$ is of finite type, if there is an integer $\nu$, satisfying $3\le\nu<\infty$, such that $h$ is of class $C^\nu$ and

$$|h''(t)|+|h^{(3)}(t)|+\cdots+|h^{(\nu)}(t)|\neq 0, \quad \text{for all } t\in\mathbb{R}$$

In the realm of Fourier analysis, the most important and general result about homeomorphisms of the circle is due to R Kaufman, who showed in 1974 that a finite-type homeomorphism $h$ transports $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$. We shall analyze in detail such seminal result.

## Homeomorphism of the Circle of Finite Type

In this section we prove the theorem of R Kaufman mentioned before, which means that it is sufficient for a homeomorphism of the circle $h$ to have a certain amount of curvature in order to transport $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$. We present a simple proof of this fact, based on a result due to Stein and Wainger.

If $f:\mathbb{T}\to\mathbb{C}$ is a continuous function and if

$$\hat{f}_n=\frac{1}{2\pi}\int_{-\pi}^{\pi} f(t)e^{-int}\,dt, \quad n\in\mathbb{Z}$$

denote the Fourier coefficients of $f$, then $f\in\mathcal{A}(\mathbb{T})$ if and only if

$$\sum_{n\in\mathbb{Z}}|\hat{f}_n|=\lim_{N\to\infty}\sum_{-N}^{N}|\hat{f}_n|<\infty$$

Of course, $\mathcal{A}(\mathbb{T})$ is a Banach space with the norm

$$\|f\|_{\mathcal{A}(\mathbb{T})}=\sum_{n\in\mathbb{N}}|\hat{f}_n|$$

The space $\mathcal{U}(\mathbb{T})$ is defined as the space of all continuous functions $f:\mathbb{T}\to\mathbb{C}$ such that

$$\sum_{-N}^{N}\hat{f}_n e^{int}\to f(t), \quad \text{when } N\to\infty, \quad \text{for all } t\in[-\pi,\pi]$$

uniformly on $\mathbb{T}$, that is, $\mathcal{U}(\mathbb{T})$ is the space of continuous functions from $\mathbb{T}$ to $\mathbb{C}$ that are the uniform limit of their Fourier partial sums

$$S_N(f,t)=\sum_{-N}^{N}\hat{f}_n e^{int}$$

Hence, under the natural norm given by

$$\|f\|_{\mathcal{U}(\mathbb{T})} = \sup\{|S_N(f,t)|\colon N \in \mathbb{N} = \{0,1,\ldots\} \text{ and } t \in [-\pi,\pi]\}$$

the space $\mathcal{U}(\mathbb{T})$ is a Banach space.

We shall prove:

**Theorem 1** (Kaufman 1974). *Let $h$ be a homeomorphism of the circle of class $C^\nu$, with $\nu \geq 3$. Suppose that*

$$|h''(t)| + |h^{(3)}(t)| + \cdots + |h^{(\nu)}(t)| \neq 0, \quad \textit{for all } t \in \mathbb{R}$$

*Then, $h$ transports $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$, that is, $f \circ h \in \mathcal{U}(\mathbb{T})$, whenever $f \in \mathcal{A}(\mathbb{T})$.*

It follows from the theorem that an analytic homeomorphism of the circle transports $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$. To see this, suppose that $h$ is not of finite type. Then, for each $n \geq 3$, there exists $t_n \in [-\pi,\pi]$ such that $h^{(j)}(t_n) = 0$ for all $j \in \{2,\ldots,n\}$. Since $\{t_n\}$ has a convergent subsequence, there exists $t \in [-\pi,\pi]$ such that $h^{(j)}(t) = 0$ for all $j \geq 2$. This implies that $h''$ must be a constant function and, therefore, $h(t) = \pm t + \alpha$. Since we know that this kind of homeomorphism preserves $\mathcal{A}(\mathbb{T})$, we are done.

One can ask why to demand $\nu \geq 3$. The answer is easy. Since $h(t+2\pi) = h(t) \pm 2\pi$ for all $t \in \mathbb{R}$, it follows that $h'(t+2\pi) = h'(t)$ for all $t \in \mathbb{R}$, that is, $h'$ is a periodic function of period $2\pi$. So, it will always exist a point $t \in (\pi,\pi)$ such that $h''(t) = 0$.

We can also infer from the theorem that a $C^\infty$ homeomorphism of the circle that has no flat point, that is, no point $t$ such that $h^{(j)}(t) = 0$ for all $j \geq 2$, transports $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$. This is obvious, because the negation of being of finite type implies the existence of a flat point. It is not true, however, that every $C^\infty$ homeomorphism of the circle transports $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$.

The proof of the theorem is based on the two lemmas that follows. The first lemma was obtained by Stein and Wainger, who proved it in a more general setting in 1965, although that proof was only published five years later. The second lemma was proved by R Kaufman in 1974.

**Lemma 2** (Stein and Wainger 1970). *Let $p(t)$ be a real polynomial of degree $d$. Then*

$$\left|\int_{-r}^{r} e^{ip(t)}\frac{dt}{t}\right| \leq 6(2^{d+1}) - 2d - 10 = 2d + 2\sum_{k=0}^{d}[3(2^k) - 2]$$

*for all $r > 0$.*

**Lemma 3** (Kaufman 1974). *Let $f$ be a real function of class $C^k$ on the interval $[-r,r]$, with $k \geq 2$. Suppose that $1 \leq |f^{(k)}(t)| \leq b$ for all $t \in [-r,r]$. Then*

$$\left|\int_{-r}^{r} e^{if(t)}\frac{dt}{t}\right| \leq C(k,b)$$

*where $C(k,b)$ is a constant that depends only on $k$ and $b$.*

We shall see that Lemma 3 can be proved from Lemma 2 in a quite simple way. The proof given by R Kaufman for Lemma 3 does not make use of Lemma 2 at all. Also, it is not difficult to see that Lemma 2 follows from Lemma 3, if we consider $d \geq 2$. So, they are indeed equivalent results.

Before getting into the proof of these two lemmas, let us state a result which is the primary tool in dealing with oscillatory integrals as those in the lemmas.

**Lemma 4** (Van der Corput lemma). *Let $f$ be real valued and smooth in $[a,b]$, with $0 < a < b$. Suppose that $|f^{(k)}(t)| \geq \lambda > 0$ for all $t \in [a,b]$. Then*

$$\left|\int_{a}^{b} e^{if(t)}\frac{dt}{t}\right| \leq [3(2^k) - 2]\frac{\lambda^{-1/k}}{a}$$

*holds if*

*(i)* $k \geq 2$, *and*
*(ii)* $k = 1$ *and $f'(t)$ is monotonic.*

Now, let us prove the two lemmas and Theorem 1.

**Proof of Lemma 2** The proof is by induction on the degree of the polynomial. Suppose that $p(t)$ is a polynomial of degree 0, that is, $p(t)$ is a constant function. In this case the result is trivial, since the integral is equal to zero.

By induction, assume that the statement is true for polynomials of degree less than or equal to $d$. Let

$$p(t) = a_{d+1}t^{d+1} + a_d t^d + \cdots + a_1 t + a_0, \quad a_{d+1} \neq 0$$

Make the change of variables $t = |a_{d+1}|^{-1/(d+1)}s$. Then we have

$$\int_{-r}^{r} e^{ip(t)}\frac{dt}{t} = \int_{-\sigma}^{\sigma} e^{i(q(t) \pm t^{d+1})}\frac{dt}{t}$$

where $\sigma = |a_{d+1}|^{1/(d+1)} r$ and $q(t)$ is a polynomial of degree at most equal to $d$. Suppose $\sigma > 1$. Then

$$\begin{aligned}\left|\int_{-\sigma}^{\sigma} e^{i(q(t)\pm t^{d+1})}\frac{dt}{t}\right| &\le \left|\int_{1}^{\sigma} e^{i(q(-t)\pm(-t)^{d+1})}\frac{dt}{t}\right| \\ &+ \left|\int_{1}^{\sigma} e^{i(q(t)\pm t^{d+1})}\frac{dt}{t}\right| \\ &+ \left|\int_{-1}^{1} e^{i(q(t)\pm t^{d+1})}\frac{dt}{t}\right| \\ &\le I + II + III\end{aligned}$$

By Van der Corput lemma, $I \le [3(2^{d+1}) - 2]$ and $II \le [3(2^{d+1}) - 2]$, so $I + II \le 6(2^{d+1}) - 4$. Now

$$\begin{aligned}III &\le \left|\int_{-1}^{1}\left[e^{i(q(t)\pm t^{d+1})} - e^{iq(t)}\right]\frac{dt}{t}\right| + \left|\int_{-1}^{1} e^{iq(t)}\frac{dt}{t}\right| \\ &\le \int_{-1}^{1}|t|^d\,dt + 6(2^{d+1}) - 2d - 10 \\ &\le 2 + 6(2^{d+1}) - 2d - 10\end{aligned}$$

since the degree of $q(t)$ is at most equal to $d$. So

$$\begin{aligned}&I + II + III \\ &\quad\le 6(2^{d+1}) - 4 + 2 + 6(2^{d+1}) - 2d - 10 \\ &\quad= 6(2^{d+1}) - 2(d+1) - 10\end{aligned}$$

On the other hand, if $\sigma \le 1$, then

$$\begin{aligned}&\left|\int_{-\sigma}^{\sigma} e^{i(q(t)\pm t^{d+1})}\frac{dt}{t}\right| \\ &\quad\le \left|\int_{-\sigma}^{\sigma}\left[e^{i(q(t)\pm t^{d+1})} - e^{iq(t)}\right]\frac{dt}{t}\right| + \left|\int_{-\sigma}^{\sigma} e^{iq(t)}\frac{dt}{t}\right| \\ &\quad\le 2 + 6(2^{d+1}) - 2d - 10 \\ &\quad\le 2 + 6(2^{d+1}) - 2d - 10 + 6(2^{d+1}) - 4 \\ &\quad\le 6(2^{d+1}) - 2(d+1) - 10\end{aligned}$$

and the proof is completed. □

**Proof of Lemma 3** Assume first that $r > 1$. Then

$$\begin{aligned}&\left|\int_{-r}^{r} e^{if(t)}\frac{dt}{t}\right| \\ &\quad\le \left|\int_{1}^{r} e^{if(-t)}\frac{dt}{t}\right| + \left|\int_{1}^{r} e^{if(t)}\frac{dt}{t}\right| + \left|\int_{-1}^{1} e^{if(t)}\frac{dt}{t}\right| \\ &\quad= I + II + III\end{aligned}$$

Since $|f^{(k)}(t)| \ge 1$ and $k \ge 2$, then by Van der Corput lemma, $I \le [3(2^k) - 2]$ and $II \le [3(2^k) - 2]$. (Note that we have to assume $k \ge 2$ in order to apply Van der Corput lemma, since we know nothing about the monotonicity of $f'(t)$.)

To evaluate $III$, we proceed as following:

$$\begin{aligned}f(t) &= f(0) + f'(0)t + \cdots + \frac{f^{(k-1)}(0)}{(k-1)!}t^{k-1} + \frac{f^{(k)}(\sigma_t t)}{k!}t^k \\ &= p(t) + f^{(k)}(\sigma_t t)\frac{t^k}{k!}\end{aligned}$$

where the number $\sigma_t$ depends on $t$ and $0 < \sigma_t < 1$. So

$$\begin{aligned}&\left|\int_{-1}^{1} e^{if(t)}\frac{dt}{t}\right| \\ &\quad\le \left|\int_{-1}^{1}\left[e^{i(p(t)+f^{(k)}(\sigma_t t)\frac{t^k}{k!})} - e^{ip(t)}\right]\frac{dt}{t}\right| + \left|\int_{-1}^{1} e^{ip(t)}\frac{dt}{t}\right| \\ &\quad\le b\frac{2}{k!} + 6(2^k) - 2(k-1) - 10\end{aligned}$$

by Lemma 2, since $p(t)$ is a polynomial of degree at most equal to $k-1$.

On the other hand, if $r \le 1$, it also follows from Lemma 2 that

$$\begin{aligned}&\left|\int_{-r}^{r} e^{if(t)}\frac{dt}{t}\right| \\ &\quad\le \left|\int_{-r}^{r}\left[e^{i(p(t)+f^{(k)}(\sigma_t t)\frac{t^k}{k!}} - e^{ip(t)}\right]\frac{dt}{t}\right| + \left|\int_{-r}^{r} e^{ip(t)}\frac{dt}{t}\right| \\ &\quad\le b\frac{2}{k!} + 6(2^k) - 2(k-1) - 10\end{aligned}$$

Hence

$$\left|\int_{-r}^{r} e^{if(t)}\frac{dt}{t}\right| \le C(k, b)$$

and we are done. □

**Proof of Theorem 1** Let $h$ be a homeomorphism of the circle satisfying the hypotheses of the theorem.

We claim: there exists $\delta > 0$ such that, for all $x \in [-\pi, \pi]$, there is $k$ depending on $x$, with $2 \le k \le \nu$, such that $|h^{(k)}(t + x)| \ge \delta$ for all $t$ satisfying $|t| \le \delta$.

The proof of the claim is simple: suppose that there is no such $\delta$. Then, for each $n \in \mathbb{N}$ and each $k$ with $2 \le k \le \nu$, there exist $x_n \in [-\pi, \pi]$ and $t_{kn}$ such that $|t_{nk}| \le 1/n$ and $|h^{(k)}(t_{nk} + x_n)| < 1/n$. Taking a subsequence if necessary, we have $x_n \to x \in [-\pi, \pi]$. Also, $t_{kn} \to 0$ when $n \to \infty$ for all such $k$. So, $h^{(k)}(t_{kn} + x_n) \to h^{(k)}(x)$ when $n \to \infty$. Since $|h^{(k)}(t_{kn} + x_n)| < 1/n$, we conclude that $h^{(k)}(x) = 0$ for all $k$ with $2 \le k \le \nu$, thus reaching a contradiction.

Now, let $f \in \mathcal{A}(\mathbb{T})$. So, $\sum_{-\infty}^{\infty}|\hat{f}_n| < \infty$, thus implying that

$$f(t) = \sum_{-\infty}^{\infty}\hat{f}_n e^{int} = \lim_{N\to\infty}\sum_{-N}^{N}\hat{f}_n e^{int}$$

Hence

$$f(h(t)) = \sum_{-\infty}^{\infty} \hat{f}_n e^{inh(t)} = \lim_{N\to\infty} \sum_{-N}^{N} \hat{f}_n e^{inh(t)}$$

Put $g_N(t) = \sum_{n=-N}^{N} \hat{f}_n e^{inh(t)}$. Since $g_N$ is smooth, we have $g_N \in \mathcal{U}(\mathbb{T})$ for all $N \in \mathbb{N}$. If $g(t)$ stands for $f(h(t))$, then $g_N \to g$ uniformly, since $f \in \mathcal{A}(\mathbb{T})$. Thus, it suffices to prove that $g \in \mathcal{U}(\mathbb{T})$. This happens if and only if $S_m(g,x) = \sum_{k=-m}^{m} \hat{g}_k e^{ikx}$ converges uniformly to $g$ as $m \to \infty$, that is, given $\epsilon > 0$, there exists $m_0 \in \mathbb{N}$ such that $|S_m(g,x) - g(x)| < \epsilon$ for all $m > m_0$ and $x \in [-\pi, \pi]$.

We have

$$\begin{aligned}&|S_m(g,x) - g(x)|\\&\quad \le |g_N(x) - g(x)| + |S_m(g_N,x) - g_N(x)|\\&\qquad + |S_m(g_N,x) - S_m(g,x)|\end{aligned}$$

for all $m, n \in \mathbb{N}$. Since $g_N \to g$ uniformly and $g_N \in \mathcal{U}(\mathbb{T})$, the last inequality shows that we need to demonstrate that, for each $\epsilon > 0$, there exists $N_0 \in \mathbb{N}$ such that

$$\begin{aligned}&|S_m(g_N,x) - S_m(g,x)| < \epsilon\\&\quad \forall\, N > N_0, x \in [-\pi,\pi] \quad \text{and} \quad m \in \mathbb{N}\end{aligned}$$

thus proving that $S_m(g_N,x) \to S_m(g,x)$ uniformly in $x$ and $m$ when $N \to \infty$.

But, if $K > N \in \mathbb{N}$, we have

$$\begin{aligned}&|S_m(g_N,x) - S_m(g_K,x)|\\&= \left|\frac{1}{2\pi}\int_{-\pi}^{\pi}(g_N(t+x) - g_K(t+x))D_m(t)\,dt\right|\\&= \left|\frac{1}{2\pi}\int_{-\pi}^{\pi}\left(\sum_{n=-N}^{N}\hat{f}_n e^{inh(t+x)} - \sum_{n=-K}^{K}\hat{f}_n e^{inh(t+x)}\right)\right.\\&\qquad \left.\times D_m(t)\,dt\right|\\&\le \left|\frac{1}{2\pi}\int_{-\pi}^{\pi}\left(\sum_{K\ge|n|\ge N}\hat{f}_n e^{inh(t+x)}\right)D_m(t)\,dt\right|\\&\le \frac{1}{2\pi}\sum_{K\ge|n|\ge N}|\hat{f}_n|\left|\int_{-\pi}^{\pi} e^{inh(t+x)}D_m(t)\,dt\right|\end{aligned}$$

where

$$D_m(t) = \sum_{k=-m}^{m} e^{ikt} = \frac{\sin(m+(1/2))t}{\sin(t/2)}$$

is the Dirichlet kernel.

Hence, we are done if we show that

$$\left|\int_{-\pi}^{\pi} e^{inh(t+x)}D_m(t)\right| \le C \qquad [1]$$

where C is a constant that does not depend on $m$, $n$, and $x$.

To prove that the oscillatory integral above is bounded, we make use of Lemma 3. We have that

$$D_m(t) = \frac{2\sin(mt)}{t} + O(1)$$

on any compact subset of $(-2\pi, 2\pi)$, that is,

$$\begin{aligned}&\left|\frac{\sin(m+(1/2))t}{\sin(t/2)} - \frac{2\sin(mt)}{t}\right|\\&\quad \le \left|\frac{t\cos(t/2) - 2\sin(t/2)}{t\sin(t/2)}\right| + 1 \le C^*\end{aligned}$$

where the constant $C^*$ does not depend on $m$, on any compact subset of $(-2\pi, 2\pi)$.

In order to prove [1], consider $x \in [-\pi, \pi]$. We have already proved that there exists $k$ (depending on $x$), with $2 \le k \le \nu$, such that $|h^{(k)}(t+x)| \ge \delta > 0$ for all $t$ such that $|t| \le \delta$. Therefore,

$$\begin{aligned}&\left|\int_{-\pi}^{\pi} e^{inh(t+x)}\frac{\sin(mt)}{t}\,dt\right| \le \left|\int_{-\delta}^{\delta} e^{inh(t+x)}\frac{\sin(mt)}{t}\,dt\right|\\&\quad + 2\log\left(\frac{\pi}{\delta}\right)\end{aligned}$$

We can assume that $n$ is a positive integer: if $n$ is negative, we take complex conjugate; and if $n = 0$, the integral is trivially bounded, as we see by integration by parts or by Van der Corput lemma. (Indeed, we do not need to worry about $n = 0$, since it is necessary to bound the integral only for large $n$.)

So, assuming that $n$ is a positive integer, we change variables: define $t = rs$, where $r = n^{-1/k}\delta^{-1/k}$. Since $\sin(mt) = (e^{imt} - e^{-imt})/(2i)$, we have

$$\begin{aligned}&\left|\int_{-\delta}^{\delta} e^{inh(t+x)}\frac{\sin(mt)}{t}\,dt\right|\\&\quad \le \left|\int_{-\delta}^{\delta} e^{i[nh(t+x)+mt]}\frac{dt}{t}\right| + \left|\int_{-\delta}^{\delta} e^{i[nh(t+x)-mt]}\frac{dt}{t}\right|\\&\quad = \left|\int_{-\delta/r}^{\delta/r} e^{i[nh(rs+x)+mrs]}\frac{ds}{s}\right|\\&\qquad + \left|\int_{-\delta/r}^{\delta/r} e^{i[nh(rs+x)-mrs]}\frac{ds}{s}\right|\end{aligned}$$

Put $\phi(t) = nh(rt+x) + mrt$ and $\psi(t) = nh(rt+x) - mrt$. We have $\phi^{(k)}(t) = nr^k h^{(k)}(rt+x)$ and $\psi^{(k)}(t) = nr^k h^{(k)}(rt+x)$. But, since $nr^k = 1/\delta$, we conclude that

$$\begin{aligned}&\left|\phi^{(k)}(t)\right| = \left|\psi^{(k)}(t)\right|\\&\quad = \frac{1}{\delta}\left|h^{(k)}(rt+x)\right| \ge 1, \quad \forall\, t \in \left[-\frac{\delta}{r}, \frac{\delta}{r}\right]\end{aligned}$$

Also,

$$\begin{aligned}|\phi^{(k)}(t)| = |\psi^{(k)}(t)| &\le b_k \\ &= \frac{1}{\delta}\max\left\{|h^{(k)}(s)|\colon -2\pi \le s \le 2\pi\right\}\end{aligned}$$

for all $t \in [-\delta/r, \delta/r]$. Therefore, by Lemma 3, we get

$$\begin{aligned}\left|\int_{-\delta/r}^{\delta/r} e^{i\phi(t)} \frac{dt}{t}\right| &\le C(k, b_k) \\ &\le \max\{C(j, b_j)\colon\ 2 \le j \le \nu\}\end{aligned}$$

and

$$\begin{aligned}\left|\int_{-\delta/r}^{\delta/r} e^{i\psi(t)} \frac{dt}{t}\right| &\le C(k, b_k) \\ &\le \max\{C(j, b_j)\colon\ 2 \le j \le \nu\}\end{aligned}$$

This concludes the proof. □

## Diffeomorphisms of the Circle

In this section we study the circle diffeomorphisms. This theory goes back to Poincaré (1885), who studied circle diffeomorphisms to decide when differential equations on the torus have periodic orbits of a specified type. For this he introduced the rotation number as an important dynamical invariant, which later turned out to be very fruitful in the theory of dynamical systems, and proved that a diffeomorphism with an irrational rotation number is combinatorially equivalent to a rotation with the same rotation number.

Denjoy (1932) constructed examples of diffeomorphisms of class $C^1$ with irrational rotation number having wandering intervals, in opposition to early ideas of Poincaré. It was necessary to assume that a diffeomorphism without periodic points is more smooth, in fact $C^2$, to prove that it is topologically conjugate to the rotation.

### The Poincaré Rotation Number

Let $\widetilde{h}: \mathbb{T} \to \mathbb{T}$ be an orientation-preserving homeomorphism. Given such a map, there is a (nonunique) map $h: \mathbb{R} \to \mathbb{R}$, which is called a lift of $\widetilde{h}$, such that $\widetilde{h} \circ p = p \circ h$, where $p: \mathbb{R} \to \mathbb{T}$ is covering map $p(t) = e^{2\pi i t}$.

A lift, $h$, of $\widetilde{h}$ satisfies:

1. $h$ is monotonically increasing, that is, $h(t_1) \le h(t_2)$ if $t_1 < t_2$.
2. $h(t+1) = h(t) + 1$ for all $t \in \mathbb{R}$, so $(h - \mathrm{id})$ has period 1.
3. If $h_1$ $h_2$ are two lifts of $\widetilde{h}$, then there is an integer $k$ such that $h_2(t) = h_1(t) + k$ for all $t \in \mathbb{R}$.

These conditions immediately yield the following: the transformation $h^k := h \circ \cdots \circ h$ is monotonically increasing and $h^k(t+r) = h^k(t) + r, t \in \mathbb{R}, k \in \mathbb{N}, r \in \mathbb{Z}$.

The rotation number gives an asymptotic indication (i.e., in the limit) of the average amount of rotation of a point along an orbit. We start by defining, for a lift $h$ of $\widetilde{h}$, the number

$$\rho_0(h, t) = \lim_{k\to\infty} \frac{h^k(t) - t}{k}$$

This limit exists and does not depend on the choice of the point $t \in \mathbb{R}$; so, we denote it by $\rho_0(h)$. If $h_1$ $h_2$ are two lifts of $\widetilde{h}$, then $\rho_0(h_1, t) - \rho_0(h_2, t)$ is an integer, so

$$\rho(\widetilde{h}) := \rho_0(h, t) \bmod 1$$

is well defined. The number $\rho(\widetilde{h}) \in [0, 1)$ is called the rotation number of $\widetilde{h}$, and depends continuously on $\widetilde{h}$. For detailed proof, see Katok and Hasselblatt (1995) or Robinson (1999).

**Theorem 5** *The rotation number $\rho(\widetilde{h})$ is rational if and only if $\widetilde{h}$ has a periodic point, this is, there exist $z_0 \in S^1$ and $k \in \mathbb{N}$ such that $\widetilde{h}^k(z_0) = z_0$.*

**Proof** Take a lift $h$ of $\widetilde{h}$ such that $h(0) \in [0, 1)$. Suppose that $\rho(\widetilde{h}) = q/m$.

If $\widetilde{h}$ has no fixed point. Then $h(t) - t \in \mathbb{R} \setminus \mathbb{Z}$ for all $t \in \mathbb{R}$, since $h(t) - t \in \mathbb{Z}$ implies that $p(t)$ is a point fixed for $\widetilde{h}$. In particular, $h(t) - t \ne q$ for all $t \in \mathbb{R}$, since $h - \mathrm{id}$ is continuous and periodic, there exist real numbers $a > 0$ such that $h(t) - t < q - a$ for all $t \in \mathbb{R}$. Then

$$\begin{aligned}&h^{km}(t) - h^{(k-1)m}(t) \\ &\quad = h^m[h^{(k-1)m}(t)] - [h^{(k-1)m}(t)] \\ &\quad < q - a, \quad \forall k \in \mathbb{N} \\ &\Downarrow \\ &h^{km}(t) - t \\ &\quad = \{h^m[h^{(k-1)m}(t)] - [h^{(k-1)m}(t)]\} \\ &\qquad + \{h^m[h^{(k-2)m}(t)] - [h^{(k-2)m}(t)]\} \\ &\qquad + \{h^m[h^{(k-3)m}(t)] - [h^{(k-3)m}(t)]\} + \cdots \\ &\qquad + \{h^m(t) - t\} < k(q - a)\end{aligned}$$

So

$$\begin{aligned}\frac{q}{m} = \rho(\widetilde{h}) &= \lim_{k\to\infty} \frac{h^{mk}(t) - t}{mk} \\ &\le \frac{1}{m} \lim_{k\to\infty} \frac{k(q-a)}{k} = \frac{q-a}{m}\end{aligned}$$

proving the claim by contraposition.

To see the converse, assume that there exists a periodic point $t_0 \in \mathbb{R}$, that is, there are $m, q \in \mathbb{Z}$ such that $h^m(t_0) = t_0 + q$ then

$$h^{km}(t_0) = t_0 + kq$$

$$\Rightarrow \rho(\widetilde{h}) = \lim_{k\to\infty} \frac{h^{mk}(t_0) - t_0}{mk} = \frac{q}{m} \qquad \square$$

**Corollary 6** *A homeomorphism $\widetilde{h}:\mathbb{T}\to\mathbb{T}$ does not have periodic points if and only if the rotation number $\rho(\widetilde{h})$ is irrational.*

Let $R_\lambda$ be defined on $\mathbb{T}$ by $R_\lambda(e^{2\pi i t}) = e^{2\pi i(t+\lambda)}$. This map is called a rigid rotation of angle $\lambda$ and it is easy to see that $h_\lambda(t) = t + \lambda$ is lift of $R_\lambda$ and that $\rho(R_\lambda) = \rho(h_\lambda) = \lambda \bmod 1$.

In this example we can see the connection between the rationality of the rotation number and the existence of a periodic orbit. Assume $\lambda = m/q$ is rational. Then $h_\lambda^q(t) = t + q\lambda = t + m$. Therefore, every point is periodic with period $q$. Now, assume that $\lambda$ is irrational. Since $h_\lambda^n(t) = t + n\lambda$ for all $n$, then $R_\lambda$ has no periodic points. In this case, show that every point in $\mathbb{T}$ has a dense orbit.

Now, again let $\widetilde{h}:\mathbb{T}\to\mathbb{T}$ be any orientation-preserving homeomorphism.

**Lemma 7** *If the rotation number of $\widetilde{h}$ is rational, then all periodic orbits have the same period.*

**Proof** If $\rho(\widetilde{h}) = m/q$ with $m, q \in \mathbb{Z}$ relatively prime, then we need to show that for any periodic point $z_0 = p(t)$ (where $p(t) = e^{2\pi i t}$ is a covering space projection of $\mathbb{T}$) there is a lift $h$ of $\widetilde{h}$ such that $h(0) \in [0, 1)$ for which $h^q(t) = t + m$. If $z_0$ is periodic point, then $h^r(t) = t + s$ for some $r, s \in \mathbb{Z}$ and

$$\frac{m}{q} = \rho(\widetilde{h}) = \lim_{n\to\infty} \frac{h^{rn}(t) - t}{nr} = \lim \frac{ns}{nr} = \frac{s}{r}$$

So that $s = km$ and $r = kq$. Then by monotonicity of $h$, we have that $h^q(t) = t + m$ as claimed. $\square$

### The Poincaré Denjoy Theory

A homeomorphism of the circle with rational rotation number has all its orbits asymptotic to periodic ones and this, together with Theorem 5, yields a complete classifications of the possible asymptotic behavior when the rotation number is rational. This motivates the study of the asymptotic behavior of orbits of homeomorphisms with irrational rotation number.

The $\omega$-limit set of a point $z_0 \in \mathbb{T}$ with respect to $\widetilde{h}$ is the set $\omega(z_0) = \{z \in \mathbb{T};\ \widetilde{h}^{n_k}(z_0) \to z$ as $n_k \to \infty$, for same sequence $\{n_k\}_{k=1}^{\infty}\}$. The $\alpha$-limit set $\alpha(z_0)$ of an arbitrary point $z_0 \in \mathbb{T}$ is defined similarly (with $n_k \to -\infty$ instead $n_k \to +\infty$).

Any orbit of a rotation $R_\lambda$ with irrational $\lambda$ is dense in $\mathbb{T}$, that is, $\omega(z_0) = \alpha(z_0) = \mathbb{T}$ for all $z_0 \in \mathbb{T}$.

**Theorem 8** (Poincaré 1885). *Let $\widetilde{h}:\mathbb{T}\to\mathbb{T}$ be an orientation-preserving homeomorphism with irrational rotation number. Then the $\omega$-limit set is independent of $x$ and is either $\mathbb{T}$ or perfect and nowhere dense.*

The preceding proposition says that maps with irrational rotation number have either all orbits dense or all orbits asymptotic to a Cantor set.

We say that two maps $f, g:\mathbb{T}\to\mathbb{T}$ are topologically conjugate if there exists a homeomorphism $h:\mathbb{T}\to\mathbb{T}$ such that $h \circ f = g \circ h$. This implies that $h \circ f^n = g^n \circ h$ for every integer $n$. Hence, the conjugacy $h$ maps orbits of $f$ into orbits of $g$. If a monotone map $l:\mathbb{T}\to\mathbb{T}$ satisfies $l \circ f = g \circ l$ but is not a necessarily homeomorphism, we only have that inverse image of each point is either a point or a closed interval. We say that $l$ is a semiconjugacy between $f$ and $g$; this case $l$ maps orbits or pack of orbits of $f$ into orbits of $g$.

**Theorem 9** (Denjoy 1932). *Let $\widetilde{f}:\mathbb{T}\to\mathbb{T}$ be an orientation-preserving diffeomorphism of class $C^2$, with irrational rotation number ($\rho(\widetilde{f}) = \lambda$). Then $\widetilde{f}$ is topologically conjugate to the rigid rotation $R_\lambda$.*

Note that in spite of the hypothesis of $\widetilde{f}$ being $C^2$, we obtain only a continuous conjugacy. It took almost 50 years until Michael Herman (1979) was able to solve the more difficult problem of obtaining a smooth conjugacy for rotation number satisfying extra arithmetic conditions.

If $\widetilde{f}$ is a circle homeomorphism which does not have periodic points, then there exists a semiconjugacy $h$ between $\widetilde{f}$ and a rotation $R_\lambda$. If $h$ is not a conjugacy, then there exists a point $x$ of the circle whose inverse image by $h$ is an interval $J$. Since $h \circ \widetilde{f} = R_\lambda \circ h$, we have that $h(\widetilde{f}^n(J)) = R_\lambda^n(x)$. It follows that the intervals of the family $\{J, f(J), f^2(J), \ldots\}$ are pairwise disjoint, and the $\omega$-limit set of $J$ does not reduce to a periodic orbit. We say that $J$ is a wandering interval of the map $\widetilde{f}$. Thus, $C^2$-differentiability implies that $\widetilde{f}$ does not have a wandering interval. For details of the proof of Theorem 9, see Melo and Strien (1993).

### The Denjoy Example

Denjoy also proved the following result, which shows that the hypothesis of class $C^2$ is essential.

**Theorem 10** (Denjoy 1932). *For any irrational number $\lambda \in [0, 1)$, there exists a $C^1$-circle diffeomorphism $f$ which has a wandering interval, and rotation number equal to $\lambda$.*

**Proof** The construction of a diffeomorphism with wandering interval will be done in the following manner. Given an irrational rotation $R_\lambda(e^{2\pi i t}) = e^{2\pi i(t+\lambda)}$, cut the circle $\mathbb{T}$ at all the points of an orbit $\{z_n = R_\lambda^n(e^{2\pi i t_0});\ n \in \mathbb{Z}\}$ of $R_\lambda$. In each cut insert a segment $J_n$ of length $l_n$ where $\sum_{n=-\infty}^{\infty} l_n = 1$. We obtain in this manner a new circle longer than the first. The open intervals correspond to the gaps of the Cantor set.

In order to construct $f$ formally. Let $l_n$ be a sequence of positive real numbers with $n \in \mathbb{Z}$ satisfying

(i) $\lim_{n\to\pm\infty}(l_{n+1}/l_n) = 1$
(ii) $\sum_{n=-\infty}^{\infty} l_n = 1$
(iii) $l_n > l_{n+1}$ for $n \geq 0$
(iv) $l_n < l_{n+1}$ for $n < 0$ and
(v) $3l_{n+1} - l_n > 0$ for $n \geq 0$

For example

$$l_n = T(|n|+2)^{-1}(|n|+3)^{-1}$$

where

$$T^{-1} = \sum_{n=-\infty}^{\infty}(|n|+2)^{-1}(|n|+3)^{-1}$$

Let $J_n$ be a closed interval of length $l_n$. We place these intervals on the circle in the same order as the order of the orbit $R_\lambda^n(0)$. So to place an interval $J_n$, consider the sum of the lengths of the intervals $J_i$ where $R_\lambda^i(0)$ is between $R_\lambda^n(0)$ and 0. This determines the placement of $J_n$.

The next step is to define $f$ on the union of the $J_n$. It is necessary and sufficient for $f'(t) = 1$ on the endpoint in order for the map to have a continuous derivative when it is extended to the closure. Assume $J_n = [a_n, b_n]$, so $l_n = b_n - a_n$. The integral

$$\int_{a_n}^{b_n}(b_n - t)(t - a_n)\,dt = \frac{l_n^3}{6}$$

so

$$\frac{6(l_{n+1} - l_n)}{l_n^3}\int_{a_n}^{b_n}(b_n - t)(t - a_n)\,dt = l_{n+1} - l_n$$

Therefore, if we define $f$ for $x \in J_n$ by

$$f(x) = a_{n+1} + \int_{a_n}^{x}\left[1 + \frac{6(l_{n+1} - l_n)}{l_n^3}(b_n - t)(t - a_n)\right]dt$$

then $f(b_n) = a_{n+1} + l_n + l_{n+1} - l_n = b_{n+1}$. Also, $f$ is differentiable on $J_n$ with

$$f'(x) = 1 + \frac{6(l_{n+1} - l_n)}{l_n^3}(b_n - x)(x - a_n)$$

Thus, $f'(a_n) = 1 = f'(b_n)$. Notice that for $n < 0$, $l_{n+1} - l_n > 0$, that

$$1 \leq f'(x) \leq 1 + \frac{6(l_{n+1} - l_n)}{l_n^3}\left(\frac{l_n}{2}\right)^2 = \frac{3l_{n+1} - l_n}{2l_n}$$

and $(3l_{n+1} - l_n)/(2l_n)$ goes to 1 as $n \to -\infty$. Similarly for $n \geq 0$ and $x \in J_n$,

$$1 \geq f'(x) \geq \frac{3l_{n+1} - l_n}{2l_n} > 0$$

so $f'(x)$ goes to 1 as $n \to +\infty$ uniformly for $x \in J_n$. From these facts, it follows that $f$ is uniformly $C^1$ on the union of the interiors of the $J_n$ and has a $C^1$ extension to all of $\mathbb{T}$.

Let $\Lambda = \mathbb{T} \setminus \cup_{n\in\mathbb{Z}}\operatorname{int}(J_n)$. This is a Cantor set. The orbit of a point $x \in \Lambda$ is dense in $\Lambda$ since it is like the orbit of 0 for $R_\lambda$. Thus, $\omega(x) = \Lambda$. If $x \in \operatorname{int}(J_n)$, then there is a smaller interval $I$ whose closure is contained in $\operatorname{int}(J_n)$. Since the interval $J_n$ never returns to $J_n$ but wanders among the other $J_k$, then $J_n$ is a wandering interval. □

## Further Results

In this section we shall state some additional results about homeomorphisms of the circle in the area of Fourier analysis.

The first result is a theorem of Pál (1914) and Bohr (1935): let $f: \mathbb{T} \to \mathbb{R}$ be a real continuous function; then, there exists a homeomorphism of the circle $h$ such that $f \circ h \in \mathcal{U}(\mathbb{T})$. The best proof of this theorem is due to Salem (1945). In 1978, Kahane and Katznelson showed that the result is still valid for $f: \mathbb{T} \to \mathbb{C}$ continuous.

A similar question was posed by Lusin: given a continuous function $f: \mathbb{T} \to \mathbb{R}$, is there a homeomorphism of the circle $h$ such that $f \circ h \in \mathcal{A}(\mathbb{T})$? The problem remained open until 1981, when Olevskii, Kahane, and Katznelson answered negatively the question: there exists a real (or complex) continuous function $f$ on the circle, such that, for all homeomorphism of the circle $h$, $f \circ h \notin \mathcal{A}(\mathbb{T})$.

It was proved by the author that there are $C^\infty$ homeomorphisms of the circle, not necessarily of finite type, that transport $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$. It is a very technical work, published in 1998, and it gives a necessary and sufficient condition for a homeomorphism of the circle with a flat point to transport $\mathcal{A}(\mathbb{T})$ into $\mathcal{U}(\mathbb{T})$.

Finally, the Denjoy theorem (Theorem 9) is rather close to being optimal. The example constructed here can be improved by obtaining a circle diffeomorphism whose first derivatives have Hölder exponent arbitrarily close to 1 (see Katok and Hasselblatt (1995)). Recent

work has dealt with the existence of a differentiable conjugacy between a diffeomorphism $f$ with irrational rotation number $\lambda$ and $R_\lambda$. Arnol, Moser, and Herman have obtained results (see Melo and Strien (1993) for a discussion of this results and references).

# Homoclinic Phenomena

**S E Newhouse**, Michigan State University, E. Lansing, MI, USA

## Introduction

Homoclinic orbits (or motions) were first defined by Poincaré in his treatise on the "restricted three-body problem." (Poincaré 1987) Further advances were made by Birkhoff (Birkhoff 1960) in the 1930s, and, by Smale in the 1960s. Since that time, they have been studied by many people and have been shown to be intimately related to our understanding of nonlinear dynamical systems. There are many systems which possess homoclinic orbits. In one striking example (as discussed in the book of Moser (1973), they can be used to account for the unbounded oscillatory motion discovered by Sitnikov in the three-body problem. They also commonly occur in two-dimensional mappings derived from periodically forced oscillations (e.g., see the book by Guckenheimer and Holmes (1983).

Roughly speaking, a homoclinic orbit is an orbit of a mapping or differential equation which is both forward and backward asymptotic to a periodic orbit which satisfies a certain nondegeneracy condition called "hyperbolicity." On its own, such an orbit is only of mild interest. However, these orbits induce quite interesting structures among nearby orbits, and this latter fact is responsible for the main importance of homoclinic orbits. In addition, when homoclinic orbits are created in a parametrized system, many interesting and unexpected phenomena arise.

In this article, we first describe the history and basic properties of homoclinic orbits. Next, we consider some simple polynomial diffeomorphisms of the plane (the so-called Hénon family) which exhibit homoclinic orbits. Subsequently, we discuss a general theorem due to Katok which gives sufficient conditions for the existence of such orbits. Finally, we briefly consider issues related to homoclinic bifurcations and some of their consequences.

## Homoclinic Orbits in Diffeomorphisms

Consider a discrete dynamical system given by a $C^r$ diffeomorphism $f: M \to M$ where $M$ is a $C^\infty$ manifold and $r$ is a positive integer. That is, $f$ is bijective and both $f$ and $f^{-1}$ are $r$-times continuously differentiable. Given a point $x \in M$, set $x_0 = x$. For non-negative integers $n$ we inductively define $x_{n+1} = f(x_n)$ and $x_{-n-1} = f^{-1}(x_{-n})$. We also write $f^n(x) = x_n$ for $n$ in the set $\mathbf{Z}$ of all integers. The "orbit" of $x$ is the set $O(x) = \{f^n(x): n \in Z\}$.

A "periodic point" $p$ of $f$ is a point such that there is a positive integer $N > 0$ such that $f^N(p) = p$. The least such number $\tau(p)$ is called the "period" of $p$. If $\tau(p) = 1$, we call $p$ a "fixed point." The periodic point $p$ with period $\tau$ is called called "hyperbolic" if all eigenvalues of the derivative $Df^\tau(p)$ at $p$ have absolute value different from 1. For convenience, we refer to the eigenvalues of $Df^\tau(p)$ as eigenvalues associated to $p$. If $p$ is a hyperbolic periodic point all of whose associated eigenvalues have norm less than one, we call $p$ a "sink" or "attracting periodic point." The opposite case in which all associated eigenvalues have norm larger than one is called a "source." A hyperbolic periodic point $p$ which is neither a source nor a sink is called a "saddle" or "hyperbolic saddle."

Given a saddle $p$ of period $\tau$, we consider the set $W^s(p) = W^s(p, f)$ of points $y \in M$ which are forward asymptotic to $p$ under the iterates $f^{n\tau}$. That is, the points $y \in M$ such that $f^{n\tau}(y) \to p$ as $n \to \infty$. This is called the "stable set" of $p$. Similarly, we consider the "unstable set" of $p$ which we may define as $W^u(p) = W^u(p, f) = W^s(p, f^{-1})$. The stable manifold theorem guarantees that $W^s(p)$ and $W^u(p)$ are injectively immersed submanifolds of $M$ whose dimensions add up to dim $M$. In these cases, they are called the stable and unstable manifolds of $p$, respectively. A point $q \in W^s(p) \bigcap W^u(p) \setminus \{p\}$ is called a "homoclinic point" of $p$ (or of the pair $(f, p)$). If the submanifolds $W^s(p)$ and $W^u(p)$ meet transversely at $q$, then $q$ is called a "transverse homoclinic point." Otherwise, $q$ is called a "homoclinic tangency."

In the special case when $M$ is a two-dimensional manifold, the stable and unstable manifolds of a saddle periodic point $p$ are injectively immersed curves in $M$. A transverse homoclinic point $q$ of $p$ is a point of intersection off $p$ where the curves are not tangent to each other. This is depicted in Figure 1 for the case of a saddle fixed point for the map $H(x, y) = (7 - x^2 - y, x)$, a member of the so-called Hénon family, which we will discuss later. The figure was made using the numerical package "Dynamics" which comes with the book by Nusse and Yorke (1998).

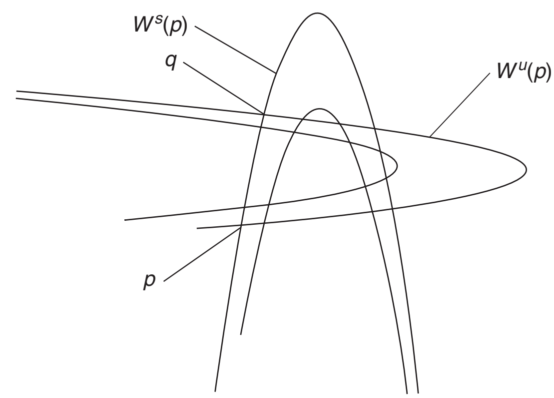

**Figure 1** Stable and unstable manifolds in the map $H(x, y) = (7 - x^2 - y, x)$ for the fixed point $p \approx (-3.83, -3.83)$.

One easily sees that every point in the orbit of a transverse homoclinic point $q$ of a hyperbolic saddle fixed point $p$ is again a transverse homoclinic point of $p$. Also, the curves $W^u(p)$ and $W^s(p)$ are invariant; that is, $f(W^u(p)) = W^u(p)$ and $f(W^s(p)) = W^s(p)$. This implies that the curves $W^u(p)$ and $W^s(p)$ extend, wind around, and accumulate on each other forming a complicated web.

Upon seeing this complicated structure in the restricted three-body problem, Poincaré very poetically wrote (p. 389, Poincaré 1987)

> Que l'on cherche à se représenter la figure formée par ces deux courbes et leurs intersections en nombre infini dont chacune correspond à une solution doublement asymptotique, ces intersections forment une sorte de treillis, de tissu, de réseau à mailles infiniment serrées; chacune des deux courbes ne doit jamais se recouper elle-même, mais elle doit se replier sur elle-même d'une manière trés complexe pour venir recouper une infinité de fois toutes les mailles du réseau.
> On sera frappé de la complexité de cette figure, que je ne cherche même pas à tracer. Rien n'est plus propre à nous donner une idée de la complication du problème des trois corps et en général de tous les problèmes de Dynamique où il n'y a pas d'intégrale uniforme ...

The next major advance concerning homoclinic orbits was made by Birkhoff (1960), who proved that in every neighborhood of a transverse homoclinic point of a surface diffeomorphism, one can find infinitely many distinct periodic points. Birkhoff also presented a symbolic description of the nearby orbits and noticed the analogy with Hadamard's description of geodesics on a surface. Birkhoff's analysis was generalized by Smale to arbitrary dimension, and, in addition, Smale gave a simpler analysis of the associated nearby orbits in terms of compact zero-dimensional

symbolic spaces which we now call “shift spaces” or “topological Markov chains.”

Once one knows that a diffeomorphism $f$ has a transverse homoclinic point for a saddle periodic point $p$, it is interesting to consider the closure of the orbits of all such homoclinic points. This turns out to be a closed invariant set containing a dense orbit and a countable dense set of periodic saddle points (Newhouse 1980). It is usually called a “homoclinic closure” or $h$-closure. These sets form the basis of chaotic or irregular motions in nonlinear systems.

## The Smale Horseshoe Map and Associated Symbolic System

To understand the geometric picture discovered by Smale, it is best to start with a concrete example of a diffeomorphism of the plane known as the “Smale horseshoe diffeomorphism.”

Given any homeomorphism $f : X \to X$ on a space $X$ and a subset $U \subset X$, let us define $I(f, U)$ to be the set of points $x \in X$ such that $f^n(x) \in U$ for every integer $n$. Thus, we have

$$I(f, U) = \bigcap_{n \in \mathbf{Z}} f^n(U)$$

We call $I(f, U)$ the invariant set of $f$ in $U$, or, alternatively, the invariant set of the pair $(f, U)$.

We now construct a special diffeomorphism $f$ of the Euclidean plane to itself in which $U = Q$ is the unit square and for which $I(f, U)$ has a very interesting structure. It is this map which is usually known as the Smale horseshoe map.

Let $Q = [0, 1] \times [0, 1]$ be the unit square in the plane $\boldsymbol{R}^2$. Let $0 < \alpha < 1/2$, and consider a diffeomorphism $f : \boldsymbol{R}^2 \to \boldsymbol{R}^2$ which is a composition of two diffeomorphisms $f = T_2 \circ T_1$ as follows. The map $T_1(x, y) = (\alpha^{-1}x, \alpha y)$ contracts vertically, expands horizontally, and maps $Q$ to the thin rectangle $Q_1 = \{(x, y) : 0 \le x \le \alpha^{-1}, 0 \le y \le \alpha\}$ which is short and wide. The map $T_2$ bends the right side of $Q_1$ up and around so that $T_2(Q_1) = f(Q)$ has the shape of a “horseshoe” or “rotated arch.” We arrange for $T_2$ to take the lower-right corner of $Q_1$ up to the upper-left corner of $Q$ in such a way that $f(Q)$ meets $Q$ in two full width subrectangles which we call $R_1$ and $R_2$. This can be done in such a way that the preimages $R_1^{-1} = T_1^{-1}(R_1)$ and $R_2^{-1} = T_1^{-1}(T_2^{-1}(R_2))$ are both full-height subrectangles of $Q$, and the restricted maps $f_1 \stackrel{\text{def}}{=} f \mid R_1^{-1}$ and $f_2 \stackrel{\text{def}}{=} f \mid R_2^{-1}$ are both affine. Thus, we arrange that $f_1$ is simply the restriction of $T_1$ to $R_1^{-1}$, and the map $f_2$ can be expressed in formulas as $f_2(x, y) = (-\alpha^{-1}x + \alpha^{-1}, -\alpha y + 1)$. This construction implies that $f$ will have the origin $p = (0, 0)$ as a

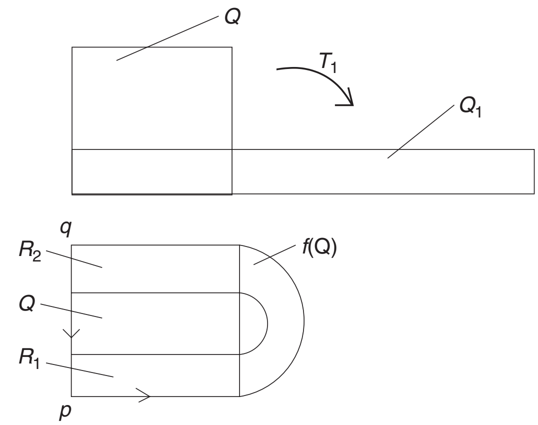

**Figure 2** The horseshoe map.

hyperbolic fixed point. We label the upper-left corner $(0, 1)$ of $Q$ with the letter $q$. It follows that the bottom and left edges of $Q$ will be in the unstable and stable manifolds of $p$, respectively, and we have indicated this in Figure 2 with small arrows.

The above construction gives us a diffeomorphism $f$ of the plane $\boldsymbol{R}^2$ such that $Q_1^+ \stackrel{\text{def}}{=} f(Q) \bigcap Q = R_1 \bigcup R_2$ is the union of two full-width subrectangles of $Q$. We wish to describe $I(f, Q)$. We begin with the sets $Q^+ = \bigcap_{n \ge 0} f^n(Q)$ and $Q^- = \bigcap_{n \ge 0} f^{-n}(Q)$. Thus, $Q^+$ is simply the set of points in $Q$ whose backward orbits stay in $Q$, and $Q^-$ is the set of points whose forward orbits stay in $Q$. For $i = 1, 2$, each rectangle $R_i$ is mapped to a thin horseshoe in $f(Q)$ which meets $Q$ in two full-width subrectangles. Combining these for $i = 1, 2$ gives four full-width rectangles as shaded in Figure 3. Thus, $Q \bigcap f(Q) \bigcap f^2(Q)$ consists of these four subrectangles. **Figure 3** shows the sets $f^2(Q), f^{-2}(Q)$ as well as the shaded rectangles we just mentioned.

Continuing in this way, one sees that, for each $n > 0$, the set $Q_n^+ = Q \bigcap f(Q) \bigcap \ldots \bigcap f^n(Q)$ consists of $2^n$ full-width subrectangles of $Q$, each with height

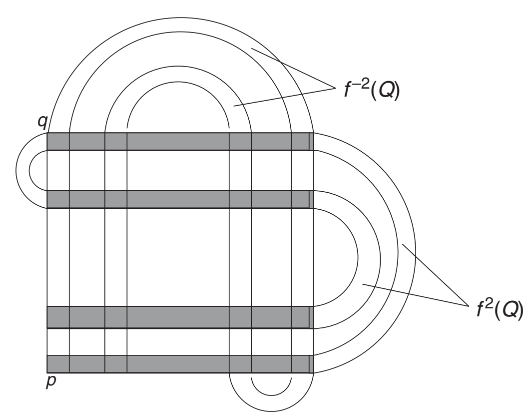

**Figure 3** The sets $f^2(Q)$ and $f^{-2}(Q)$ for the horseshoe map $f$.

$\alpha^n$. It follows that $Q^+ = \bigcap_n f^n(Q)$ is an interval times a Cantor set. Analogously, $Q^-$ is a Cantor set times an interval, and the set $I(f, Q)$ is a Cantor set in the plane. Let us recall the definition of a Cantor set $C$ in a metric space $X$. We first define a Cantor space $C$ to be a compact, perfect, totally disconnected metric space. That is, $C$ is a compact metric space, whose connected components are points such that every point $x$ in $C$ is a limit point of $C \setminus \{x\}$. A Cantor set $C$ in a metric space $X$ is a subset which is a Cantor space in the induced subspace (relative) topology.

The dynamics of $f$ on the invariant set $I(f, Q)$ can be conveniently described as follows.

Let $\Sigma_2 = \{1, 2\}^{\mathbf{Z}}$ be the set of doubly infinite sequences of 1's and 2's. Writing elements $\boldsymbol{a} \in \Sigma_2$ as $\boldsymbol{a} = (a_i) = (a_i)_{i \in Z}$, we define a metric $\rho$ on $\Sigma_2$ by

$$\rho(\boldsymbol{a}, \boldsymbol{b}) = \sum_{n \in \mathbf{Z}} \frac{1}{2^{|n|}} |a_i - b_i|$$

The pair $(\Sigma_2, \rho)$, then, is a Cantor space.

The "left-shift automorphism" on $\Sigma_2$ is the map $\sigma : \Sigma_2 \to \Sigma_2$ defined by $\sigma(\boldsymbol{a})_i = a_{i+1}$ for each $i \in \mathbf{Z}$. This is a homeomorphism from $\Sigma_2$ to itself. It has a dense orbit and a dense set of periodic points.

For a point $x \in I(f, Q)$, define an element $\phi(x) = \boldsymbol{a} = (a_i) \in \Sigma_2$ by $a_i = j$ if and only if $f^i(x) \in R_j$. It turns out that the map $\phi : I(f, Q) \to \Sigma_2$ is a homeomorphism such that $\sigma\phi = \phi f$.

In general, given two discrete dynamical systems $f : X \to X$, and $g : Y \to Y$, a homeomorphism $h : X \to Y$ such that $gh = hf$ is called a topological conjugacy from the pair $(f, X)$ to the pair $(g, Y)$. When such a conjugacy exists, the two systems have virtually the same dynamical properties.

In the present case, one sees that the dynamics of $f$ on $I(f, Q)$ is completely described by that of $\sigma$ on $\Sigma_2$.

It turns out the the Smale horseshoe map contains essentially all of the geometry necessary to describe the orbit structures near homoclinic orbits. To begin to see this, recall that the left and bottom boundaries of $Q$ were in the stable and unstable manifolds of $p$. Extending these curves as in Figure 4, one sees that the three corners of $Q$ different from $p$ are, in fact, all transverse homoclinic points of $p$.

It was a great discovery of Smale that, in the case of a general transverse homoclinic point, one sees the above geometric structure after taking some power $f^N$ of the diffeomorphism $f$. Thus, we have

**Theorem 1** (Smale). *Let $f : M \to M$ be a $C^1$ diffeomorphism of a manifold $M$ with a hyperbolic periodic point $p$ and a transverse homoclinic point $q$ of the pair $(f, p)$. Then, one can find a positive integer $N$ and a compact neighborhood $U$ of the points $p$ and $q$ such that the pair $(f^N, I(f^N, U))$ is topologically conjugate to the full 2-shift $(\sigma, \Sigma_2)$.*

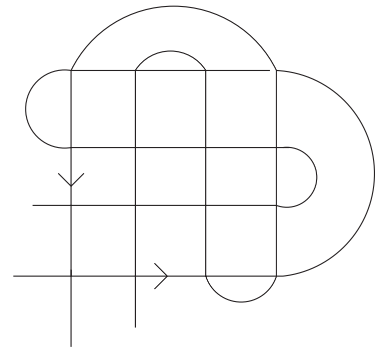

**Figure 4** Stable and unstable manifolds in the horseshoe map.

In modern language, we can assert that more is true. Let $\Lambda(f) = \bigcup_{0 \le j < N} f^j(I(f^N, U))$ be the $f$-orbit of the set $I(f^N, U)$. Then, $\Lambda(f)$ is a compact zero-dimensional hyperbolic basic set for $f$ with $V \stackrel{\text{def}}{=} \bigcup_{0 \le j < N} f^j(U)$ as an "adapted" or "isolating" neighborhood. This means that $\Lambda(f) = \bigcap_{n \in Z} f^n(V)$ is a compact, zero-dimensional hyperbolic set (see Robinson (1999) for definitions and related references) contained in the interior of $V$ and $f \mid \Lambda(f)$ has a dense orbit. If $g$ is $C^1$ near $f$, then $\Lambda(g) \stackrel{\text{def}}{=} \bigcap_{n \in Z} g^n(V)$ is a hyperbolic basic set for $g$ and the pairs $(f, \Lambda(f))$ and $(g, \Lambda(g))$ are topologically conjugate.

To get some appreciation for the magnitude of the contribution here, one might note the complicated arguments employed by Poincaré at the end of Poincaré (1987) to show that so-called heteroclinic points (intersections between stable and unstable manifolds of saddles with different orbits) existed. Birkhoff found a symbolic description (using infinitely many symbols) of the orbits near a transverse homoclinic orbit from which the existence of both infinitely many periodic and heteroclinic points is obvious. Smale extended the treatment of transverse homoclinic points to all dimensions, and found the symbolic description (using two symbols for some iterate of the map) given above. Moreover, Smale proved the "robustness" of these structures: they persist under small $C^1$ perturbations. Note that Poincaré's discovery of homoclinic points was in 1899, Birkhoff's results came in 1935, and Smale's results came in 1965. Thus, the above advances took over 65 years!

One can understand the geometry of Smale's construction fairly easily in the two-dimensional case. Let $q$ be the transverse homoclinic point of the saddle fixed point $p$ of the $C^r$ diffeomorphism $f$ on the plane $\mathbf{R}^2$. Given a small neighborhood $\tilde{U}$ of $p$, let

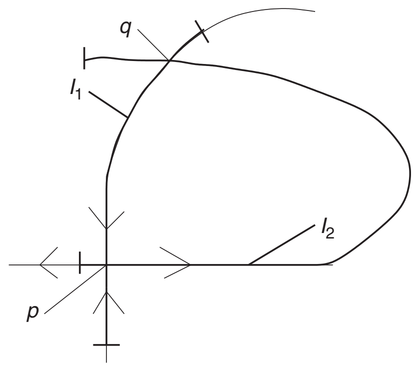

**Figure 5** The curves $I_1 \subset W^s(p)$ and $I_2 \subset W^u(p)$.

$W^s(p, \tilde{U})$ denote connected component of $W^s(p) \bigcap \tilde{U}$ containing $p$, and define $W^u(p, \tilde{U})$ similarly. We may choose $C^r$ coordinates $(x, y)$ so that in some small neighborhood $\tilde{U}$ of $p$, the point $p$ corresponds to $(0, 0)$, the set $W^u(p, \tilde{U})$ corresponds to $(y = 0)$, and the set $W^s(p, \tilde{U})$ corresponds to $(x = 0)$. We assume that $\tilde{U}$ is small enough that $f$ in $\tilde{U}$ is closely approximated by its derivative $Df_{(0,0)}$. Hence, $f$ nearly contracts vertical directions and expands horizontal directions in $\tilde{U}$.

Take compact arcs $I_1 \subset W^s(p)$ and $I_2 \subset W^u(p)$ both containing the points $p$ and $q$ as in Figure 5.

Let $D$ be a curvilinear rectangle which is a slight thickening of $I_1$. The forward iterates $f^i(D)$ will stay near $I_1$ for a while and then start to approach $I_2$. If we choose $D$ appropriately, we can arrange for some high iterate $f^N(D)$ to be a slight thickening of $I_2$ as in Figure 6. This looks geometrically like the horseshoe map. Let $A_1$ be the connected component of the intersection $D \bigcap f^N(D)$ containing $p$, and let $A_2$ be the connected component of the intersection $D \bigcap f^N(D)$ containing $q$. These sets (which are shaded in **Figure 6**) play the role of the rectangles $R_1$ and $R_2$, respectively, in the horseshoe construction. We use the set $A_1 \bigcup A_2$ for $U$ in Theorem 1.

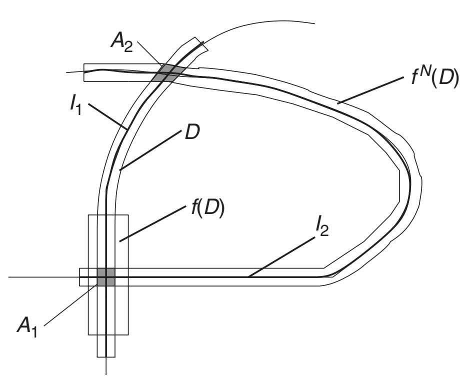

**Figure 6** The curvilinear rectangle $D$ and its $N$th iterate $f^N(D)$ are geometrically like the horseshoe map.

## The Hénon Family

To give explicit formulas for the horseshoe map above is somewhat tedious, and it is of interest to note that similar properties occur in maps with simple formulas. Indeed, such properties occur quite often in a well-known family of maps known as the "Hénon family." As we have mentioned, the map in Figure 1 provides an example.

One may simply define a Hénon map as a diffeomorphism $H = (H_1(x, y), H_2(x, y))$ with inverse $G(x, y) = (G_1(x, y), G_2(x, y))$ such that all the maps $F_i(x, y), G_i(x, y)$ are polynomials of degree at most two. It is known (see, e.g., Friedland and Milnor (1989)) that such maps $H$ have constant Jacobian determinant, and, up to affine conjugacy, may be represented in the form $H = H_{a,b}(x, y) = (a - x^2 - by, x)$ with $a$, $b$ constants and $b \neq 0$. This makes sense when all the terms are real or complex. In the real case, we speak of the real Hénon family and, in the complex case, we speak of the complex Hénon family.

The real Hénon family was first presented by the physicist M Hénon in 1976 as perhaps the simplest nonlinear diffeomorphism of the plane exhibiting a so-called "strange attractor." These mappings in the real and complex cases have been the focus of much attention. Our interest here is that, at least for certain parameters $a$, $b$, they provide concrete globally defined maps whose dynamics are analogous to that of the horseshoe diffeomorphism. In fact, Devaney and Nitecki (1979) proved (in the real case) that for fixed $b \neq 0$, there is a constant $a_0 > 0$ such that if $a > a_0$, then the set $B_{a,b}$ of bounded orbits of $H_{a,b}$ is a compact zero-dimensional set and the pair $(H_{a,b}, B_{a,b})$ is topologically conjugate to $(\sigma, \Sigma_2)$. In addition, it can be shown that the invariant set $B_{a,b}$ is a single hyperbolic $h$-closure. Analogous results are true for the complex Hénon family and proofs were originally given in the thesis of Ralph Oberste–Vorth (unpublished) under the supervision of John Hubbard at Cornell University. More recent proofs are in Newhouse (2004) and Hruska (2004). Many interesting results have been obtained for the complex Hénon map by Bedford and Smillie and Sibony and Fornaess (see the references in Hruska (2004).

## Homoclinic Points in Systems with Positive Topological Entropy

There is an invariant of topological conjugacy which is known as the topological entropy. In a certain sense, this gives a quantitative measurement of the amount of complicated or chaotic motion in the system.

Let $f: X \to X$ be a continuous self-map of the compact metric space $(X, d)$. For a positive integer $n > 0$, we define an $n$-orbit to be a finite sequence $O(x, n) = \{x, f(x), \ldots, f^{n-1}(x)\}$. Given a positive real number $\epsilon > 0$, we say that two $n$-orbits $O(x, n)$ and $O(y, n)$ are "$\epsilon$-distinguishable" if there is a $0 \leq j < n$ such that $d(f^j x, f^j y) > \epsilon$. Another way to look at this is the following. Define the so-called $d_n$-metric on $X$ by setting $d_n(x, y) = \max_{0 \leq j < n} d(f^j x, f^j y)$. Then, the two $n$-orbits $O(x, n), O(y, n)$ are $\epsilon$-distinguishable if and only if $d_n(x, y) > \epsilon$. It follows from compactness of $X$ and the uniform continuity of each of the maps $f^j, 0 \leq j < n$, that the number $r(n, \epsilon, f)$ of $\epsilon$-distinguishable $n$-orbits is finite for each given $\epsilon > 0$ and each positive integer $n$. We define the number

$$h(f) = \lim_{\epsilon \to 0} \limsup_{n \to \infty} \frac{1}{n} \log r(n, \epsilon, f)$$

This means that, for some sequence of integers $n_1 < n_2 < \ldots$, the map $f$ has roughly $e^{n_i h(f)}$ $\epsilon$-distinguishable $n_i$-orbits for $i$ large and $\epsilon$ small.

The number $h(f)$ is called the topological entropy of the map $f$. It may be infinite for homeomorphisms, but it is always finite for smooth maps on finite-dimensional manifolds. The number $h(f)$ has many nice properties. For instance, $h(f^N) = N h(f)$ for every positive integer $N$, and, if $f$ is a homeomorphism, then $h(f^{-1}) = h(f)$. Further, if $f$ and $g$ are topologically conjugate, then $h(f) = h(g)$. The so-called "variational principle for topological entropy" asserts that $h(f)$ is the supremum of the measure-theoretic entropies of the invariant probability measures for $f$. Our interest in this invariant here is the following theorem of Katok.

**Theorem 2**(Katok). *Let $f$ be a $C^2$ diffeomorphism of a compact two-dimensional manifold $M$ to itself with positive topological entropy. Then, $f$ has transverse homoclinic points.*

In fact, Katok extended this theorem (see the supplement in Hasselblatt and Katok (1995)) to show that, if $h(f) > 0$ and $\epsilon > 0$, then there is a compact zero-dimensional hyperbolic basic set $\Lambda$ for $h$ such that $h(f, \Lambda) > h(f) - \epsilon$. Thus, one can find nice invariant topologically transitive sets for $f$ (i.e., sets with dense orbits) on which the topological entropies of restriction of $f$ are arbitrarily close to that of $f$.

This theorem has the interesting consequence that the map $f \to h(f)$ is lower-semicontinuous on the space of $C^2$ diffeomorphisms of a surface. It was proved in Newhouse (1989) (and, independently by Yomdin (1987)) that the map $f \to h(f)$ is upper-semicontinuous on the space of $C^\infty$ diffeomorphisms of any compact manifold. Combining these results gives the theorem that the map $f \to h(f)$ is continuous on the space of $C^\infty$ diffeomorphisms on a compact surface, and that positivity of $h(f)$ implies the existence of transverse homoclinic points.

It is also worth noting that, for any continuous self-map $f: M \to M$ on a compact manifold $M$, one has the inequality $h(f) \geq \log |\mu|$ where $\mu$ is the eigenvalue of largest norm of the induced map $f_\star$ on the first real homology group (Manning 1975). Putting this together with Theorem 2 gives the fact that there are whole homotopy classes of diffeomorphisms on surfaces all of whose elements have transverse homoclinic points. For instance, consider a $2 \times 2$ matrix

$$L = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

with integer entries, determinant 1, and eigenvalues $\lambda_1, \lambda_2$ with $0 < |\lambda_1| < 1 < |\lambda_2|$. Let $\tilde{L}: \boldsymbol{T}^2 \to \boldsymbol{T}^2$ be the induced diffeomorphism on the two-dimensional torus $\boldsymbol{T}^2$. This is an example of what is called an "Anosov" diffeomorphism. In this case the number $\mu$ above is simply $\lambda_2$, and this holds for any diffeomorphism $f$ of $\boldsymbol{T}^2$ which can be continuously deformed into $\tilde{L}$. Hence, any such $f$ must have transverse homoclinic points.

## Homoclinic Tangencies

Let $\{f_\lambda, \lambda \in [0,1]\}$ be a parametrized family of $C^r$ diffeomorphisms of the plane with $\lambda$ an external parameter. It frequently occurs that there is a hyperbolic saddle fixed point $p_\lambda$ for each parameter $\lambda$ moving continuously with $\lambda$ such that, at some value $\lambda_0$, a homoclinic tangency is created at a point $q_0$. This means that there are an $\epsilon > 0$, a small neighborhood $U$ of $q_0$, and curves $\gamma_\lambda^u \subset W^u(p_\lambda)$, $\gamma_\lambda^s \subset W^s(p_\lambda)$ such that $\gamma_\lambda^s \bigcap \gamma_\lambda^u = \emptyset$ for $\lambda_0 - \epsilon < \lambda < \lambda_0, \gamma_{\lambda_0}^s \bigcap \gamma_{\lambda_0}^u = \{q_0\}$, and $\gamma_\lambda^s \bigcap \gamma_\lambda^u$ consists of two distinct points for $\lambda_0 < \lambda < \lambda + \epsilon$. In most cases, the tangency of $\gamma_{\lambda_0}^u$ and $\gamma_{\lambda_0}^s$ at $q_0$ will be of the second order, and we will assume that occurs here. The geometry is as in **Figure 7**.

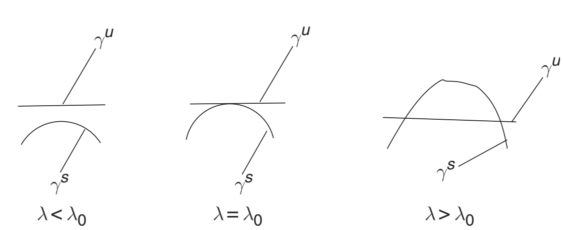

**Figure 7** Creation of a homoclinic tangency.

The creation of homoclinic tangencies is part of the general subject of "homoclinic bifurcations." A recent survey of this subject is in the book by Bonatti *et al.* (2005). Typical results are the following. If $p = p_{\lambda_0}$ is a saddle fixed point whose derivative is area-decreasing (i.e., $|\text{Det}(Df(p))| < 1$), then there are infinitely many parameters $\lambda$ near $\lambda_0$ for which each transverse homoclinic point of $p_\lambda$ is a limit of periodic sinks (asymptotically stable periodic orbits) (Newhouse 1979, Robinson 1983). In addition, so-called strange attractors and SRB measures appear (Mora and Viana 1993).

Finally, we mention that recently it has been shown that, generically in the $C^r$ topology for $r \geq 2$, homoclinic closures associated to a homoclinic tangency (in dimension 2) have maximal Hausdorff dimension (Theorem 1.6 in Downarowicz and Newhouse (2005)).

# Hopf Algebra Structure of Renormalizable Quantum Field Theory

**D Kreimer**, IHES, Bures-sur-Yvette, France

## Overview

Renormalization theory is a venerable subject put to daily use in many branches of physics. Here, we focus on its applications in quantum field theory, where a standard perturbative approach is provided through an expansion in Feynman diagrams. Whilst the combinatorics of the Bogoliubov recursion, solved by suitable forest formulas, has been known for a long time, the subject regained interest on the conceptual side with the discovery of an underlying Hopf algebra structure behind these recursions.

Perturbative expansions in quantum field theory are organized in terms of one-particle irreducible (1PI) Feynman graphs. The goal is to calculate the corresponding 1PI Green functions order by order in the coupling constants of the theory, by applying Feynman rules to these 1PI graphs of a

renormalizable theory under consideration. This allows one to disentangle the problem into an algebraic part and an analytic part.

For the algebraic part, one studies Feynman graphs as combinatorial objects which lead to the Lie and Hopf algebras discussed below. Feynman rules then assign analytic expressions to these graphs, with the analytic structure of finite renormalized quantum field theory largely dictated by the underlying algebra.

The objects of interest in quantum field theory are the 1PI Green functions. They are parametrized by the quantum numbers – masses, momenta, spin, and such – of the particles participating in the scattering process under consideration. We call a set of such quantum numbers an external leg structure $\underline{r}$. For example, the three terms in the Lagrangian of massless quantum electrodynamics correspond to

$\underline{r} \in$  [1]

Note that the Lagrangian $L$ of massless quantum electrodynamics is obtained accordingly as

$L =$ 
$$= \bar{\psi}\partial\psi + \bar{\psi}A\psi + \tfrac{1}{4}F^2 \qquad [2]$$

where $\hat{\phi}$ are coordinate space Feynman rules.

The renormalized 1PI Green function in momentum space, $G_{\mathrm{R}}^{\underline{r}}(\{g\};\{p\},\{m\};\mu)$, is obtained as the image under renormalized Feynman rules $\phi_{\mathrm{R}}$ applied to a series of graphs:

$$\Gamma^{\underline{r}} = 1 + \sum_{k=1}^{\infty} g^k c_k^{\underline{r}} \equiv 1 + \sum_{\mathrm{res}(\Gamma)=\underline{r}} g^{|\Gamma|}\frac{\Gamma}{\mathrm{Sym}(\Gamma)} \qquad [3]$$

Here $\underline{r}$ is a given such external leg structure, while $c_k^{\underline{r}}$ is the finite sum of 1PI graphs having $k$ loops,

$$c_k^{\underline{r}} = \sum_{\substack{\mathrm{res}(\Gamma)=\underline{r}\\ |\Gamma|=k}} \frac{\Gamma}{\mathrm{Sym}(\Gamma)} \qquad [4]$$

and $0 < g < 1$ is a coupling constant. The generalization to the case of several couplings $\{g\}$ and masses $\{m\}$ is straightforward. In the above, the sum is over all 1PI graphs with the same given external leg structure. We have denoted the map which assigns $\underline{r}$ to a given graph a residue, for example,

 [5]

The unrenormalized but regularized Feynman rules $\phi$ assign to a graph a function

$$\phi(\Gamma)(\{g\};\{p\},\{m\};\mu,z) = \int \prod_{v\in\Gamma^{[0]}} \delta^{(4)}\left(\sum_{f \text{ incident } v} k_f\right) \prod_{e\in\Gamma^{[1]}_{\mathrm{int}}} \mathrm{Prop}(k_e)\frac{\mathrm{d}^4 k_e}{4\pi^2} \qquad [6]$$

and formally the unrenormalized Green function

$$G_{\mathrm{u}}^{\underline{r}}(\{g\};\{p\},\{m\};\mu,z) = \phi(\Gamma^{\underline{r}})(\{g\};\{p\},\{m\};\mu,z) \qquad [7]$$

which is a function of a suitably chosen regulator $z$. Note that in [6] the four-dimensional Dirac-$\delta$ distribution guarantees momentum conservation at each vertex and restricts the number of four-dimensional integrations to the number of independent cycles in the graph. It is assumed that the reader is familiar with the readily established fact that these integrals suffer from UV singularities, which render the integration over the momenta in internal cycles ill-defined. We also remind the reader that the problem persists in coordinate space, where one confronts the continuation of products of distributions to regions of coinciding support. We restrict ourselves here to a discussion of the situation in momentum space and refer the reader to the literature for the situation in coordinate space.

Ignoring problems of convergence in the sum over all graphs, the problem of renormalization is to make sense of these functions term by term: We have to determine invertible series $Z^{\underline{r}}(\{g\},z)$ in the couplings $g$ such that the modified Lagrangian

$$\tilde{L} = \sum_{\underline{r}} Z^{\underline{r}}(\{g\},z)\,\hat{\phi}(\underline{r}) \qquad [8]$$

produces a perturbation series in graphs that allows for the removal of the regulator $z$.

This amounts to a transition from unrenormalized to renormalized Feynman rules $\phi \to \phi_{\mathrm{R}}$. Let us first describe how this transition is achieved using the Lie and Hopf algebra structure of the perturbative expansion, which is described in detail below:

- Decide on the free fields and local interactions of the theory, appropriately specifying quantum numbers (spin, mass, flavor, color, and such) of fields, restricting interactions so as to obtain a renormalizable theory.
- Consider the set of all 1PI graphs with edges corresponding to free-field propagators. Define vertices for local interactions. This allows one to construct a pre-Lie algebra of graph insertions. Antisymmetrize this pre-Lie product to get a Lie algebra $\mathcal{L}$ of graph insertions and define the Hopf algebra $\mathcal{H}$ which is dual to the enveloping algebra $\mathcal{U}(\mathcal{L})$ of this Lie algebra.
- Realize that the coproduct and antipode of this Hopf algebra give rise to the forest formula, which generates local counter-terms upon introducing a Rota–Baxter map, a renormalization scheme in physicists' parlance.

- Use the Hochschild cohomology of this Hopf algebra to show that one can absorb singularities in local counter-terms.
- Determine the corepresentations of this Hopf algebra to identify the sub-Hopf algebras corresponding to time-ordered products in physical fields. This is most easily achieved by rewriting the Dyson–Schwinger equations using Hochschild 1-cocycles.

The last point exhibits close connections, in particular, between the structure of gauge theories and the corepresentation theory of their perturbative Hopf algebras which we discuss below in brief.

This program can be carried out in coordinate space as well as momentum space renormalization. It has given a firm mathematical background to the process of renormalization, justifying the practice of quantum field theory. The notion of locality has achieved a precise formulation in terms of the Hochschild cohomology of the perturbation expansion. In momentum space, this approach emphasizes the connections to number theory, which emerge when one investigates the role of the Hopf algebra primitives, which in turn furnish the Hochschild 1-cocycles underlying locality.

The next sections describe the above setup in some detail.

## Lie and Hopf Algebras of Graphs

All algebras are supposed to be over some field $\mathbb{K}$ of characteristic zero, associative and unital, and similarly for coalgebras. The unit (and, by abuse of notation, also the unit map) will be denoted by $\mathbb{I}$, the counit map by $\bar{e}$. All algebra homomorphisms are supposed to be unital. A bialgebra $(A = \bigoplus_{i=0}^{\infty} A_i, m, \mathbb{I}, \Delta, \bar{e})$ is called graded connected if $A_i A_j \subset A_{i+j}$ and $\Delta(A_i) \subset \bigoplus_{j+k=i} A_j \otimes A_k$, and if $\Delta(\mathbb{I}) = \mathbb{I} \otimes \mathbb{I}$ and $A_0 = k\mathbb{I}, \bar{e}(\mathbb{I}) = 1 \in \mathbb{K}$ and $\bar{e} = 0$ on $\bigoplus_{i=1}^{\infty} A_i$. We call $\ker \bar{e}$ the augmentation ideal of $A$ and denote by $P$ the projection $A \to \ker \bar{e}$ onto the augmentation ideal, $P = \mathrm{id} - \mathbb{I}\bar{e}$. Furthermore, we use Sweedler's notation, $\Delta(h) = \sum h' \otimes h''$, for the coproduct. We define

$$\mathrm{Aug}^{(k)} = \Bigg( \underbrace{P \otimes \cdots \otimes P}_{k \text{ times}} \Bigg) \Delta^{k-1}, \qquad A \to \{\ker \bar{e}\}^{\otimes k} \tag{9}$$

as a map into the $k$-fold tensor product of the augmentation ideal. We let $A^{(k)} = \ker \mathrm{Aug}^{(k+1)} / \ker \mathrm{Aug}^{(k)}, \forall\, k \geq 1$. All bialgebras considered here are bigraded in the sense that

$$A = \bigoplus_{i=0}^{\infty} A_{(i)} = \bigoplus_{k=0}^{\infty} A^{(k)} \tag{10}$$

where $A_{(k)} \subset \oplus_{j=1}^{k} A^{(j)}$ for all $k \geq 1$. $A_{(0)} \simeq A^{(0)} \simeq \mathbb{K}$.

The first construction we have to study is the pre-Lie algebra structure of 1PI graphs.

### The Pre-Lie Structure

For each Feynman graph we have vertices as well as internal and external edges. External edges are edges that have an open end not connected to a vertex. They indicate the particles participating in the scattering amplitude under consideration and each such edge carries the quantum numbers of the corresponding free field. The internal edges and vertices form a graph in their own right. For an internal edge, both ends of the edge are connected to a vertex.

We consider 1PI Feynman graphs. A graph $\Gamma$ is 1PI if and only if all graphs, obtained by removal of any one of its internal edges, are still connected. Such 1PI graphs are naturally graded by their number of independent loops, the rank of their first homology group $H_{[1]}(\Gamma, \mathbb{Z})$. We write $|\Gamma|$ for this degree of a graph $\Gamma$. Note that $|\mathrm{res}(\Gamma)| = 0$, where we let $\mathrm{res}(\Gamma)$ be the graph obtained when all edges in $\Gamma^{[1]}_{\mathrm{int}}$ shrink to a point, as before. Note that the graph obtained in this manner consists of a single vertex, to which the edges $\Gamma^{[1]}_{\mathrm{ext}}$ are attached.

For a 1PI graph $\Gamma, \Gamma^{[0]}$ denotes its set of vertices and $\Gamma^{[1]} = \Gamma^{[1]}_{\mathrm{int}} \cup \Gamma^{[1]}_{\mathrm{ext}}$ its set of internal and external edges. In addition, let $\omega_{\underline{r}}$ be the number of spacetime derivatives appearing in the corresponding monomial in the Lagrangian.

Having specified free quantum fields and local interaction terms between them, one immediately obtains the set of 1PI graphs. One can then consider for a given external leg structure $\underline{r}$ the set of graphs with that external leg structure. For a renormalizable theory, we can define a superficial degree of divergence,

$$\omega = \sum_{\underline{r} \in \Gamma^{[1]}_{\mathrm{int}} \cup \Gamma^{[0]}} \omega_{\underline{r}} - 4|H_{[1]}(\Gamma, \mathbb{Z})| \tag{11}$$

for each such external leg structure: $\omega(\Gamma) = \omega(\Gamma')$ if $\mathrm{res}(\Gamma) = \mathrm{res}(\Gamma')$; all graphs with the same external leg structure have the same superficial degree of divergence, and only for a finite number of distinct external leg structures $\underline{r}$ will this degree indeed signify a divergence.

This leaves a finite number of external leg structures to be considered to which we restrict ourselves from now. Our first observation is that there is a natural pre-Lie algebra structure on 1PI graphs.

To this end, we define a bilinear operation

$$\Gamma_1 * \Gamma_2 = \sum_{\Gamma} n(\Gamma_1, \Gamma_2; \Gamma)\Gamma \qquad [12]$$

where the sum is over all 1PI graphs $\Gamma$. Here, $n(\Gamma_1, \Gamma_2; \Gamma)$ is a section coefficient which counts the number of ways in which a subgraph $\Gamma_2$ can be reduced to a point in $\Gamma$ such that $\Gamma_1$ is obtained. The above sum is evidently finite as long as $\Gamma_1$ and $\Gamma_2$ are finite graphs, and the graphs which contribute necessarily fulfill $|\Gamma| = |\Gamma_1| + |\Gamma_2|$ and $\mathrm{res}(\Gamma) = \mathrm{res}(\Gamma_1)$.

One then has the following theorem.

**Theorem 1** *The operation* $*$ *is pre-Lie*:

$$[\Gamma_1 * \Gamma_2] * \Gamma_3 - \Gamma_1 * [\Gamma_2 * \Gamma_3] = [\Gamma_1 * \Gamma_3] * \Gamma_2 - \Gamma_1 * [\Gamma_3 * \Gamma_2] \qquad [13]$$

which is evident when one rewrites the $*$-product in suitable gluing operations.

To understand this theorem, note that the equation claims that the lack of associativity in the bilinear operation $*$ is invariant under permutation of the elements indexed 2, 3. This suffices to show that the antisymmetrization of this map fulfills a Jacobi identity. Hence, we get a Lie algebra $\mathcal{L}$ by antisymmetrizing this operation:

$$[\Gamma_1, \Gamma_2] = \Gamma_1 * \Gamma_2 - \Gamma_2 * \Gamma_1 \qquad [14]$$

This Lie algebra is graded and of finite dimension in each degree. Let us look at a couple of examples for pre-Lie products:

 [15]

 [16]

 [17]

 [18]

 [19]

 [20]

Together with $\mathcal{L}$ one is led to consider the dual of its universal enveloping algebra $\mathcal{U}(\mathcal{L})$ using the theorem of Milnor and Moore. For this we use the above grading by the loop number.

This universal enveloping algebra $\mathcal{U}(\mathcal{L})$ is built from the tensor algebra

$$T = \bigoplus_k T^k, \quad T^k = \underbrace{\mathcal{L} \otimes \cdots \otimes \mathcal{L}}_{k \text{ times}} \qquad [21]$$

by dividing out the ideal generated by the relations

$$a \otimes b - b \otimes a = [a, b] \in \mathcal{L} \qquad [22]$$

Note that in $\mathcal{U}(\mathcal{L})$ we have a natural concatenation product $m_*$. Furthermore, $\mathcal{U}(\mathcal{L})$ carries a natural Hopf algebra structure with this product. For that, the Lie algebra $\mathcal{L}$ furnishes the primitive elements:

$$\Delta_*(a) = a \otimes 1 + 1 \otimes a, \quad \forall\, a \in \mathcal{L} \qquad [23]$$

It is, by construction, a connected finitely graded Hopf algebra which is co-commutative but not commutative. We can then consider its graded dual, which will be a Hopf algebra $\mathcal{H}(m, \mathbb{I}, \Delta, \bar{e})$ that is commutative but not cocommutative. One finds it upon using a Kronecker pairing

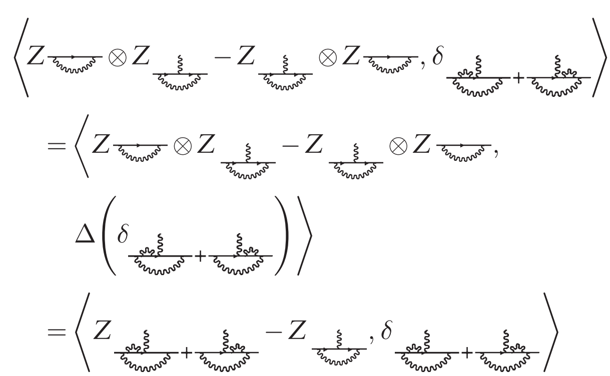
$$< Z_\Gamma, \delta_{\Gamma'} > = \begin{cases} 1, & \Gamma = \Gamma' \\ 0, & \text{else} \end{cases} \qquad [24]$$

The space of primitives of $\mathcal{U}(\mathcal{L})$ is in one-to-one correspondence with the set $\mathrm{Indec}(\mathcal{H})$ of indecomposables of $\mathcal{H}$, which is the linear span of its generators. One finds the following theorem.

**Theorem 2**

$$< Z_{\Gamma_1} \otimes Z_{\Gamma_2} - Z_{\Gamma_2} \otimes Z_{\Gamma_1},\ \delta_\Gamma > = < Z_{[\Gamma_2, \Gamma_1]}, \delta_\Gamma > \qquad [25]$$

For example, one finds



$= 2$ [26]

$\mathcal{H}$ is a graded commutative Hopf algebra which suffices to describe renormalization theory, as we see in the next section. We have formulated it for the superficially divergent 1PI graphs of the theory with the understanding that the residues of these graphs are in one-to-one correspondence with the terms in the Lagrangian of a given theory. Often, several terms in a Lagrangian correspond to graphs with the same number and type of external legs, but correspond to different form-factor projections of the graph. In such cases, the above approach can be easily adopted considering suitably colored or

labeled graphs. A similar remark applies if one desires to incorporate renormalization of superficially convergent Green functions, which requires nothing more than the consideration of an easily obtained semidirect product of the Lie algebra of superficially divergent graphs with the abelian Lie algebra of superficially convergent graphs.

#### The Principle of Multiplicative Subtraction

The above algebra structures are available once one has decided on the set of 1PI graphs of interest. We now use them toward the renormalization of any such chosen local quantum field theory.

From the above, 1PI graphs $\Gamma$ provide the linear generators $\delta_\Gamma$ of the Hopf algebra $\mathcal{H} = \oplus_{i=0}^{\infty} H_i$, where $\mathcal{H}_{\text{lin}} = \text{span}(\delta_\Gamma)$ and their disjoint union provides the commutative product.

Now let $\Gamma$ be a 1PI graph. We find the Hopf algebra $\mathcal{H}$ as described above to have a coproduct explicitly given as $\Delta : \mathcal{H} \to \mathcal{H} \otimes \mathcal{H}$:

$$\Delta(\Gamma) = \Gamma \otimes 1 + 1 \otimes \Gamma + \sum_{\gamma \subset \Gamma} \gamma \otimes \Gamma/\gamma \qquad [27]$$

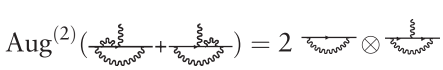
where the sum is over all unions of 1PI superficially divergent proper subgraphs, and we extend this definition to products of graphs so that we get a bialgebra.

While the Lie bracket inserted graphs into each other, the coproduct disentangles them. It is this latter operation which is needed in renormalization theory: we have to render each subgraph finite before we can construct a local counter-term. That is precisely what the Hopf algebra structure maps do.

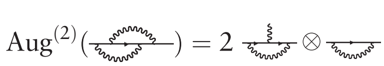
Having a coproduct, two further structure maps of $\mathcal{H}$ are immediate: the counit and the antipode. The counit $\bar{e}$ vanishes on any nontrivial Hopf algebra element, $\bar{e}(1) = 1, \bar{e}(X) = 0$. The antipode is

$$S(\Gamma) = -\Gamma - \sum_{\gamma \subset \Gamma} S(\gamma)\Gamma/\gamma \qquad [28]$$

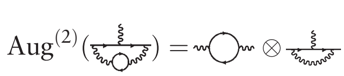
We can work out a few coproducts and antipodes as follows:



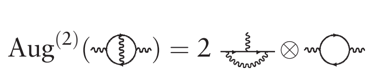
[29]



[30]



[31]



[32]

[33]

[34]

We give just one example for an antipode:

[35]

Note that for each term in the sum $\tilde{\Delta}(\Gamma) = \sum_i \Gamma'_{(i)} \otimes \Gamma''_{(i)}$, we have unique gluing data $G_i$ such that

$$\Gamma = \Gamma''_{(i)} \leftarrow_{G_i} \Gamma'_{(i)}, \quad \forall\, i \qquad [36]$$

These gluing data describe the necessary bijections to glue the components $\Gamma'_{(i)}$ back into $\Gamma''_{(i)}$ so as to obtain $\Gamma$: using them, we can reassemble the whole from its parts. Each possible gluing can be interpreted as a composition in the insertion operad of Feynman graphs.

We have by now obtained a Hopf algebra generated by combinatorial elements, 1PI Feynman graphs. Its existence is automatic from the above choices of interactions and free fields. What remains to be done is a structural analysis of these algebras for the renormalizable theories we are confronted with in four spacetime dimensions.

The assertion underlying perturbation theory is the fact that meaningful approximations to physical observable quantities can be found by evaluating these graphs using Feynman rules.

First, as disjoint scattering processes give rise to independent amplitudes, one is led to the study of characters of the Hopf algebra, maps $\phi : \mathcal{H} \to V$ such that $\phi \circ m = m_V(\phi \otimes \phi)$.

Such maps assign to any element in the Hopf algebra an element in a suitable target space $V$. The study of tree-level amplitudes in lowest-order perturbation theory justifies assigning to each edge a propagator and to each elementary scattering process a vertex, which define the Feynman rules $\phi(\text{res}(\Gamma))$ and the underlying Lagrangian, on the level of residues of these very graphs. Graphs are constructed from edges and vertices which are provided precisely by the residues of those divergent graphs, hence one is led to assign to each Feynman graph an evaluation in terms of an integral over the continuous quantum numbers assigned to edges or vertices, which leads to the familiar integrals over momenta in closed loops mentioned before.

Then, with the Feynman rules providing a canonical character $\phi$, we will have to make one further choice: a renormalization scheme. The need for such a choice is no surprise: after all we are eliminating short-distance singularities in the graphs,

which renders their remaining finite part ambiguous, albeit in a most interesting manner.

Hence, we choose a map $R : V \to V$, from which we obviously demand that it does not modify the UV-singular structure, and furthermore that it obeys

$$R(xy) + R(x)R(y) = R(R(x)y) + R(xR(y)) \quad [37]$$

which guarantees the multiplicativity of renormalization and is at the heart of the Birkhoff decomposition, which emerges below: it tells us that elements in $V$ split into two parallel subalgebras given by the image and kernel of $R$. Algebras for which such a map exists are known as Rota–Baxter algebras. The role Rota–Baxter algebras play for associative algebras is similar to the role Yang–Baxter algebras play for Lie algebras. The structure of these algebras allows one to connect renormalization theory to integrable systems. In addition, most of the results obtained initially for a specific renormalization scheme, such as minimal subtraction, can also be obtained, in general, upon a structural analysis of the corresponding Rota–Baxter algebras.

To see how all the above comes together in renormalization theory, we define a further character $S_R^\phi$ that deforms $\phi \circ S$ slightly and delivers the counter-term for $\Gamma$ in the renormalization scheme $R$:

$$\begin{aligned} S_R^\phi(\Gamma) &= -Rm_V(S_R^\phi \otimes \phi \circ P)\Delta \\ &= -R[\phi(\Gamma)] - R\left[\sum_{\gamma\subset\Gamma} S_R^\phi(\gamma)\phi(\Gamma/\gamma)\right] \end{aligned} \quad [38]$$

which should be compared with the undeformed

$$\begin{aligned} \phi \circ S &= m_V(S \circ \phi \otimes \phi \circ P)\Delta \\ &= -\phi(\Gamma) - \sum_{\gamma\subset\Gamma} \phi \circ S(\gamma)\phi(\Gamma/\gamma) \end{aligned} \quad [39]$$

The fact that $R$ is a Rota–Baxter map ensures that $S_R^\phi$ is an element of the character group $\mathcal{G}$ of the Hopf algebra, $S_R^\phi \in \mathrm{Spec}(\mathcal{G})$. Note that we have now determined the modified Lagrangian:

$$Z^{\underline{r}} = S_R^\phi(\Gamma^{\underline{r}}) \quad [40]$$

The classical results of renormalization theory follow immediately using this group structure: we obtain the renormalization of $\Gamma$ by the application of a renormalized character

$$S_R^\phi \star \phi(\Gamma) = m_V(S_R^\phi \otimes \phi)\Delta \quad [41]$$

and Bogoliubov's $\bar{R}$ operation as

$$\begin{aligned} \bar{R}(\Gamma) &= m_V(S_R^\phi \otimes \phi)(\mathrm{id} \otimes P)\Delta(\Gamma) \\ &= \phi(\Gamma) + \sum_{\gamma\subset\Gamma} S_R^\phi(\gamma)\phi(\Gamma/\gamma) \end{aligned} \quad [42]$$

so that

$$S_R^\phi \star \phi(\Gamma) = \bar{R}(\Gamma) + S_R^\phi(\Gamma) \quad [43]$$

Here, $S_R^\phi \star \phi$ is an element in the group of characters of the Hopf algebra, with the group law given by the convolution

$$\phi_1 \star \phi_2 = m_V \circ (\phi_1 \otimes \phi_2) \circ \Delta \quad [44]$$

so that the coproduct, counit, and coinverse (the antipode) give the product, unit, and inverse of this group, as befits a Hopf algebra. This Lie group has the previous Lie algebra $\mathcal{L}$ of graph insertions as its Lie algebra: $\mathcal{L}$ exponentiates to $\mathcal{G}$.

What we have achieved above is a local renormalization of quantum field theory. Let $M^{\underline{r}}$ be a monomial in the Lagrangian $L$ of degree $\omega_{\underline{r}}$:

$$M^{\underline{r}} = D_{\underline{r}}\{\phi\} \quad [45]$$

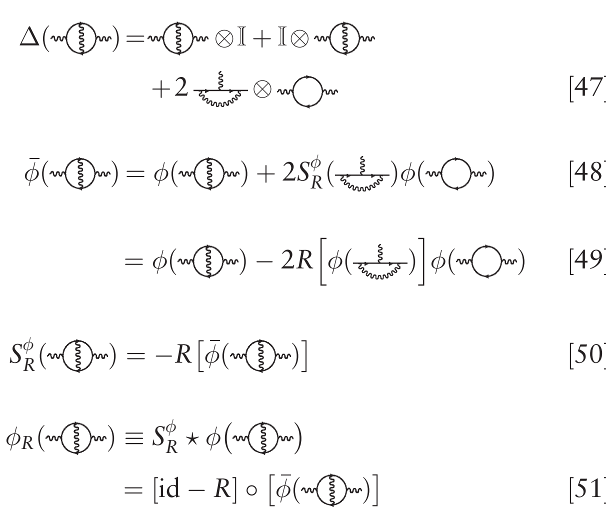
Then one can prove, using the Hochschild cohomology of $\mathcal{H}$:

**Theorem 3** (*Locality*)

$$Z^{\underline{r}} D_{\underline{r}}\{\phi\} = D_{\underline{r}} Z^{\underline{r}}\{\phi\} \quad [46]$$

*that is, renormalization commutes with infinitesimal spacetime variations of the fields.*

We can now work out the renormalization of a Feynman graph $\Gamma$:



The formulas [47]–[51] are given in their recursive form. Zimmermann's original forest formula solving this recursion is obtained when we trace our considerations back to the fact that the coproduct can be written in nonrecursive form as a sum over forests, and similarly for the antipode.

## Diffeomorphisms of Physical Parameters

In the above, we have effectively obtained a Birkhoff decomposition of the Feynman rules $\phi \in \mathrm{Spec}(\mathcal{G})$ into two characters – $\phi_+^R = S_R^\phi \star \phi \in \mathrm{Spec}(\mathcal{G})$ and $\phi_-^R = S_R^\phi \in \mathrm{Spec}(\mathcal{G})$ – for any Rota–Baxter map $R$. Thanks to Atkinson's theorem, this is possible for any renormalization scheme $R$. For the minimal subtraction scheme, it amounts to the decomposition of the Laurent series $\phi(\Gamma)(\epsilon)$, which has poles of finite order in the regulator $\epsilon$, into a part holomorphic at the origin and a part holomorphic at complex infinity. This has a particularly nice geometric interpretation upon considering the Birkhoff decomposition of a loop around the origin, providing the clutching data for the two half-spheres defined by that very loop.

Whilst in this manner a satisfying understanding of perturbative renormalization is obtained, the character group $\mathcal{G}$ remains rather poorly understood. On the other hand, renormalization can be captured by the study of diffeomorphisms of physical parameters as, by definition, the range of allowed modification in renormalization theory is determined by the variation of the coefficients of monomials $\hat{\phi}(\underline{r})$ of the underlying Lagrangian

$$L = \sum_{\underline{r}} Z^{\underline{r}} \hat{\phi}(\underline{r}) \qquad [52]$$

Thus, one desires to obtain the whole Birkhoff decomposition at the level of diffeomorphisms of the coupling constants.

The crucial step toward that goal is to realize the role of a standard quantum field-theoretic formula of the form

$$g_{\mathrm{new}} = g_{\mathrm{old}} Z^g \qquad [53]$$

where

$$Z^g = \frac{Z^v}{\prod_{e \in \mathrm{res}(v)^{[1]}_{\mathrm{ext}}} \sqrt{Z^e}} \qquad [54]$$

for some vertex $v$, which obtains the new coupling in terms of a diffeomorphism of the old. This formula provides, indeed, a Hopf algebra homomorphism from the Hopf algebra of diffeomorphisms to the Hopf algebra of Feynman graphs, regarding $Z^g$ (a series over counter-terms for all 1PI graphs with the external leg structure corresponding to the coupling $g$), in two different ways: it is, at the same time, a formal diffeomorphism in the coupling constant $g_{\mathrm{old}}$ and a formal series in Feynman graphs. As a consequence, there are two competing coproducts acting on $Z_g$. That both give the same result defines the required homomorphism, which transposes to a homomorphism from the largely unknown group of characters of $\mathcal{H}$ to the one-dimensional diffeomorphisms of this coupling.

In summary, one finds that a couple of basic facts enable one to make a transition from the abstract group of characters of a Hopf algebra of Feynman graphs (which, incidentally, equals the Lie group assigned to the Lie algebra with universal enveloping algebra the dual of this Hopf algebra) to the rather concrete group of diffeomorphisms of physical observables. These steps are given as follows:

- Recognize that $Z$ factors are given as counterterms over a formal series of graphs starting with 1, graded by powers of the coupling, hence invertible.
- Recognize the series $Z_g$ as a formal diffeomorphism, with Hopf algebra coefficients.
- Establish that the two competing Hopf algebra structures of diffeomorphisms and graphs are consistent in the sense of a Hopf algebra homomorphism.
- Show that this homomorphism transposes to a Lie algebra and hence Lie group homomorphism.

The effective coupling $g_{\mathrm{eff}}(\varepsilon)$ now allows for a Birkhoff decomposition in the space of formal diffeomorphisms.

**Theorem 4** *Let the unrenormalized effective coupling constant $g_{\mathrm{eff}}(\varepsilon)$ viewed as a formal power series in $g$ be considered as a loop of formal diffeomorphisms and let $g_{\mathrm{eff}}(\varepsilon) = (g_{\mathrm{eff}_-})^{-1}(\varepsilon)\, g_{\mathrm{eff}_+}(\varepsilon)$ be its Birkhoff decomposition in the group of formal diffeomorphisms. Then the loop $g_{\mathrm{eff}_-}(\varepsilon)$ is the bare coupling constant and $g_{\mathrm{eff}_+}(0)$ is the renormalized effective coupling.*

The above results hold as they stand for any massless theory which provides a single coupling constant. If there are multiple interaction terms in the Lagrangian, one finds similar results relating the group of characters of the corresponding Hopf algebra to the group of formal diffeomorphisms in the multidimensional space of coupling constants.

## The Role of Hochschild Cohomology

The Hochschild cohomology of the combinatorial Hopf algebras which we discuss here plays three major roles in quantum field theory:

1. it allows one to prove locality from the accompanying filtration by the augmentation degree coming from the kernels $\ker \mathrm{Aug}^{(k)}$;

2. it allows one to write the quantum equations of motion in terms of the Hopf algebra primitives, elements in $\mathcal{H}_{\text{lin}} \cap \{\ker \text{Aug}^{(2)}/\ker \text{Aug}^{(1)}\}$; and
3. it identifies the relevant sub-Hopf algebras formed by time-ordered products.

Before we discuss these properties, let us first introduce the relevant Hochschild cohomology.

### Hochschild Cohomology of Bialgebras

Let $(A, m, \mathbb{I}, \Delta, \epsilon)$ be a bialgebra, as before. We regard linear maps $L : A \to A^{\otimes n}$ as $n$-cochains and define a coboundary map $b, b^2 = 0$ by

$$bL := (\text{id} \otimes L) \circ \Delta + \sum_{i=1}^{n} (-1)^i \Delta_i \circ L + (-1)^{n+1} L \otimes \mathbb{I} \qquad [55]$$

where $\Delta_i$ denotes the coproduct applied to the $i$th factor in $A^{\otimes n}$, which defines the Hochschild cohomology of $A$.

For the case $n = 1$, for $L : A \to A$, [55] reduces to

$$bL = (\text{id} \otimes L) \circ \Delta - \Delta \circ L + L \otimes \mathbb{I} \qquad [56]$$

The category of objects $(A, C)$, which consists of a commutative bialgebra $A$ and a Hochschild 1-cocycle $C$ on $A$, has an initial object $(\mathcal{H}_{\text{rt}}, B_+)$, where $\mathcal{H}_{\text{rt}}$ is the Hopf algebra of (nonplanar) rooted trees, and the closed but nonexact 1-cocycle $B_+$ grafts a product of rooted trees together at a new root as described below.

The higher ($n > 1$) Hochschild cohomology of $\mathcal{H}_{\text{rt}}$ vanishes, but in what follows, the closedness of $B_+$ will turn out to be crucial.

### The Hopf Algebra of Rooted Trees

A rooted tree is a simply connected contractible compact graph with a distinguished vertex, the root. A forest is a disjoint union of rooted trees. Isomorphisms of rooted trees or forests are isomorphisms of graphs preserving the distinguished vertex/vertices. Let $t$ be a rooted tree with root $o$. The choice of $o$ determines an orientation of the edges of $t$, away from the root, say. Forests are graded by the number of vertices they contain.

Let $\mathcal{H}_{\text{rt}}$ be the free commutative algebra generated by rooted trees. The commutative product in $\mathcal{H}_{\text{rt}}$ corresponds to the disjoint union of trees, such that monomials in $\mathcal{H}_{\text{rt}}$ are scalar multiples of forests. We demand that the linear operator $B_+$ on $\mathcal{H}_{\text{rt}}$, defined by

$$B_+(\mathbb{I}) = \bullet \qquad [57]$$

$B_+(t_1 \dots t_n) =$  [58]

is a Hochschild 1-cocycle, which makes $\mathcal{H}_{\text{rt}}$ a Hopf algebra. The resulting coproduct can be described as follows:

$$\Delta(t) = \mathbb{I} \otimes t + t \otimes \mathbb{I} + \sum_{adm\ c} P_c(t) \otimes R_c(t) \qquad [59]$$

where the sum goes over all admissible cuts of the tree $t$. Such a cut of $t$ is a nonempty set of edges of $t$ that are to be removed. The forest which is disconnected from the root upon removal of those edges is denoted by $P_c(t)$ and the part which remains connected to the root is denoted by $R_c(t)$. A cut $c(t)$ is admissible if, for each vertex $l$ of $t$, it contains at most one edge on the path from $l$ to the root.

This Hopf algebra of nonplanar rooted trees is the universal object after which all such commutative Hopf algebras $\mathcal{H}$ providing pairs $(\mathcal{H}, B)$, for $B$ a Hochschild 1-cocycle, are formed.

**Theorem 5** *The pair $(\mathcal{H}_{\text{rt}}, B_+)$, unique up to isomorphism, is universal among all such pairs. In other words, for any pair $(\mathcal{H}, B)$ where $\mathcal{H}$ is a commutative Hopf algebra and B a closed nonexact 1-cocycle, there exists a unique Hopf algebra morphism $\mathcal{H}_{\text{rt}} \xrightarrow{\rho} \mathcal{H}$ such that $B \circ \rho = \rho \circ B_+$.*

This theorem suggests that we investigate the Hochschild cohomology of the Hopf algebras of 1PI Feynman graphs. It clarifies the structure of 1PI Green functions.

### The Roles of Hochschild Cohomology

The Hochschild cohomology of the Hopf algebras of 1PI graphs sheds light on the structure of 1PI Green function in at least four different ways:

- it gives a coherent proof of locality of counterterms – the very fact that

$$[Z^{\underline{r}}, D_{\underline{r}}] = 0 \qquad [60]$$

  means that the coefficients in the Lagrangian remain independent of momenta, and hence the Lagrangian remains a polynomial expression in fields and their derivatives;
- the quantum equation of motions takes a very succinct form, identifying the Dyson kernels with the primitives of the Hopf algebra;
- sub-Hopf algebras emerge from the study of the Hochschild cohomology, which connects the representation theory of these Hopf algebras to the structure of theories with internal symmetries; and
- these Hopf algebras are intimately connected to the structure of transcendental functions, such as

the generalized polylogarithms, which play a prominent role these days ranging from applied particle physics to recent developments in mathematics.

To determine the Hochschild 1-cocycles of some Feynman graph Hopf algebra $\mathcal{H}$, one determines first the primitives graphs $\gamma$ of the Hopf algebra, which, by definition, fulfill the condition

$$\Delta(\gamma) = \gamma \otimes \mathbb{I} + \mathbb{I} \otimes \gamma \qquad [61]$$

Using the pre-Lie product above, one then determines the maps

$$B_+^\gamma : \mathcal{H} \to \mathcal{H}_{\text{lin}} \qquad [62]$$

such that

$$B_+^\gamma(h) = B_+^\gamma(h) \otimes \mathbb{I} + (\text{id} \otimes B_+^\gamma)\Delta(h) \qquad [63]$$

where $B_+^\gamma(h) = \sum_\Gamma n(\gamma, h, \Gamma)\Gamma$. The coefficients $n(\gamma, h, \Gamma)$ are closely related to the section coefficients noted earlier.

Using the definition of the Bogoliubov map $\bar{\phi}$, this immediately shows that

$$S_R^\phi(B_+^\gamma(h)) = \int D_\gamma \leftarrow_{G_i} \phi_{\text{R}}(h) \qquad [64]$$

which proves locality of counter-terms upon recognizing that $B_+^\gamma$ increases the augmentation degree. Here, the insertion of the functions for the subgraph is achieved using the relevant gluing data of [36].

To recover the quantum equation of motions from the Hochschild cohomology, one proves that

$$\Gamma^{\underline{r}} = 1 + \sum_\gamma \frac{g^\gamma}{\text{Sym}(\gamma)} B_+^\gamma(X_\gamma) \qquad [65]$$

where

$$X_\gamma = \prod_{e \in \gamma^{[1]}\text{int}} \prod_{v \in \gamma^{[0]}} \frac{\Gamma^{\underline{v}}}{\Gamma^{\underline{e}}} \qquad [66]$$

has the required solution. Upon application of the Feynman rules, the maps $B_+^\gamma$ turn into the integral kernels of the usual Dyson–Schwinger equations. This allows for new nonperturbative approaches which are a current theme of investigation.

Finally, we note that the 1-cocycles introduced above allow one to determine sub-Hopf algebras of the form

$$\Delta(c_n^r) = \sum P(\{c_j^s\}) \otimes c_j^r \qquad [67]$$

where the $c_j^s$ are defined in eqn [3]. These algebras do not necessitate the considerations of single Feynman graphs any longer, but allow one to establish renormalization directly for the sum of all graphs at a given loop order. Hence, they establish a Hopf algebra structure on time-ordered products in momentum space. For theories with internal symmetries, one expects and indeed finds that the existence of these subalgebras establishes relations between graphs that are same as the Slavnov–Taylor identities between the couplings in the Lagrangian.

## Outlook

Thanks to the Hopf and Lie algebra structures described above, quantum field theory has started to reveal its internal mathematical structure in recent years, which connects it to a motivic theory and arithmetic geometry. Conceptually, quantum field theory has been the most sophisticated means by which a physicist can describe the character of the physical law. We have slowly begun to understanding that, in its short–distance singularities, it encapsulates concepts of matching beauty. We can indeed expect local point-particle quantum field theory to remain a major topic of mathematical physics investigations in the foreseeable future.

# Hopf Algebras and $q$-Deformation Quantum Groups

**S Majid**, Queen Mary, University of London,
London, UK

## Introduction

Quantum groups are a remarkable generalization of conventional groups using an algebraic language by now quite well known to mathematical physicists. This language is first and foremost the concept of a "Hopf algebra." In fact, the axioms of a Hopf algebra are so attractive from a mathematical point of view that they were proposed in the 1940s long before the advent of truly representative examples, which did not come until the 1980s (from mathematical physics). Until then, they were used mainly by mathematicians as a way for redoing group theory and Lie algebra theory in a more uniform way.

It is remarkable that at least three points of view lead to the same axioms of a Hopf algebra:

1. *Generalized symmetry* A generalization of a usual group algebra or enveloping algebra of a Lie algebra that can nevertheless act on other algebraic objects. The structure that controls this is the "coproduct" $\Delta: H \to H \otimes H$, while the group or Lie structure is encoded in the algebra $H$ which is typically not changed up to isomorphism. $\Delta$ allows $H$ to act on tensor products and this is needed to define what it means, for example, for a product $A \otimes A \to A$ of an algebra to be an intertwiner. The usual flip map between two representations $V \otimes W \to W \otimes V$ is not typically an intertwiner any more, instead that is provided by an $R$-matrix solving the Yang–Baxter equations (YBE).
2. *Noncommutative geometry* A generalization of the coordinate algebra of functions on a conventional group to allow noncommutative or "quantum" coordinate algebras. Here the group structure is encoded in a coproduct $\Delta: H \to H \otimes H$ in a way which would, in the case of functions on a group, be defined by the group product. It is typically not changed, the change being in the algebra.
3. *Duality* An object that admits observer–observed duality or Fourier transform. Such a duality is known for abelian groups, lost for nonabelian groups but re-emerges for Hopf algebras. If there is to be an algebra with product $H \otimes H \to H$, then there should also be a "coproduct" $\Delta: H \to H \otimes H$ to maintain the duality symmetry. Then a suitable dual space $H^*$ is also a Hopf algebra, with the roles of product and coproduct interchanged.

In line with these main ideas are three known classes of true quantum groups, and these remain the main types of example at the time of writing: the $q$-deformed enveloping algebras $U_q(g)$ of Drinfeld and Jimbo, their duals as quantizations of the Drinfeld–Sklyanin Poisson bracket on a simple Lie group (both of these arising from quantum inverse scattering but also in the case of $\mathbb{C}_q[SU_2]$ from $C^*$-algebras) and the bicrossproduct quantum groups based on Lie group factorizations (arising from ideas for Planck-scale physics and quantum gravity). The latter are self-dual and hence are both generalized symmetries and noncommutative or quantum geometries at the same time. The impact of such quantum groups has been very far reaching from a mathematician's point of view, spanning revolutions in the theory of knot and 3-manifold invariants, Poisson geometry, new directions in noncommutative geometry, to name some. In physics they are, at the time of writing, beginning seriously to be applied in a variety of contexts beyond the original ones, such as in bookkeeping overlapping divergences in general quantum field theories, quantum computing, and construction of anyons. This article will mention some of these, but just as groups have many different roles in physics, one can expect that quantum groups and variants of them can and will have diverse roles as well. What follows is a short overview.

## Hopf Algebras and First Examples

The general theory works over any field $k$ but (to be concrete) we write our examples over $\mathbb{C}$; one can also have examples over, say, the field $\mathbb{Z}_2$ of two elements. A Hopf algebra then is:

1. An algebra $H$ with unit which is also a "coalgebra" with counit, that is, there are maps $\Delta: H \to H \otimes H, \epsilon: H \to k$ obeying:

$$(\Delta \otimes \mathrm{id})\Delta = (\mathrm{id} \otimes \Delta)\Delta$$
$$(\epsilon \otimes \mathrm{id})\Delta = (\mathrm{id} \otimes \epsilon)\Delta = \mathrm{id}$$

2. $\Delta, \epsilon$ should be algebra homomorphisms.
3. There should be a map $S: H \to H$ called the antipode or "linearized inverse" obeying

$$\cdot(\mathrm{id} \otimes S)\Delta = \cdot(S \otimes \mathrm{id})\Delta = 1\epsilon$$

If the third axiom is not obeyed one has a "quantum semigroup" or "bialgebra." Note also that $S$ looks nothing like a usual inverse and it is not, yet it plays the same role. For example, we can define conjugation or the "adjoint action" of any Hopf algebra on itself by

$$\mathrm{Ad}_a(b) = \sum a_{(1)} b S a_{(2)}, \quad \Delta a = \sum a_{(1)} \otimes a_{(2)}$$

where we use here the "Sweedler notation" for $\Delta a$ a sum of unspecified pieces in $H \otimes H$. Moreover, if it exists, then $S$ is unique and (it can be shown) $S(ab) = (Sb)S(a)$ for all $a, b \in H$, just like an inverse.

The self-duality of these axioms is evident from the first one: a coalgebra is just an algebra with its product map $H \otimes H \to H$, unit element (viewed as a map $k \to H$ sending 1 to 1) and the associativity and unity axioms all written backwards. Meanwhile, the middle axiom means in explicit terms $\Delta(ab) = (\Delta a)(\Delta b), \epsilon(ab) = \epsilon(a)\epsilon(b)$ for all $a, b \in H$ and $\Delta(1) = 1 \otimes 1, \epsilon(1) = 1$. This may not look self-dual but it is equivalent to saying that the product and unit are coalgebra homomorphisms. Indeed, if one takes the trouble to write out all the axioms as commutative diagrams, the set of axioms is invariant under arrow reversal. Such arrow reversal can also be concretely implemented, for example, by taking adjoints. Thus, the coproduct dualizes to a map $(H \otimes H)^* \to H^*$ and since $H^* \otimes H^* \subseteq (H \otimes H)^*$ we have a product on the dual $H^*$. If the dual space is defined correctly, one also has a coproduct by dualizing the product, etc. One says that two Hopf algebras $H, H'$ are "in duality" if their maps are adjoint to each other in such a way.

The role of quantum groups as generalized symmetries is typified by the following examples. Thus, let $G$ be a group; then its group algebra $\mathbb{C}G$ defined as a vector space (written here over $\mathbb{C}$) with basis identified with $G$ and product given by the group product extended linearly, is a Hopf algebra with

$$\Delta g = g \otimes g, \ \epsilon g = 1, \ Sg = g^{-1}, \quad \forall g \in G$$

Likewise, if $\mathfrak{g}$ is a Lie algebra, then its universal enveloping algebra $U(\mathfrak{g})$ generated by $\mathfrak{g}$ is a Hopf algebra with

$$\Delta \xi = \xi \otimes 1 + 1 \otimes \xi, \quad \epsilon \xi = 0, \quad S\xi = -\xi, \quad \forall \xi \in \mathfrak{g}$$

The two examples are related if one informally allows exponentials, then $g = e^{\xi}$ has coproduct

$$\Delta e^{\xi} = e^{\Delta \xi} = e^{\xi \otimes 1 + 1 \otimes \xi} = e^{\xi} \otimes e^{\xi}$$

using axiom 2 and that $\xi \otimes 1, 1 \otimes \xi$ commute in the tensor product algebra.

The coproduct structures are therefore implicit already in Lie theory and group theory. As for any Hopf algebra $\Delta$, specifies how the algebra $H$ acts in a tensor product of two representations. For groups the tensor product is diagonal ($g$ acts on each copy), for Lie algebras it is additive (e.g., the addition of angular momenta). In general, the action of $a \in H$ is defined as the action of $\Delta a$ on the tensor product. This has far-reaching consequences. For example, for the product $A \otimes A \to A$ of an algebra to be covariant means that $H$ acting before and after the product map gives the same answer, similarly for the unit map where $k$ has the trivial representation afforded by $\epsilon$, that is,

$$h \triangleright (ab) = \sum (h_{(1)} \triangleright a)(h_{(2)} \triangleright b), \quad h \triangleright 1 = \epsilon(h)1$$

for all $a, b \in A$ and $h \in H$. What that means in the case of a group is therefore $g \triangleright (ab) = (g \triangleright a)(g \triangleright b)$ or $G$ acts by automorphisms. What it means for a Lie algebra is $\xi \triangleright (ab) = (\xi \triangleright a)b + a(\xi \triangleright b)$, that is, $\mathfrak{g}$ acts by derivations. This is how Hopf algebra theory unifies group theory and Lie algebra theory and potentially takes us beyond.

In another, dual, point of view, if $G$ is a group defined by polynomial equations in $\mathbb{C}^n$, then the Hilbert's "nullstellensatz" in algebraic geometry says that it corresponds algebraically to a commutative nilpotent-free algebra with $n$ generators, called its "coordinate algebra" $H = \mathbb{C}[G]$. The group product then corresponds to $\Delta$ making $\mathbb{C}[G]$ into a Hopf algebra. If one replaces $\mathbb{C}$ by any field, one has an algebraic group over the field. For example, the group $\mathrm{SL}_2(\mathbb{C}) \subset \mathbb{C}^4$ has coordinate algebra generated by four functions $a, b, c, d$ where $a$ at matrix $g \in \mathrm{SL}_2(\mathbb{C})$ has value $g_{11}$ the 1,1 entry of the matrix, similarly $b(g) = g_{12}$ etc. Then $\mathbb{C}[\mathrm{SL}_2]$ is the commutative algebra generated by $a, b, c, d$ with the relation $ad - bc = 1$. A little thought about matrix multiplication should convince the reader that

$$\Delta \begin{pmatrix} a & b \\ c & b \end{pmatrix} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \otimes \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

where we have written the operation on each generator as an array and where matrix multiplication is understood (so $\Delta a = a \otimes a + b \otimes c$, etc.). The counit and antipode are

$$\epsilon \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

$$S \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} d & -b \\ -c & a \end{pmatrix}$$

One could also let $G$ be a finite group, in which case the algebra $\mathbb{C}(G)$ of (say complex-valued) functions on it is more obviously a Hopf algebra with

$$(\Delta a)(g, h) = a(gh), \ \epsilon(a) = a(1), \ (Sa)(g) = a(g^{-1})$$

for any function $a \in \mathbb{C}(G)$. Here we identify $\mathbb{C}(G) \otimes \mathbb{C}(G) = \mathbb{C}(G \times G)$ or functions in two variables on the group. These examples are dually paired with $U(\mathfrak{g})$ in the Lie case and $\mathbb{C}G$ in the finite case, respectively.

In such a coordinate algebra point of view, usual constructions in group theory appear expressed backwards with arrows reversed. So an action of the group appears for such a Hopf algebra $H$ as a "coaction" $\Delta_R : V \to V \otimes H$ (here a right coaction, one can similarly have $\Delta_L$ a left coaction). It obeys

$$(\Delta_R \otimes \mathrm{id})\Delta_R = (\mathrm{id} \otimes \Delta)\Delta_R, \qquad (\mathrm{id} \otimes \epsilon)\Delta_R = \mathrm{id}$$

which are the axioms of an algebra acting written backwards for the coalgebra of $H$ "coacting." An example is the right action of a group on itself which in the coordinate ring point of view is $\Delta_R = \Delta$, that is, the coproduct viewed as a right coaction. It is the algebra of $H$ that determines the tensor product of two coactions, so, for example, $A$ is a coaction algebra in this sense if $\Delta_R : A \to A \otimes H$ is a coalgebra and an algebra homomorphism. Similarly, in this coordinate point of view, an integral on the group means a map $\int : H \to k$ and right invariance translates into invariance under the right coaction, or

$$\left(\int \otimes \mathrm{id}\right)\Delta = 1 \int$$

There is a theorem that such an integration, if it exists, is unique up to scale. In the finite-dimensional case it always exists, for any field $k$. At least in this case, let $\exp = \sum_i e_i \otimes f^i$ for a basis $\{e_i\}$ of $H$ and $\{f^i\}$ a dual basis. Then an application of the integral is Fourier transform $H \to H^*$ defined by

$$\mathcal{F}(a) = \int \sum_i e_i a \otimes f^i$$

with properties that one would expect of Fourier transform. The inverse is given similarly the other way up to a normalization factor and using the antipode of $H$. This is one among the many results from the abstract theory of Hopf algebras, see Sweedler (1969) and Larson and Radford (1988) among others.

A given Hopf algebra $H$ does not know which point of view one is taking on it; the axioms of a Hopf algebra include and unify both enveloping and coordinate algebras. So an immediate consequence is that constructions which are usual in one point of view give new constructions when the wrong point of view is taken (put another way, the self-duality of the axioms means that any general theorem has a second theorem for free, given, if we keep the interpretation of $H$ fixed, by reversing all arrows in the original theorem and its proof). Even the elementary examples above are quite interesting for physics if taken "upside down" in this way. For example, if $G$ is nonabelian, then $\mathbb{C}G$ is noncommutative, so it cannot be functions on any actual group. But it is a Hopf algebra, so one could think of it as being like $\mathbb{C}(\hat{G})$, where $\hat{G}$ is not a group but a quantum group defined as $\mathbb{C}(\hat{G}) = \mathbb{C}G$. The latter is a well-defined Hopf algebra viewed the wrong way. So this is an application of noncommutative geometry to allow nonabelian Fourier transform $\mathcal{F} : \mathbb{C}(G) \to \mathbb{C}G$. Similarly, $U(\mathfrak{g})$ is noncommutative but one could view it upside down as a quantization of $\mathbb{C}[\mathfrak{g}^*] = S(\mathfrak{g})$ (the symmetric algebra on $\mathfrak{g}$). To do this let us scale the generators of $\mathfrak{g}$ so that the relations on $U(\mathfrak{g})$ have the form $\xi\eta - \eta\xi = \lambda[\xi, \eta]$ where $\lambda$ is a deformation parameter. Then the Poisson bracket that this algebra quantizes (deforms) is the Kirillov–Kostant one on $\mathfrak{g}^*$ where $\{\xi, \eta\} = [\xi, \eta]$. Here $\xi, \eta$ on the left-hand side are regarded as functions on $\mathfrak{g}^*$, while on the right-hand side we take their Lie bracket and then regard the result as a function on $\mathfrak{g}^*$. Examples which have been used successfully in physics include:

$$[t, x_i] = \mathrm{i}\lambda x_i \qquad \left(\text{bicrossproduct model } \mathbb{R}^{1,3}_\lambda\right)$$
$$[x_i, x_j] = \mathrm{i}2\lambda\epsilon_{ijk}x_k \qquad \left(\text{spin space model } \mathbb{R}^3_\lambda\right)$$

(summation understood over $k$). In both cases, we may develop geometry on these algebras using quantum group methods as if they were coordinates on a usual space (*see* Bicrossproduct Hopf Algebras and Noncommutative Spacetime). They are versions of $\mathbb{R}^n$ because the coproduct which expresses the addition law on the noncommutative space is the additive one according to the above. In the second case, setting the Casimir to the value for a spin $j$ is the quadratic relation of a "fuzzy sphere." As algebras, the latter are just the algebras of $(2j+1)\times(2j+1)$ matrices.

Going the other way, we can take a classical coordinate ring $\mathbb{C}[G]$ and regard it upside down as some kind of group or enveloping algebra but with a nonsymmetric $\Delta$. In the finite group case, an action of $\mathbb{C}(G)$ just means a $G$-grading. Here if an element $v$ of a vector space has $G$-valued degree $|v|$ then $a \triangleright v = a(|v|)v$ is the action of $a \in \mathbb{C}(G)$. Alternatively, this is the same thing as a right coaction of $\mathbb{C}G, \Delta_R v = v \otimes |v|$. Thus, the notion of group representation and group grading are also unified. This is familiar in physics for abelian groups (a $U(1)$ action is the same thing as a $\mathbb{Z}$-grading) but works fine using Hopf algebra methods for nonabelian groups and beyond.

Returning to axioms, if one wants to speak of real forms and unitary representations, this corresponds, for Hopf algebras, to $H$ a $*$-algebra over $\mathbb{C}$ with

$$\Delta^*(\ ) = \tau(*\otimes *)\Delta, \qquad * \circ S = S^{-1}\circ *$$

where $\tau$ (throughout this article) denotes transposition of tensor factors. This requires in particular that $S$ in invertible (which is not assumed for a general Hopf algebra though it does hold in the finite-dimensional case and in all examples of interest). Thus, $\mathbb{C}[\mathrm{SU}_2]$ denotes the above with a certain $*$ structure whereby the matrix of generators is unitary.

## *q*-Deformation Enveloping Algebras

For a genuinely representative example of a Hopf algebra, consider, $U_q(sl_2)$ defined with noncommutative generators and relations, coproduct etc.,

$$\begin{aligned} q^{h/2}x_\pm q^{-h/2} &= q^{\pm 1}x_\pm \\ [x_+, x_-] &= \frac{q^h - q^{-h}}{q - q^{-1}} \\ \Delta x_\pm &= x_\pm \otimes q^{h/2} + q^{-h/2}\otimes x_\pm \\ \Delta q^{h/2} &= q^{h/2}\otimes q^{h/2} \\ \epsilon x_\pm &= 0, \quad \epsilon q^{h/2} = 1 \\ S x_\pm &= -q^{\pm 1}x_\pm, \qquad S q^{h/2} = q^{-h/2} \end{aligned}$$

The actual generators here are $x_\pm, q^{\pm h/2}$ but the notation is intended to be suggestive: if $h$ existed and we took the limit $q \to 1$, we would have the usual enveloping algebra of the Lie algebra $sl_2$. The quantum group $U_q(su_2)$ is the same with the $*$-structure $h^* = h, x_\pm^* = x_\mp$ when $q$ is real (there are other possibilities).

Two words of warning here. Although some authors write $q = e^{\hbar/2}$, the parameter $q$ here has little to do with quantization. In fact, the cases of direct relevance to physics are $q^{2\pi i/(2+k)}$, where $k$ is the level of the Wess–Zumino–Witten (WZW) model in which this quantum group appears as a generalized symmetry. This quantum group also (first) appeared in the theory of exactly solvable lattice models, namely the Ising model with an applied external magnetic field: $q \neq 1$ is a measure of the resulting nonhomogeneity of the model. Its origins go further back to the algebraic Bethe ansatz and the emergence of the YBE in such models (Baxter 1982). The general $U_q(\mathfrak{g})$ emerged from this context in Drinfeld (1987) and Jimbo (1985) and the same remark applies (*see* Affine Quantum Groups; Yang–Baxter Equations).

The second warning is that at least informally (if one works with $H$ and allows formal power series etc.), the algebra here is isomorphic to usual $U(sl_2)$, that is, it looks deformed but the true deformation is not here but in the coproduct, which enters into the tensor product of representations. The latter are labeled as usual because the algebra is not really changed, for example, the unitary ones of $U_q(su_2)$ are labeled by spin. The spin-$\frac{1}{2}$ one even looks the same with $x_\pm, h$ represented by the standard Pauli matrices. Tensor products of representations start to look different but their multiplicities are the same as classically and if $V, W$ are representations then $V\otimes W \cong W \otimes V$. Because the coproduct above is not symmetric in its two factors, this isomorphism $\Psi_{V,W} = \tau \circ R_{V,W}$ has $R_{V,W}$ nontrivial. From the formulas given, the reader can compute that

$$R_{1/2,1/2} = q^{-1/2}\begin{pmatrix} q & 0 & 0 & 0 \\ 0 & 1 & q - q^{-1} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & q \end{pmatrix}$$

in a tensor product basis. For this particular quantum group, and others like it, one finds that these "$R$-matrices" obey the braid relations as a version of the YBE. As a result, they can and do lead to knot invariants; the one above leads to the Jones knot invariant as a polynomial in $q$. Briefly, one represents the knot on a plane, assigns $R$ or $R^{-1}$ to each braid crossing and takes a suitable trace (*see* The Jones Polynomial).

Since such features hold in any representation, these matrices are in fact representations of an invertible element $\mathcal{R} \in H \otimes H$ provided one allows $h$ as a generator and formal power series:

$$\mathcal{R} = q^{(h\otimes h)/2}\, e_{q^{-2}}^{(q-q^{-1})e\otimes f}; \; e = x_+ q^{h/2}, \; f = q^{-h/2}x_-$$

where

$$e_q(x) = \sum_{m=0}^{\infty}\frac{x^m}{[m]_q!}, \qquad [m]_q = \frac{1-q^m}{1-q}$$

are the $q$-exponential and $q$-integer, respectively. Their proper explanation is in the section "Braided groups and quantum planes." This $\mathcal{R}$ is called the "universal R-matrix" or quasitriangular structure and obeys

$$\tau\Delta = \mathcal{R}(\Delta\ )\mathcal{R}^{-1}$$
$$(\Delta\otimes \mathrm{id})\mathcal{R} = \mathcal{R}_{13}\mathcal{R}_{23}, \qquad (\mathrm{id}\otimes\Delta)\mathcal{R} = \mathcal{R}_{13}\mathcal{R}_{12}$$

and from the axioms of a Hopf algebra, one may deduce that the YBE

$$\mathcal{R}_{12}\mathcal{R}_{13}\mathcal{R}_{23} = \mathcal{R}_{23}\mathcal{R}_{13}\mathcal{R}_{12}$$

hold in the algebra. This induces the YBE for matrices $R_{V,W}$ in the representation $V\otimes W$. Such a

Hopf algebra is called "quasitriangular" and its representations form a braided category (*see* Braided and Modular Tensor Categories). Even if $\mathcal{R}$ for a quasitriangular Hopf algebra is defined by a power series, the $R_{V,W}$ in finite-dimensional representations are typically actual matrices.

Of considerable interest is the special case when $q$ is a primitive $n$th root of unity. In this case the quasitriangular Hopf algebra $u_q(sl_2)$ has the above generators but the additional relations

$$e^n = f^n = 0, \qquad g^n = 1; \quad g = q^h$$

which render the algebra generated by $e, f, g$ as $n^3$-dimensional. The algebra no longer has a matrix block decomposition (is not semisimple) and not all representations descend to it. For example, if $n$ is odd, then only representations of dimension $\leq n$ descend. Other than this, one has many of the features of a classical enveloping algebra now for this finite-dimensional object. There is evidence that such objects over $\mathbb{C}$ are intimately related to classical Lie algebras but over a finite field.

Finally, there is a similar theory of $U_q(\mathfrak{g})$ for all Lie algebras determined by symmetrizable Cartan matrices $\{a_{ij}\}$, including affine ones. Here $i, j \in I$ an indexing set and $a_{ij} = 2i \cdot j / i \cdot i \in \{0, -1, -2, \ldots\}$ for $i \neq j$, where $\cdot$ is a symmetric bilinear form on the root lattice $\mathbb{Z}[I]$ generated by $I$ with $i \cdot i$ a positive even integer. To be precise, one should also fix a "root datum" in the form of an inclusion $\mathbb{Z}[I] \subseteq X$ of the root lattice into a choice of character lattice $X$ and an inclusion $\mathbb{Z}[I] \subseteq Y$ of the coroot lattice (also labeled by $I$) into the cocharacter lattice $Y$ (the dual of $X$). Here the evaluation pairing is required to restrict to $\langle \check{i}, j \rangle = a_{ij}$ if $i, j \in I$ and $\check{i}$ is $i$ viewed in the cocharacter lattice $Y$. We let $q_i = q^{i \cdot i/2}$ and require $q_i^2 \neq 1$ for all $i$ (or one may consider $q$ as an indeterminate). We have generators $e_i, f^i$ for $i \in I$ and invertible $g_a$ for $a$ each generator of $Y$, and the relations

$$g_a e_i = q^{\langle a,i \rangle} e_i g_a, \qquad f^i g_a = q^{\langle a,i \rangle} g_a f^i$$

$$[e_i, f^j] = \frac{g_{\check{i}}^{i \cdot i/2} - g_{\check{i}}^{-i \cdot i/2}}{q_i - q_i^{-1}} \delta_i^j$$

$$\sum_{r=0}^{1-a_{ij}} (-1)^r \begin{pmatrix} 1 - a_{ij} \\ r \end{pmatrix}_{q_i} (e_i)^r e_j (e_i)^{1-a_{ij}-r} = 0$$

for all $i \neq j$ and an identical set for the $\{f^i\}$. The coalgebra and antipode are

$$\Delta e_i = e_i \otimes g_{\check{i}}^{i \cdot i/2} + 1 \otimes e_i$$

$$\Delta f^i = f^i \otimes 1 + g_{\check{i}}^{-i \cdot i/2} \otimes f^i$$

$$\Delta g_a = g_a \otimes g_a, \quad \epsilon(g_a) = 1, \quad \epsilon(e_i) = \epsilon(f^i) = 0$$

$$S g_a = g_a^{-1}, \quad S e_i = -e_i g_{\check{i}}^{-i \cdot i/2}, \quad S f^i = -g_{\check{i}}^{i \cdot i/2} f^i$$

The $q$-Serre relations are those above involving the $q$-binomial coefficients, defined now using the symmetric $q$-integers $(m)_q = (q^m - q^{-m})/(q - q^{-1})$. They have their true explanation as

$$\mathrm{Ad}_{(e_i)^{1-a_{ij}}}(e_j) = 0$$

where Ad is a braided group adjoint action in the sense of the section "Braided groups and quantum planes." Notice that while the root generators are modeled on the Lie algebra, the Cartan generators are modeled on the torus of an algebraic group, which contains global information. Thus, the more precise form of $U_q(sl_2)$ is the $e$, $f$, $g$ form with the generator $g = q^h$ as above, with $\mathbb{Z}[I] \subsetneq X$ and $\mathbb{Z}[I] = Y$. Meanwhile $U_q(psl_2)$ has the square root of this as generator (what we called $q^{h/2}$ before) with $\mathbb{Z}[I] = X$ and $\mathbb{Z}[I] \subsetneq Y$ where the strict inclusion has $\check{1} = 2$ in the lattice $\mathbb{Z}$. Note that, in the complex case, $SL_2$ has compact real form $SU_2$ while its quotient, $PSL_2$, has compact real form $SO_3$, so these are distinguished at the Hopf algebra level. In general, the root datum has an associated reductive algebraic group which is simply connected when $Y = \mathbb{Z}[I]$ and generated by its adjoint representation when $X = \mathbb{Z}[I]$. The complexified character lattice is a sublattice of the more familiar Lie algebra weight lattice and labels representations that extend to the (algebraic) group. Langlands duality interchanges the roles of $X, Y$. These subtleties are lost when we work over formal power series with $q = e^{\lambda/2}$ and Lie-algebra-like Cartan generators.

These objects are mathematically so interesting that some authors define "quantum groups" as nothing more than this particular extension of the theory of Lie algebras, Cartan matrices and root systems. Among the deepest theorems is the existence of the Lusztig–Kashiwara canonical basis which is obtained from $q = 0$ but valid also at $q = 1$ (i.e., for classical enveloping algebras) and which has the remarkable property of inducing bases coherently across highest-weight representations. From a physicist's point of view, however, there are many other Hopf algebras rather more closely connected with actual quantization. Most often, the terms quantum group and Hopf algebra are used interchangeably.

There is similarly a reduced version $u_q(\mathfrak{g})$. The simplest of all possible cases, even simpler than $u_q(sl_2)$, is for what one could call $u_q(1)$ with a single generator $g$ and

$$g^n = 1, \ \Delta g = g \otimes g, \ \epsilon g = 1, \ S g = g^{-1}$$

$$\mathcal{R}_q = \frac{1}{n} \sum_{a,b=0}^{n-1} q^{-ab} g^a \otimes g^b$$

where $q$ is a primitive $n$th root of unity. The Hopf algebra is the same as the group algebra $\mathbb{C}\mathbb{Z}_n = \mathbb{C}(\hat{\mathbb{Z}}_n)$ but the $\mathcal{R}$ is nontrivial. A representation means a $\hat{\mathbb{Z}}_n$-graded space, that is, graded into degrees $0, 1, \ldots, n-1$. The braiding matrices have the diagonal form $R_{V_a, W_b} = q^{ab}$ on components of degree $a$, $b$, respectively. The braided category generated in this case is the one where anyons live. From this point of view, $u_q(g)$ generate the category where nonabelian anyons live. Here $\mathcal{R}_{q^2}$ (in place of $q^{(h\otimes h)/2}$) along with an additional $e_{q^{-2}}$ factor as above gives the quasitriangular structure of $u_q(sl_2)$. The physical model here is the rational conformal field theory mentioned above with these anyons as particular bound states. There is a proposal to use them in the construction of quantum computers.

## q-Deformation Coordinate Algebras

From the coordinate algebra point of view, the corresponding deformation to the one in the last section is the Hopf algebra $\mathbb{C}_q[SL_2]$ with noncommuting generators and relations

$$\begin{aligned} ca &= qac, & ba &= qab \\ db &= qbd, & dc &= qcd \\ bc &= cb, & da - ad &= (q - q^{-1})bc \\ ad - q^{-1}bc &= 1 \end{aligned}$$

The coalgebra has the same matrix form on the generators as for $\mathbb{C}[SL_2]$ and the antipode and $*$-structure (for $\mathbb{C}_q[SU_2]$) are

$$S\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} d & -qb \\ -q^{-1}c & a \end{pmatrix} = \begin{pmatrix} a & c \\ b & d \end{pmatrix}^*$$

Its duality pairing with $U_q(sl_2)$ is afforded by the $2 \times 2$ Pauli-matrix representation of the latter. The $\mathbb{C}_q[SU_2]$ Hopf $*$-algebra may be completed to a $C^*$-algebra.

One similarly has $\mathbb{C}_q[G]$ for all semisimple Lie groups $G$ and their various real forms. From an axiomatic point of view, such quantum groups are "coquasitriangular" in the sense that there is a map $\mathcal{R}: H \otimes H \to k$ such that

$$\sum \mathcal{R}(a_{(1)} \otimes b_{(1)}) a_{(2)} b_{(2)} = \sum b_{(1)} a_{(1)} \mathcal{R}(a_{(2)} \otimes b_{(2)})$$

for all $a, b \in H$ and

$$\begin{aligned} \mathcal{R}(ab \otimes c) &= \sum \mathcal{R}(a \otimes c_{(1)}) \mathcal{R}(b \otimes c_{(2)}) \\ \mathcal{R}(a \otimes bc) &= \sum \mathcal{R}(a_{(1)} \otimes c) \mathcal{R}(a_{(2)} \otimes b) \end{aligned}$$

for all $a, b, c \in H$. We also require that $\mathcal{R}$ is invertible in a certain sense. These are just the arrow reversal of the axioms of a quasitriangular structure. In general, for the deformation of a linear algebraic group we will have some $n^2$ generators $t^i{}_j$, now taken to be noncommutative, and with a matrix form of coalgebra

$$\Delta t^i{}_j = t^i{}_k \otimes t^k{}_j, \qquad \epsilon t^i{}_j = \delta^i{}_j$$

For the compact real form we will have $St^i{}_j = t^{j*}{}_i$. Moreover, from the first of the above axioms we will have among the relations

$$R^i{}_a{}^k{}_b t^a{}_j t^b{}_l = t^k{}_b t^i{}_a R^a{}_j{}^b{}_l$$

where $R^i{}_j{}^k{}_l = \mathcal{R}(t^i{}_j \otimes t^k{}_l)$ is a matrix $R \in M_n \otimes M_n$ obeying the YBE. If we take only these quadratic relations, we have the "Faddier Reshetikhin Takhtajan (FRT) bialgebra" $A(R)$ and it can be shown (see Majid 1995) that $R$ extends to a coquasitriangular structure $\mathcal{R}$ on it. However, in our case we also have

$$\begin{aligned} R^{-1}{}^i{}_j{}^k{}_l &= \mathcal{R}\left(St^i{}_j \otimes t^k{}_l\right) \\ \tilde{R}^i{}_j{}^k{}_l &= \mathcal{R}\left(t^i{}_j \otimes St^k{}_l\right) \end{aligned}$$

where $\tilde{R} = ((R^{t_2})^{-1})^{t_2}$ ($t_2$ transposition in the second factor of $M_n$) is called the "second inverse" of $R$. With these additional matrices, one may define a $q$-determinant and antipode relations as well (Majid 1995). One may also generate a rigid braided monoidal category and reconstruct a Hopf algebra $\check{A}(R)$ from it. In this way, the $R$-matrix plays a role similar to that of the structure constants of a Lie algebra and can in principle define the quantum group coordinate algebra. Such $R$-matrices have been classified in low dimension and include multiparameter and other deformations of classical group coordinate algebra as well as other nonstandard quantum groups.

In the $\mathbb{C}_q[G]$ examples it is not the coalgebra which is essentially deformed but the algebra. We already see this above on the generators but the coproduct of a product of generators may look different. Nonetheless, one can identify the vector space that the products generate with that of $\mathbb{C}[G]$ and at least informally with respect to a deformation parameter express the product as a power series in the undeformed product (a $\bullet$-product deformation). For generic values, one still has a Peter–Weyl decomposition $\mathbb{C}_q[G] = \oplus (V \otimes V^*)$, where the sum is over irreducibles corepresentations, which can be identified with the classical representations of the algebraic group. One can make the same decomposition for $\mathbb{C}[G]$ and identify the matrix blocks $V \otimes V^*$ in order to find this $\bullet$-product. Also, since this is a flat deformation, it follows that the commutator at lowest order defines a Poisson bracket on $G$, given by

$$\{t^i{}_j, t^k{}_l\} = t^i{}_a t^k{}_b r^a{}_j{}^b{}_l - r^i{}_a{}^k{}_b t^a{}_j t^b{}_l$$

and this Poisson bracket is compatible with the group product $G\times G\to G$ as a Poisson map (because the Hopf algebra coproduct was an algebra map). Here $r$ is the first order part in the expansion of the $R$-matrix. A Lie group equipped with a Poisson bracket compatible in this way is called a "Poisson Lie group." On general functions its Poisson bivector is generated by the first order part $r\in\mathfrak{g}\otimes\mathfrak{g}$ in the expansion of $\mathcal{R}$ in the $q$-deformed enveloping algebra. In place of the YBE obeyed by $\mathcal{R}$, we have the "classical Yang–Baxter equations (CYBE),"

$$[r_{12},r_{23}]+[r_{12},r_{13}]+[r_{13},r_{23}]=0$$

In this way, one may characterize an "infinitesimal version" of $U_q(\mathfrak{g})$ as $(\mathfrak{g},r,\delta)$ where $\delta:\mathfrak{g}\to\mathfrak{g}\otimes\mathfrak{g}$ is the leading part of $\tau\Delta-\Delta$ and makes the triple into a quasitriangular "Lie Bialgebra" (*see* Classical $r$-Matrices, Lie Bialgebras, and Poisson Lie Groups).

Finally, returning to our example, when $q$ is an $n$th root of unity, one has the $q$-Frobenius Hopf algebra homomorphism

$$\mathbb{C}[SL_2]\hookrightarrow\mathbb{C}_q[SL_2]$$

$$\begin{pmatrix}a & b\\ c & d\end{pmatrix}\mapsto\begin{pmatrix}a^n & b^n\\ c^n & d^n\end{pmatrix}$$

that is, a classical copy sitting inside the quantum group. Quotienting by this means adding the relations

$$a^n=d^n=1,\qquad b^n=c^n=0$$

which gives the finite-dimensional reduced quantum group $\mathbb{C}_q^{\mathrm{red}}[SL_2]$. Similarly for other $\mathbb{C}_q^{\mathrm{red}}[G]$. These reduced quantum groups provide finite noncommutative geometries having the geometric flavor of the classical geometry but where geometry and physics (such as electromagnetic gauge theory modes) are fully computable.

## Self-Dual Quantum Groups

The arrow-reversibility of the axioms of a quantum group make it possible to search for self-dual quantum groups or for quantum groups which, if not self-dual, have a self-dual form. This leads to the bicrossproduct quantum groups coming from models of quantum gravity (Majid 1988) (*see* Bicrossproduct Hopf Algebras and Noncommutative Spacetime).

The context here is that of Figure 1 which shows how Hopf algebras relate to other objects and to duality in a representation-theoretic sense. Along the central axis, we have put self-dual categories or in physical terms categories admitting Fourier transform. This is clear for abelian Groups where the

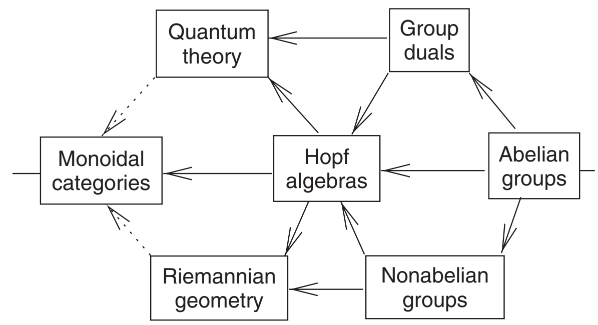

**Figure 1** Role of Hopf algebras along the self-dual axis.

dual $\hat{G}$ of an abelian group $G$ is also an abelian group. Below the axis, we have nonabelian groups which we view as toy models of geometries with curvature. Every compact Lie group, for example, has an associated Killing metric. Above the axis, a nonabelian group dual $\hat{G}$ means to construct unitary representations etc., which we view as toy models of quantum theory. We have seen that Hopf algebras are another self-dual category and provide a framework in which both groups and group duals can be unified (see the section "Hopf algebras and first examples"). Thus, $G$ can be viewed as a coordinate Hopf algebra $\mathbb{C}(G)$ or $\mathbb{C}[G]$ in the finite or Lie cases, and $\hat{G}$ as the dual Hopf algebra $\mathbb{C}G$ or $U(\mathfrak{g})$ as a definition of the coordinate algebra "$\mathbb{C}(\hat{G})$." Note that $\hat{G}$ is not merely the set of representations, as these alone are not enough to reconstruct the group (e.g., both $S^1$ and $SO_3$ have the same set). We see that Hopf algebras are a microcosm for the unification of quantum theory and gravity. Hopf algebra duality interchanges the role of position and momentum on the one hand and of quantum and gravitational effects on the other. A self-dual Hopf algebra has both aspects unified and interchanged by the self-duality.

One can also ask what the next most general self-dual category of objects is in which to look for more general unifications. One answer here is the category whose objects are themselves categories $\mathcal{C}$ equipped with a tensor product (a "monoidal category") and a monoidal functor to a fixed monoidal category $\mathcal{V}$. Motivated by the above, a theorem from the 1980s is that for any such $\mathcal{C}$ there is a dual $\mathcal{C}^0$ of "representations in $\mathcal{V}$" (Majid 1991a). The dotted arrows in Figure 1 indicate that this may be a setting for more ambitious models than those achieved by Hopf algebras alone. In fact, the $\mathcal{C}^0$ construction was one of the ingredients going into the invention of 2-categories a few years later. See also several articles on TQFT (such as Topological Quantum Field Theory: Overview; Axiomatic Approach to Topological Quantum Field Theory; Duality in Topological Quantum Field Theory).

The simplest self-dual quantum group is $\mathbb{C}[x]$ as the Hopf algebra of polynomial functions on a line with additive coproduct. This is dually paired with itself in the form of the enveloping algebra $U(gl_1) = \mathbb{C}[p]$ with pairing

$$\langle p^m, x^n \rangle = (-\mathrm{i})^n \delta_{m,n} n!$$

and similarly for higher-dimensional flat space. In the case of $\mathbb{C}[x]$, a basis is $x^n$ and from the above the dual basis is $(\mathrm{i}p)^n/n!$. Hence the canonical element is $\exp = \mathrm{e}^{\mathrm{i}x \otimes p}$ so that Hopf algebra Fourier transform on a suitable completion of these algebras reduces to usual Fourier transform.

A more nontrivial example (Majid 1988) is given by the "Planck-scale Hopf algebra" $\mathbb{C}[x] \blacktriangleright\!\!\triangleleft \mathbb{C}[p]$ which has algebra and coalgebra

$$[p, x] = \mathrm{i}\hbar(1 - \mathrm{e}^{-\gamma x}), \qquad \Delta x = x \otimes 1 + 1 \otimes x$$
$$\Delta p = p \otimes \mathrm{e}^{-\gamma x} + 1 \otimes p, \qquad \epsilon x = \epsilon p = 0$$
$$Sx = -x, \qquad Sp = -p\mathrm{e}^{\gamma x}$$

The actual generator here should be $\mathrm{e}^{\gamma x}$ rather than $x$ for an algebraic treatment (otherwise one should allow power series or use $C^*$-algebras). The dually paired Hopf algebra has the same form $\mathbb{C}[p] \triangleright\!\!\blacktriangleleft \mathbb{C}[x]$, with new parameters $\hbar' = 1/\hbar$ and $\gamma' = \hbar\gamma$ and quantum group Fourier transform connects the two. More details and the general construction of Hopf algebras $\mathbb{C}[M] \blacktriangleright\!\!\triangleleft U(\mathfrak{g})$ with dual $U(\mathfrak{m}) \triangleright\!\!\blacktriangleleft \mathbb{C}[G]$ are in the article on "bicrossproduct" Hopf algebras (*see* Bicrossproduct Hopf Algebras and Noncommutative Spacetime). These quantize particles in $M$ moving under momentum Lie group $G$ with Lie algebra $\mathfrak{g}$ and vice versa. The states of one (in a $C^*$-algebra context) lie in the algebra of observables of the other ("observable–state duality"). The data required are a matched pair of actions of $(G, M)$ on each other. Such equations correspond locally to a factorization of a larger group $G \bowtie M$ but typically have singularities and other features in keeping with a toy model of Einstein's equations.

There are, by the time of writing, many applications of bicrossproducts beyond the original one, including a Poincaré quantum group for the $\mathbb{R}^{1,3}_\lambda$ mentioned in the section "Hopf algebras and first examples," with links to Planck-scale physics. There is also a bicrossproduct quantum group $\mathbb{C}[G^*] \blacktriangleright\!\!\triangleleft U(\mathfrak{g})$ canonically associated to any simple Lie algebra $\mathfrak{g}$ and related to $T$-duality. The classical data here are Lie bialgebras and solutions of the CYBE as in the section "$q$-Deformation coordinate algebras," however there is no known relation with the $q$-deformation Hopf algebras themselves. Finite group bicrossproducts are also interesting and examples (but not with both actions nontrivial) were already in the works of GI Kac in the 1960s.

These constructions also work when the groups above are themselves Hopf algebras. For example, any finite-dimensional Hopf algebra $H$ has a "quantum double" $D(H) = H \bowtie H^{*\mathrm{op}}$, where the double cross product $\bowtie$ is by mutual coadjoint actions. The cross-relations between the two sub-Hopf algebras are

$$\sum \langle h_{(1)}, a_{(1)} \rangle h_{(2)} a_{(2)} = \sum a_{(1)} h_{(1)} \langle h_{(2)}, a_{(2)} \rangle$$

for $h \in H$ and $a \in H^*$. The construction is due to Drinfeld (1987) while the $\bowtie$ form is due to the author. Moreover, $D(H)$ is quasitriangular with $\mathcal{R} = \exp$, the canonical element used in the Fourier transform on $H$. Its representations consist of vector spaces where $H$ acts and at the same time $H^{*\mathrm{op}}$ acts or (which makes sense when $H$ is infinite dimensional) where $H$ coacts, in a compatible way. Such objects are called "crossed modules" because when $H = \mathbb{C}G$, one has exactly a linearization of the crossed $G$-sets of JC Whitehead. They are a special case of the $\mathcal{C}^0$ construction mentioned above.

Finally, one can also view the $q$-deformed linear spaces on which quantum groups such as $U_q(\mathfrak{g})$ act as self-dual Hopf algebras under an additive coproduct. However, this needs to be as braided groups or Hopf algebras with braid statistics, see the next section. The simplest example here is the "braided line" $B = \mathbb{C}[x]$ developed not as above but as a self-dual Hopf algebra with $q$-statistics. Its "bosonization" gives a self-dual Hopf algebra $U_q(b_+) \subset U_q(sl_2)$, and similarly for other $U_q(b_+) \subset U_q(\mathfrak{g})$. Perhaps more surprisingly, the quantum groups $U_q(\mathfrak{g})$ and $\mathbb{C}_q[G]$ also both have canonical braided group versions (a process called "transmutation") and as such they too are isomorphic. This isomorphism extends the linear isomorphism $\mathfrak{g} \to \mathfrak{g}^*$ afforded by the Killing form of any semisimple Lie algebra. In physical terms, what this means is that there is in $q$-deformed geometry just one self-dual object $B_q(G)$ with two different scaling limits

$$U(\mathfrak{g}) \longleftarrow B_q(G) \to \mathbb{C}[G]$$

as $q \to 1$, and the structure of which underlies the deeper structure of $U_q(\mathfrak{g})$ and $\mathbb{C}_q[G]$ as well.

## Braided Groups and Quantum Planes

A super quantum group or super-Hopf algebra is not a quantum group or Hopf algebra since the key homomorphism property of $\Delta : H \to H \otimes H$ is modified: one must use in the target $H \underline{\otimes} H$ the $\mathbb{Z}_2$-graded or super tensor product of super algebras. Here,

$$(a \otimes b)(c \otimes d) = (-1)^{|b||c|} ac \otimes bd$$

for elements of degree $|b|, |c|$. Super quantum groups $U_q(gl_{m|n})$ etc., have been constructed and have an analogous theory to the bosonic versions above. Super spaces in physics are associated to differential forms and in the same way a bicovariant exterior algebra on a quantum group $H$ is generally a super quantum group. Here the exterior algebra is generated on by 1-forms and the coproduct on 1-forms is

$$\underline{\Delta} = \Delta_{\mathrm{L}} + \Delta_{\mathrm{R}}$$

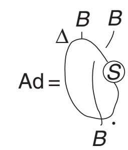
Here $\Delta_{\mathrm{L,R}}$ are the coactions of $H$ on 1-forms induced by the left and right coaction of $H$ on itself.

For a true understanding of quantum groups one must, however, go beyond such objects to "braided groups" or Hopf algebras with braid statistics (see Majid 1995). This theory was introduced by the author in the early 1990s as a more systematic method for $q$-deformation of structures in physics based on $q$-group covariance. We have seen that a quasitriangular quantum group, or any Hopf algebra through its double, generates a braided category with the flip map $\tau$ replaced by a braiding $\Psi_{V,W}$ between any two representations. Anything which is covariant under the quantum group means by definition that it lives in the braided category. Working with such "braided algebras" is similar to working with superalgebras except that one should use $\Psi$ in place of the graded transposition in any algebraic construction. In particular, two braided algebras have a natural "braided tensor product" also in the category. In concrete terms,

$$(a \otimes b)(c \otimes d) = a\Psi(b \otimes c)d$$

Then a Hopf algebra in the braided category or braided group is $B$, an algebra in the category along with a coalgebra and antipode, where $\underline{\Delta}: B \to B\underline{\otimes}B$ is an algebra homomorphism (*see* Braided and Modular Tensor Categories).

Next, we have mentioned in the section "*q*-Deformation enveloping algebras" that $q$-algebras generate topological invariants, but we now turn this on its head and use braid diagrams to do $q$-algebra. We write all operations as flowing down the page, any transpositions in the algebraic construction are expressed as a braid crossing $\Psi = \times$ or its inverse by the reversed braid crossing, and any other operations as nodes. Thus, a product is denoted $\curlyvee$ and a coproduct $\curlywedge$. Algebraic information "flows" along these "wires" much like the way that information flows along the wiring in a computer, except that under- and over-crossings represent distinct nontrivial operators. (In fact, one may formulate topological quantum computers exactly in this way.) In this notation, tensor products are denoted by juxtaposition and the trivial object in the category is omitted. In particular, one has the axioms and all general theorems of Hopf algebras at this diagrammatic level. For example, the adjoint action of any braided group $B$ on itself is (see Majid 1995)



In any concrete example, such diagrams turn into $R$-matrix formulas where $\Psi = \tau R$ as explained in the section "*q*-Deformation enveloping algebras."

A basic example of a braided group is the braided $q$-plane $\mathbb{C}_q^2$ with generators $x, y$ and relations $yx = qxy$. Its coproduct is the additive one $\underline{\Delta}x = x \otimes 1 + 1 \otimes x$ (and similarly for $y$) reflecting addition in the plane, but this is extended to products as a braided group with braiding $q^{1/2}R_{1/2,1/2}$ in terms of the $R$-matrix in the section "*q*-Deformation enveloping algebras." The extra factor here means that $\mathbb{C}_q^2$ lives in the braided category of representations of $U_q(gl_2) = \widetilde{U}_q(sl_2)$ (i.e., with an additional central $U_q(1)$ generator to provide the $q^{1/2}$). More precisely, the category is that of corepresentations of $\mathbb{C}_q[GL_2] = \widetilde{\mathbb{C}}_q[SL_2]$. The coaction in this case is

$$\Delta_{\mathrm{R}}(x\ y) = (x\ y) \otimes \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

where the additional central generator is encoded in the $q$-determinant (which is no longer set equal to 1). Notice that $q^{1/2}R_{1/2,1/2}$ has eigenvalues $q, -q^{-1}$ (one says that it is $q$-Hecke). Another braided group, associated now to the second eigenvalue is $\mathbb{C}_q^{0|2}$ with generators $\xi, \eta$ and relations $\eta\xi = -q^{-1}\xi\eta$, $\xi^2 = \eta^2 = 0$. It is the quadratic algebra dual of $\mathbb{C}_q^2$ (Manin 1988).

One has natural braided linear spaces for the whole family $\mathbb{C}_q[G]$, on which the latter coact after central extension. The general construction is as follows. If $V$ is an object in a braided category (e.g., the fundamental representation of a quantum group), let $T(V)$ be the tensor algebra generated by a basis $\{e_i\}$ of $V$ with no relations and the additive braided coproduct as above. Assume that $V$ has a dual $V^*$ in the category, and similarly form $T(V^*)$ with dual basis generators $\{f^i\}$. These two braided groups will be dually paired by extending the evaluation map to products, which takes the form of "braided integers" (see Majid 1995)

$$\langle f^{i_m} \cdots f^{i_1}, e_{j_1} \cdots e_{j_n} \rangle = \delta_{n,m}[n, \Psi]!^{i_1 \cdots i_n}_{j_1 \cdots j_n}$$

$$[n, \Psi] = \mathrm{id} + \Psi_{12} + \Psi_{12}\Psi_{23} + \cdots + \Psi_{12} \cdots \Psi_{n-1,n}$$

We now quotient by the kernels of this pairing to obtain $B(V), B(V^*)$ as two nondegenerately paired braided groups. This quotient generates all the relations, which are very often but not necessarily quadratic (in practice, one typically imposes only the quadratic relations to have braided groups with a possibly degenerate pairing). The construction is due to the author. Moreover, we can define partial derivatives on these braided groups by $\underline{\Delta} a = 1 \otimes a + e_i \otimes \partial^i a + \cdots$ for any $a$ in the algebra, that is, as an infinitesimal generator of translations under the braided group law; similarly exp, indefinite and Gaussian integration, Fourier transform, etc. The simplest example here is $B = \mathbb{C}[x]$ viewed not as a usual Hopf algebra but as a braided group in the category of $\mathbb{Z}$-graded spaces with $\Psi(x \otimes x) = qx \otimes x$. Also in this example the braided addition law on $\mathbb{C}[x]$ is

$$\underline{\Delta} x^n = \sum_{m=0}^{n} \begin{bmatrix} n \\ m \end{bmatrix}_q x^m \otimes x^{n-m}$$

defined by $[m]_q$, and the partial derivative defined by it is the Jackson (1908) $q$-derivative

$$\partial f(x) = \frac{f(x) - f(qx)}{x(1-q)}$$

while $\underline{\Delta} e_q(x) = e_q(x) \otimes e_q(x)$ if we allow power series. Such objects occur in the theory of $q$-special functions (*see* $q$-Special Functions).

Among deeper theorems (see Majid 1995, 2002), there is a triangular decomposition

$$U_q(\mathfrak{g}) = U_q(n_-) \rtimes T \ltimes U_q(n_+)$$

where $U_q(n_+)$ is a braided group and $U_q(n_-)$ is dually paired to its opposite. $T$ denotes the torus generators $\{g_a\}$ in the section "$q$-Deformation enveloping algebras." More generally, if $\mathfrak{g}_0 \subset \mathfrak{g}$ is a principal embedding of Lie algebras (given by an inclusion of Dynkin diagrams), then $U_q(\mathfrak{g}) = B^* \rtimes \widetilde{U_q(\mathfrak{g}_0)} \ltimes B^{\mathrm{op}}$ for some additive braided group of additional root generators and its dual. The general construction $B^* \rtimes H \ltimes B^{\mathrm{op}}$ here is "double bosonization" which associates to dual braided groups $B, B^*$ in the category of representations of some quasitriangular Hopf algebra $H$, a new quasitriangular Hopf algebra. The simplest example $B = \mathbb{C}[x]$ lives in the category of representations of $T = U_q(1)$ in an algebraic form. The dual is another braided line $\mathbb{C}[p]$ and $\mathbb{C}[p] \rtimes U_q(1) \ltimes \mathbb{C}[x]$ is a version of $U_q(sl_2)$. In this way, the braided line $\mathbb{C}[x]$ is at the root of all $q$-deformation quantum groups.

An earlier theorem is that for any braided group $B$ covariant under a (co)quasitriangular $H$, we have its 'bosonization' $B \rtimes H$. There is a similar "biproduct" if $B$ lives in the category of crossed modules for any Hopf algebra $H$. These have been extensively applied in physics notably in the construction of inhomogeneous quantum groups. Similar to $\mathbb{C}_q^2$ (but as a $*$-algebra), there is a natural self-dual $q$-Minkowski space $B = \mathbb{R}_q^{1,3}$ which is covariant under $U_q(\widetilde{so_{1,3}})$, and its bosonization is the $q$-Poincaré plus dilations group $\mathbb{R}_q^{1,3} \rtimes U_q(\widetilde{so_{1,3}})$. It is not possible to avoid the dilation here. The double-bosonization extends this to the $q$-conformal group $U_q(so_{2,4})$. The braided adjoint action becomes the action of conformal translations on $\mathbb{R}_q^{1,3}$. The construction of $q$-propagators and $q$-deformed physics on such $q$-Minkowski space was achieved in the mid 1990s as one of the main successes of the theory of braided groups.

This $\mathbb{R}_q^{1,3}$ can be given also as a matrix of generators, relations, $*$-structure and, a second braided coproduct:

$$\beta\alpha = q^2 \alpha\beta, \quad \gamma\alpha = q^{-2}\alpha\gamma, \quad \delta\alpha = \alpha\delta$$
$$\beta\gamma = \gamma\beta + (1 - q^{-2})\alpha(\delta - \alpha)$$
$$\delta\beta = \beta\delta + (1 - q^{-2})\alpha\beta$$
$$\gamma\delta = \delta\gamma + (1 - q^{-2})\gamma\alpha$$
$$\underline{\Delta}\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \underline{\otimes} \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}$$
$$\epsilon\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}^* = \begin{pmatrix} \alpha & \gamma \\ \beta & \delta \end{pmatrix}$$

This is in addition to the additive coproduct above. It corresponds to the point of view of Minkowski space as Hermitian $2 \times 2$ matrices. Note that $\underline{\Delta}$ is not a $*$-algebra map in the usual sense and indeed Hermitian matrices are not a group under multiplication, but this does form a natural braided $*$-bialgebra. If we quotient by the braided determinant relation $\alpha\delta - q^2\gamma\beta = 1$, we have the unit hyperboloid in $\mathbb{R}_q^{1,3}$ which turns out to be the braided group $B_q[SU_2]$ mentioned at the end of the previous section (as obtained canonically from $\mathbb{C}_q[SU_2]$). We now have a braided antipode

$$S\begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} = \begin{pmatrix} q^2\delta + (1 - q^2)\alpha & -q^2\beta \\ -q^2\gamma & \alpha \end{pmatrix}$$

This was the first nontrivial example of a braided group (Majid 1991b) and we see that it has two $q \to 1$ limits

$$U(su_2) \longleftarrow B_q[SU_2] \to \mathbb{C}[\text{Hyperboloid} \subset \mathbb{R}^{1,3}]$$

Because most constructions in physics can be uniformly deformed by such methods (including the totally $q$-antisymmetric tensor), one finds that $q$ provides a new regulator in which infinities in quantum field theory can be in principle be encoded as poles at $q = 1$. That transmutation from the

quantum group to its braided version unifies unitary nonabelian symmetries with pseudo-Riemannian geometry is another deeper aspect of relevance to physics. In addition, $q$-constructions have their original role in quantum integrable systems, at $q$ a root of unity and for infinite-dimensional (affine) Lie algebra deformations.

## Quasi-Hopf Algebras

Although the braided category of representations of a quantum group has a trivial "associator" $\Phi_{V,W,Z}:(V\otimes W)\otimes Z\to V\otimes(W\otimes Z)$ between any three objects, a general braided category and the diagrammatic methods of "braided algebra" in the last section do not require this (one simply translates diagrams into algebra by inserting $\Phi$ as needed). A more general object that generates such categories as its representations is a "quasi-Hopf algebra." This is a generalization of Hopf algebras in which the coproduct $\Delta:H\to H\otimes H$ is not necessarily coassociative. Instead,

$$
\begin{aligned}
&(\mathrm{id}\otimes\Delta)\Delta=\phi((\Delta\otimes\mathrm{id})\Delta\ )\phi^{-1}\\
&(\mathrm{id}\otimes\epsilon\otimes\mathrm{id})\phi=1\\
&\phi_{234}(\mathrm{id}\otimes\Delta\otimes\mathrm{id})(\phi)\phi_{123}\\
&\quad=(\mathrm{id}^2\otimes\Delta)(\phi)(\Delta\otimes\mathrm{id}^2)(\phi)
\end{aligned}
$$

for some invertible element $\phi\in H\otimes H\otimes H$. The numbers denote the position in the tensor product and one says that $\phi$ is a 3-cocycle. The axioms for the antipode and quasitriangular structure $\mathcal{R}$ are also modified. The tensor product of representations is given as usual by $\Delta$, and the braiding and associator by the actions of $\mathcal{R}$ and $\phi$.

This notion, due to Drinfeld (1990), arises when one wishes to write down the quantum groups $U_q(\mathfrak{g})$ more explicitly as built on the algebras $U(\mathfrak{g})$ (recall that they are isomorphic over formal power series). Thus, for each semisimple $\mathfrak{g}$ there is a natural (quasitriangular) quasi-Hopf algebra $(U(\mathfrak{g}),\phi,\mathcal{R})$ where $U(\mathfrak{g})$ has the usual Hopf algebra structure, $\mathcal{R}$ is an exponential of the split Casimir (or inverse Killing form) in $\mathfrak{g}\otimes\mathfrak{g}$ and $\phi$ is constructed as a solution of the Knizhnik–Zamolodchikov equations coming out of conformal field theory. This is not $U_q(\mathfrak{g})$ but it has an equivalent braided category of representations. Thus, there is an element $F\in U(\mathfrak{g})^{\otimes 2}$ (extended over formal power series) such that

$$
\begin{aligned}
&\Delta_F=F(\Delta\ )F^{-1},\qquad \mathcal{R}_F=F_{21}\mathcal{R}F^{-1}\\
&\phi_F\equiv F_{12}(\Delta\otimes\mathrm{id})(F)\phi(\mathrm{id}\otimes\Delta)(F^{-1})F_{23}^{-1}=1
\end{aligned}
$$

recovers $U_q(\mathfrak{g})$ as a quasitriangular Hopf algebra built directly on the algebra $U(\mathfrak{g})$. The conjugation operations here (and a similar process regarding the antipode) are a "Drinfeld twist" of a quasi-Hopf algebra, and such twisting by any invertible $F$ such that

$$(\epsilon\otimes\mathrm{id})F=(\mathrm{id}\otimes\epsilon)F=1$$

(a cochain) does not change the representation category up to equivalence. In the present case, the twist transforms $\phi$ into $\phi_F=1$, that is, into an ordinary Hopf algebra isomorphic over formal power series to $U_q(\mathfrak{g})$. Note that in rational conformal field theory the tensor product of representations appears as a finite-dimensional commutative associative algebra (the Verlinde algebra) with integer structure constants $N^{ij}{}_k$ (this comes from the operator-product expansion of primary fields in the theory). This is because one has more precisely a truncated representation category corresponding to $q$ a root of unity, and because we are identifying equivalent representations (so $N^{ij}{}_k$ are the multiplicity in the decomposition of a tensor product of two representations). However, if one wants to know the tensor product decomposition more fully, not just its isomorphism class, this is given in a choice of bases by recoupling matrices. Computation in terms of these shows that the actual tensor product is neither commutative nor associative, but of the form above at least in the case of the WZW model.

Hopf algebra theory typically extends to the quasi-Hopf case. For example, given a quasi-Hopf algebra $H$ there is a quantum double $D(H)$ at least in the finite-dimensional case, due to the author. An example is to take $H=\mathbb{C}(G)$ and $\phi$ a 3-cocycle on $G$ in the usual sense

$$
\begin{aligned}
&\phi(y,z,w)\phi(x,yz,w)\phi(x,y,z)\\
&\quad=\phi(x,y,zw)\phi(xy,z,w)
\end{aligned}
$$

on elements of $G$ and $\phi(x,1,y)=1$. Then $(\mathbb{C}(G),\phi)$ can be viewed as a quasi-Hopf algebra. Its double $D^{\phi}(G)$ is generated by $\mathbb{C}(G)$ as a sub-quasi-Hopf algebra and by elements of $G$ with

$$
\begin{aligned}
&x\cdot y=yx\sum_s\delta_s\chi(y,x)(s),\qquad \delta_s\cdot x=x\delta_{xsx^{-1}}\\
&\Delta x=\sum_{ab=s}\frac{\phi(x,x^{-1}ax,x^{-1}bx)\phi(a,b,x)}{\phi(a,x,x^{-1}bx)}\\
&\qquad\times x\delta_a\otimes x\delta_b
\end{aligned}
$$

in terms of a basis $\{\delta_s\}$ of $\mathbb{C}(G)$, the product of $G$ on the right, and

$$\chi(x,y)(s)=\frac{\phi(x,y,y^{-1}x^{-1}sxy)\phi(s,x,y)}{\phi(x,x^{-1}sx,y)}$$

a 2-cocycle on $G$ with values in $\mathbb{C}(G)$ (the algebra is a cocycle semidirect product). There is a quasitriangular structure $\mathcal{R} = \sum \delta_x \otimes x$. This quasi-Hopf algebra first appeared in discrete topological quantum field theory related to orbifolds in the work of Dijkgraaf, Pasquier, and Roche.

There are further generalizations in the same spirit and which are linked to conformal field theories of more general type; for example, weak (quasi-) Hopf algebras in which $\Delta 1 \neq 1 \otimes 1$ but is a projector. These have been related to quantum groupoids.

Finally, we mention some applications of twisting outside of the original context. First of all, we are not limited to starting with $U(\mathfrak{g})$: starting with any Hopf algebra or quasi-Hopf algebra $H$ we can similarly twist it to another one $H_F$ with the same algebra as $H$ and $\Delta_F, \mathcal{R}_F, \phi_F$ given by conjugation as above. The representation category remains unchanged up to equivalence, so in some sense the twisted object is equivalent. Moreover, if we start with a Hopf algebra $H$ and ask $F$ to be a 2-cocycle in the sense

$$F_{12}(\Delta \otimes \mathrm{id})(F)(\mathrm{id} \otimes \Delta)(F^{-1})F_{23}^{-1} = 1$$

then $H_F$ will remain a Hopf algebra. It has conjugated antipode (see Majid 1995)

$$S_F(a) = U(Sa)U^{-1}, \qquad U = \cdot(\mathrm{id} \otimes S)(F)$$

Many Hopf algebras are twists of more standard ones, for example, the multiparameter quantum groups tend to be twists of the standard $U_q(\mathfrak{g})$. Likewise, "triangular" Hopf algebras (where $\mathcal{R}_{21}\mathcal{R} = 1$) tend to be twists of classical group or enveloping algebras.

A second application of twists is an approach to quantization. Although it can be applied to $H$ itself, this is more interesting if we think of $H$ as a background quantum group and ask to quantize objects covariant under $H$. For the sake of discussion, we start with $H$ an ordinary Hopf algebra. We twist this to $H_F$ and denote by $\mathcal{T}$ the equivalence functor from representations of $H$ to representations of $H_F$. This functor acts as the identity on all objects and all morphisms, but comes with nontrivial isomorphisms $c_{V,W} : \mathcal{T}(V) \otimes \mathcal{T}(W) \to \mathcal{T}(V \otimes W)$ for any two objects, compatible with bracketting (see Majid 1995). Given any algebraic construction covariant under $H$, we simply apply the functor $\mathcal{T}$ to all aspects of the construction and obtain an equivalent $H_F$-covariant construction. As an example, if $A$ is an $H$-covariant algebra, then applying $\mathcal{T}$ to its product we have $\mathcal{T}(\cdot) : \mathcal{T}(A \otimes A) \to \mathcal{T}(A)$. Using $c_{A,A}$ we obtain a map

$$\bullet : \mathcal{T}(A) \otimes \mathcal{T}(A) \to \mathcal{T}(A)$$
$$a \bullet b = \cdot(F^{-1} \triangleright (a \otimes b))$$

in terms of the product in $A$. Thus, we have a new algebra $A_F$ built on the same vector space as $A$ but with a modified $\bullet$ product. This is called a "covariant twist" of an algebra and should not be confused with the Drinfeld twist above. It is due to the author in the early 1990s. If $F$ is a 2-cocycle, then $A_F$ remains associative. The transmutation construction mentioned in the section "Self-dual quantum groups" or the passage from $\mathbb{R}^4_q$ to $\mathbb{R}^{1,3}_q$ are examples in quantum group theory. Other examples include the standard Moyal product on $\mathbb{R}^n$, also called noncommutative spacetime $[x_\mu, x_\nu] = \mathrm{i}\theta_{\mu\nu}$ by string theorists (*see* Bicrossproduct Hopf Algebras and Noncommutative Spacetime).

If we do not demand that $F$ is a cocycle, then the algebra $A_F$ is still associative but in the target category, which means

$$(a \bullet b) \bullet c = (\bullet(\bullet))\Phi_{A,A,A}((a \otimes b) \otimes c)$$

Such objects are called "quasialgebras." It may still be that $\Phi_{A,A,A}$ happens to be trivial ($\phi_F$ happens to act trivially) so that $A_F$ remains associative. This turns out frequently to be the case and many quantizations in physics, including $\mathbb{C}_q[G]$ but not limited to $q$-examples, can be obtained in this way. It means that although they are associative there is a hidden nonassociativity which can surface in other constructions involving $\Phi$. The physical application here is with $H = U(\mathfrak{g})$ a classical enveloping algebra, $A$ functions on a classical manifold on which $\mathfrak{g}$ acts, and a cochain $F$. In general the resulting quasialgebra will not be associative but rather a quantization of a "quasi-Poisson manifold" obeying

$$\{a, \{b, c\}\} + \text{cylic} = 2\tilde{n}(a \otimes b \otimes c)$$

Here $\tilde{n}$ is the trivector field for the action of the lowest order part of $\phi_F$ and the (quasi)Poisson bivector is the leading-order part of $F_{21}F^{-1}$. As mentioned, there are many cases where $\tilde{n}$ (and the action of the rest of $\phi_F$) happens to be trivial.

Finally, let us give a discrete example using such quantum group methods. We consider $H = \mathbb{C}(G)$ and $F \in \mathbb{C}(G \times G)$ a cochain. Twisting by this gives $H_F = (\mathbb{C}(G), \phi_F)$ a quasi-Hopf algebra where

$$\phi_F(x, y, z) = \frac{F(y, z)F((x, yz)}{F(xy, z)F(x, y)}$$

We take $A = \mathbb{C}G$ the group algebra. The action of $\mathbb{C}(G)$ on it is the diagonal one. The modified algebra $A_F$ therefore has product

$$x \bullet y = F^{-1}(x, y)xy$$

in terms of the product in $G$, and will be a quasialgebra if $F$ is not a cocycle. For example, let

$G = (\mathbb{Z}_2)^3$ which we write additively (so elements are 3-vectors with values in $\mathbb{Z}_2$) and take

$$F(\boldsymbol{x}, \boldsymbol{y}) = (-1)^{\sum_{i<j} x_i y_j + y_1 x_2 x_3 + x_1 y_2 x_3 + x_1 x_2 y_3}$$

then,

$$\phi_F(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) = (-1)^{\boldsymbol{x} \cdot (\boldsymbol{y} \times \boldsymbol{z})}$$

Moreover, $A_F = \mathbb{O}$, the octonions (Albuquerque and Majid 1999). So these are a nonassociative quantization of the classical discrete space $(\mathbb{Z}_2)^3$. We see that they are in fact associative up to sign and with sign +1 when the corresponding 3-vectors are linearly independent.

## Noncommutative Geometry

In this article, we have frequently encountered the view of quantum groups and other noncommutative algebras as by definition the coordinate algebras on "noncommutative spaces." However, the "quantum groups approach" to such noncommutative geometry that emerges has a somewhat different flavor from other approaches, as we discuss now.

In fact, the problem of geometry at such a level was mentioned already by Dirac in the 1920s and led to theorems of Gelfand and Naimark in the 1940s and 1950s whereby a noncommutative $C^*$-algebra should be viewed as a noncommutative topological space, and of Serre and Swan in the 1960s whereby a finitely generated projective module should be viewed as a vector bundle. Algebraic $K$-theory led to further refinement of this picture and particularly, in the 1980s, to A Connes' formulation in terms of cyclic cohomology and "spectral triples" (*see* Noncommutative Geometry and the Standard Model; Noncommutative Tori, Yang–Mills and String Theory; Quantum Hall Effect; Hopf Algebra Structure of Renormalizable Quantum Field Theory; Path Integrals in Noncommutative Geometry). The quantum groups approach is less axiomatic, and consists of at least three disparate elements.

The first layer of the quantum groups approach is the theory of $q$-deformed groups and $q$-spaces on which they act, using braided category methods (such as braided linear spaces). The braided group additive law leads to partial derivatives and these define $q$-exterior algebras etc. This programme covered during the 1990s most of what is needed to $q$-deform physics in flat space at an algebraic level. Formulas here tend to be complex but controlled by $R$-matrices, and the correct $R$-matrix formulas can be found systematically by working with braided algebra as explained in the section "Braided groups and quantum planes." From a slightly different side, $q$-representation theory and the further theory of $q$-homogeneous spaces is intimately tied to a theory of $q$-special functions (such as the $q$-exponential function in the section "$q$-Deformation enveloping algebras") of interest in their own right (*see* $q$-Special Functions). The use of $*$-algebras in some cases completable to $C^*$-algebras is a point of contact with other approaches to noncommutative geometry but problems emerge when one considers the braiding. As a result, the natural $q$-Poincaré (plus dilation) quantum group is not even a Hopf $*$-algebra. Briefly, once one starts to braid the constructions, one may need to represent them with braided (not usual) Hilbert spaces and $q$-analysis.

The second layer of the quantum groups approach is based on "differential calculus" as a specification of an exterior algebra of differential forms or differential graded algebra (DGA). In general this is a wild problem but, as in classical geometry, the requirement of a quantum group covariance greatly narrows the possible calculi, although no longer to the point of uniqueness. The first examples of covariant calculi on the quantum group $\mathbb{C}_q[SU_2]$ were found by Woronowicz (1989). The bicovariant one of these was cast in $R$-matrix form by Jurco while the first actual classification results on the moduli of irreducible calculi were obtained by the author (the bicovariant ones are essentially in correspondence with irreducible representations $V$, with left-invariant differentials forming a braided group of the form $B(V \otimes V^*)$). Probably the most interesting feature of this theory is that for all $\mathbb{C}_q[G]$ the bicovariant $q$-calculus cannot be of classical dimensions. For example, for $\mathbb{C}_q[SU_2]$ the smallest nontrivial calculus is four dimensional. The "extra dimension" is a biinvariant 1-form $\theta$ which has the property that $[\theta, a] = \mathrm{d}a$ for all $a \in \mathbb{C}_q[SU_2]$ and which can be viewed as a spontaneously generated time (*see* Bicrossproduct Hopf Algebras and Noncommutative Spacetime). Quantum group methods also provide DGAs on finite groups, this time classified in the bicovariant case by nontrivial conjugacy classes. These therefore provide Lie structures on finite groups. One can go much further and define quantum principal bundles (with quantum groups as fiber) over general noncommutative algebras (Brzezinski and Majid 1993), associated bundles, frame bundles, and Riemannian geometry of the algebra (*see* Quantum Group Differentials, Bundles and Gauge Theory).

Again $q$-deformation provides key examples but the theory may then be applied to other situations.

For example, the permutation group $S_3$ has a natural connected calculus with dimensions $1:3:4:3:1$ (in other words the space has six points but each point has the local structure of a 4-manifold in some sense). It turns out to have a unique Levi-Civita type connection $\nabla$ for its invariant metric, with constant curvature. The use of DGAs here is in common with other approaches (e.g., Connes 1994) and indeed bundles associated to quantum group principal bundles and suitable connections can be shown to be projective modules. The approaches diverge at the level of spectral triples, however, and the examples of "Dirac operators" that emerge from quantum group methods do not usually obey the required axioms.

A third established layer of the quantum groups approach is to trade some of the noncommutativity for nonassociativity, as in the dual version of Drinfeld's construction, that is, $\mathbb{C}_q[G]$ in terms of classical $\mathbb{C}[G]$ as a (co)quasi-Hopf algebra. The general approach here is a quantization functor $\mathcal{T}$ which provides all constructions but which will typically bring out the underlying nonassociative geometry even when the noncommutative covariant algebras of interest is associative. For example, applying the functor to the classical exterior algebra $\Omega(G)$ gives a bicovariant $\Omega(\mathbb{C}_q[G])$ of classical dimensions but with nonassociative products (it is a supercoquasi-Hopf algebra). As before, one may then apply these quantum group methods to other algebras not related to $q$-deformation.

Beyond these are many recent developments, some of which are covered in other articles. Probably one of the most interesting frontiers, at the time of writing, is the exploration of links of both quantum groups and noncommutative geometry to number theory.

## From Classical Mechanics to Quantum Mechanics

The initial goal of semiclassical mechanics was to explore the correspondence principle, due to N Bohr in 1923, which states that one should recover the classical mechanics from the quantum mechanics as the Planck constant $h$ tends to zero. So we start with a very brief presentation of these two theories.

### Classical Mechanics

We start (with the Hamiltonian formalism) from a $C^\infty$ function $p$ on $\mathbb{R}^{2n}:(x,\xi)\mapsto p(x,\xi)$, which describes the motion of the system under consideration and is called the Hamiltonian. The variable $x$ corresponds, in the simplest case, to the position and $\xi$ to the momentum of one particle. The evolution is then described, starting at time 0 of a given point $(y,\eta)$, by the so-called Hamiltonian equations

$$\begin{aligned}\frac{\mathrm{d}x_j}{\mathrm{d}t} &= (\partial p/\partial\xi_j)(x(t),\xi(t)), \quad \text{for } j=1,\ldots,n\\ \frac{\mathrm{d}\xi_j}{\mathrm{d}t} &= -(\partial p/\partial x_j)(x(t),\xi(t)), \quad \text{for } j=1,\ldots,n\end{aligned} \qquad [1]$$

The classical trajectories are then defined as the integral curves of a vector field defined on $\mathbb{R}^{2n}$ called the Hamiltonian vector field associated with $p$ and defined by $H_p=(\partial p/\partial\xi,\ -\partial p/\partial x)$. All these definitions are more generally relevant in the framework of symplectic geometry on a symplectic manifold $M$ (but we choose, for simplicity, to explain the theory on $\mathbb{R}^{2n}$), which can be seen as the cotangent vector bundle $T^*\mathbb{R}^n$, and is the "local" model of the general situation. This space is equipped naturally with a symplectic structure defined by giving at each point a nondegenerate 2-form, which is here $\sigma:=\sum_j \mathrm{d}\xi_j\wedge\mathrm{d}x_j$. This 2-form permits us to associate canonically to a 1-form on $T^*\mathbb{R}^n_x$ a vector field on $T^*\mathbb{R}^n_x$. In this correspondence, if $p$ is a function on $T^*\mathbb{R}^n_x$, $H_p$ is associated with the differential $\mathrm{d}p$.

In this article, we consider the example of the Hamiltonian $p(x,\xi)=\xi^2+V(x)$, also called the Schrödinger Hamiltonian, as the guiding example. More specifically, the case of the harmonic oscillator, where $V$ is given by $V(x)=\sum_{j=1}^n \mu_j x_j^2$ (with $\mu_j>0$), is the most significant, which is the natural approximation of a potential near its minimum, when nondegenerate.

In the framework of the classical mechanics, the main questions could be:

- Are the trajectories bounded?
- Are there periodic trajectories?
- Is one trajectory dense in its energy surface?
- Is the energy surface compact?

The solution of these questions could be very difficult. Let us just mention the trivial fact that, if $p^{-1}(\lambda)$ is compact for some $\lambda$, then, by the conservation of energy law

$$p(x(t),y(t))=p(y,\eta) \qquad [2]$$

the whole trajectory starting of one point $(y,\eta)$ remains in the bounded set $\{p^{-1}(p(y,\eta))\}$ in $\mathbb{R}^{2n}$. This is in particular the case for the harmonic oscillator.

### Quantum Mechanics

The quantum theory was born dynamics-wise around 1920. It is structurally related to the classical mechanics in a way that we shall describe very briefly. In quantum mechanics, our basic object will be a (possibly nonbounded) self-adjoint operator defined on a dense subspace of a Hilbert space $\mathcal{H}$. In order to simplify the presentation, we shall always take $\mathcal{H}=L^2(\mathbb{R}^n)$.

This operator can be associated with $p$ by using the techniques of quantization. We choose here to present a procedure, called the Weyl quantization procedure (which was already known in 1928), which under suitable assumptions on $p$ and its derivatives, will be defined for $u\in\mathcal{S}(\mathbb{R}^n)$ by

$$\begin{aligned}p^{\mathrm{w}}(x,hD_x,h)u(x) &= (2\pi h)^{-n}\iint \exp\left(\frac{\mathrm{i}}{h}(x-y)\cdot\xi\right)\\ &\quad\times p\left(\frac{x+y}{2},\xi,h\right)u(y)\,\mathrm{d}y\,\mathrm{d}\xi\end{aligned} \qquad [3]$$

The operator $p^{\mathrm{w}}(x,hD_x,h)$ is called an $h$-pseudodifferential operator of Weyl symbol $p$. One can also write $\mathrm{Op}_h^{\mathrm{w}}(p)$ in order to emphasize that it is the operator associated to $p$ by the Weyl quantization. Here $h$ is a parameter which plays the role of the Planck constant.

Of course, one has to give a sense to these integrals and this is the object of the theory of the oscillatory integrals. If $p=1$, we observe that, by Plancherel's formula,

$$\begin{aligned}u(x) &= (2\pi h)^{-n}\iint \exp\left(\frac{\mathrm{i}}{h}(x-y)\cdot\xi\right)\\ &\quad\times u(y)\,\mathrm{d}y\,\mathrm{d}\xi\end{aligned} \qquad [4]$$

the associated operator is nothing but the identity operator. A way to rewrite any $h$-differential operator $\sum_{|\alpha|\le m} a_\alpha(x)(hD_x)^\alpha$ as an $h$-pseudodifferential operator is to apply it on both sides to [4]. In particular, we observe that if the symbol is $p(x,\xi) = \xi^2 + V(x)$, then the operator associated with $p$ by the $h$-Weyl quantization is the Schrödinger operator $-h^2\Delta + V$. Other interesting examples appear naturally in solid state physics. Let us, for example, mention the Harper operator $H$ (or almost-Mathieu; see Helffer and Sjöstrand (1989) and references therein), whose symbol is the map $(x,\xi) \mapsto \cos\xi + \cos x$, and which can also be defined, for $u \in L^2(\mathbb{R})$, by

$$(Hu)(x) = \tfrac{1}{2}(u(x+h) + u(x-h)) + \cos x\, u(x)$$

We shall later recall how to relate the properties of $p$ and those of the associated operator. More precisely, we shall describe under which conditions on $p$ the operator $p^{\mathrm{w}}(x, hD_x; h)$ is semibounded, symmetric, essentially self-adjoint, compact, with compact resolvent, trace class, Hilbert–Schmidt (see Robert (1987) for an extensive presentation). But before looking at a more general situation, let us consider the case of the Schrödinger operator $S_h = -h^2\Delta + V(x)$. If $V$ is (say, continuous) bounded from below, $S_h$, which is *a priori* defined on $\mathcal{S}(\mathbb{R}^n)$ as a differential operator, admits a unique self-adjoint extension on $L^2(\mathbb{R}^n)$. We are first interested in the nature of the spectrum. If $V(x) \to +\infty$ as $|x| \to \infty$, one can show that $S_h$, more precisely its self-adjoint realization, has compact resolvent and its spectrum consists of a sequence of eigenvalues tending to $\infty$. We are next interested in the asymptotic behavior of these eigenvalues.

In the case of the harmonic operator, corresponding to the potential

$$V(x) = \sum_{j=1}^{n} \mu_j x_j^2 \quad (\text{with } \mu_j > 0)$$

the criterion of compact resolvent is satisfied and the spectrum is described as the set of

$$\lambda_\alpha(h) = \sum_{j=1}^{n} \sqrt{\mu_j}(2\alpha_j + 1)h$$

for $\alpha \in \mathbb{N}^n$.

In this case we also have a complete description of the normalized associated eigenfunctions which are constructed recursively starting from the first eigenfunction corresponding to $\lambda_0(h) = \sum_j \sqrt{\mu_j} h$:

$$\phi_0(x;h) = \left(\prod_{j=1}^{n}\left(\frac{\sqrt{\mu_j}}{\pi h}\right)^{1/4}\right) \cdot \exp\left(-\frac{1}{2h}\sum_j \sqrt{\mu_j} x_j^2\right) \quad [5]$$

The eigenfunction $\phi_0$ is strictly positive and decays exponentially. Moreover (and here we enter in the semiclassical world), the local decay in a fixed closed set avoiding $\{0\}$ (which is measured by its $L^2$-norm) is exponentially small as $h \to 0$. In particular, this says that the eigenfunction lives asymptotically in the set $\{V(x) \le \lambda(h)\}$. This last set can also be understood as the projection by the map $(x,\xi) \mapsto x$ of the energy surface, which is classically attached to the eigenvalue $\lambda(h)$, that is, $\{(x,\xi) \in \mathbb{R}^{2n} \mid p(x,\xi) = \lambda(h)\}$. This is a typical semiclassical statement, which will be true in full generality.

### From Quantum Mechanics to Classical Mechanics: Semiclassical Mechanics

Before describing the mathematical tools involved in the exploration of the correspondence principle, let us describe a few results which are typical in the semiclassical context. They concern Weyl's asymptotics and the localization of the eigenfunctions.

**Weyl's asymptotics** We start with the case of the Schrödinger operator $S_h$, but we emphasize that the $h$-pseudodifferential techniques are not limited to this situation.

We assume that $V$ is a $C^\infty$-function on $\mathbb{R}^n$ which is semibounded and satisfies

$$\inf V < \underline{\lim}_{|x|\to\infty} V(x)$$

The Weyl theorem (which is a basic theorem in spectral theory) implies that the essential spectrum is contained in

$$\left[\underline{\lim}_{|x|\to\infty} V(x), +\infty\right]$$

It is also clear that the spectrum is contained in $[\inf V, +\infty]$. In the interval

$$I = \left[\inf V,\ \underline{\lim}_{|x|\to\infty} V(x)\right]$$

the spectrum is discrete, that is, it has only isolated eigenvalues with finite multiplicity. For any $E$ in $I$, it is consequently interesting to look at the counting function $N_h(E)$ of the eigenvalues contained in $[\inf V, E]$,

$$N_h(E) = \sharp\{\lambda_j(h); \lambda_j(h) \le E\} \quad [6]$$

The main semiclassical result is then

**Theorem 1** *With the previous assumptions, we have:*

$$\lim_{h\to 0} h^n N_h(E) = (2\pi)^{-n} \int_{V(x)\le E} (E - V(x))^{n/2}\, dx$$

The main term in the expansion of $N_h(E)$, which will be denoted by

$$W_h(E) := (2\pi h)^{-n} \int_{V(x)\le E} (E - V(x))^{n/2}\, dx$$

is called the Weyl term. It has an analog for the analysis of the counting function for Laplacians on compact manifolds (*see* Quantum Ergodicity and Mixing of Eigenfunctions and references therein), but let us emphasize that here $E$ is fixed and that one looks at the asymptotics as $h \to 0$. In the other case, $h$ is fixed and one looks at the asymptotics as $E \to +\infty$ (note that on a compact manifold and for the Laplacian, the formula $N_h(E) = N_1(E/h^2)$ permits switching between these cases).

Although this formula is rather old (first as a folk theorem), many efforts have been made by mathematicians for analyzing the remainder (see Robert (1987), Ivrii (1998) and references therein) $N_h(E) - W_h(E)$, whose behavior is again related to classical analysis. When $E$ is not a critical value of $V$, $h^{n+1}(N_h(E) - W_h(E))$ can be shown to be bounded but it appears to be $o(1)$ if the measure of the periodic points for the flow is 0 (see Ivrii (1998)).

Beyond the analysis of the counting function, one is also interested (e.g., in questions concerning the ground-state energy of an atom with a large number of particles, $N$, satisfying the Pauli exclusion principle (*see* Stability of Matter)) in other quantities like the Riesz means, which are defined, for a given $s \ge 0$, by

$$N_h^s(E) = \sum_j (E - \lambda_j)_+^s$$

The case $s = 0$ corresponds to the counting function. It is then natural to ask for the asymptotic behavior as $h \to 0$ of these functions.

We have, for example, the following result (Helffer–Robert, Ivrii–Sigal, and Ivrii; see Robert (1987) and Ivrii (1998)), which is written here in a more Hamiltonian version, when $E$ is not a critical value of $V$,

$$N_h^s(E) = (2\pi h)^{-n} \left( \int_{p_E(x,\xi)\le 0} (-p_E(x,\xi))^s\, dx \cdot d\xi \right) + \mathcal{O}(h^{\inf(1+s,2)})$$

with $p_E(x, \xi) = \xi^2 + V(x) - E$.

**Uncertainty principle and Weyl term** The Weyl term can be heuristically understood in the following way. According to the uncertainty principle, a "quantum" particle should occupy at least a volume of order $h^n$ in the phase space with the measure $dx\, d\xi$ (proportional to $(\sum_{j=1}^n d\xi_j \wedge dx_j)^n$). This guess is a consequence of the inequality

$$\frac{h}{2}\|u\|^2 \le \left( \int_{\mathbb{R}} (x - x_0)^2 |u|^2\, dx \right)^{1/2} \times \left( \int_{\mathbb{R}} \left| \left( \frac{h}{i}\frac{d}{dx} - \xi_0 \right) u \right|^2 dx \right)^{1/2}, \quad \forall u \in \mathcal{S}(\mathbb{R})$$

expressing the noncommutation of the operators $((h/i)d/dx - \xi_0)$ and (multiplication by) $(x - x_0)$. When $\|u\| = 1$ and $x_0$ (mean position) and $\xi_0$ (mean momentum) are defined by $x_0 := \int_{\mathbb{R}} x|u|^2\, dx$ and $\xi_0 := (h/i)\int_{\mathbb{R}} u'(x)\cdot \bar{u}(x)\, dx$, this inequality expresses the impossibility for a quantum particle to have a simultaneous small localization in position and momentum.

Consequently, the maximal number of "quantum" particles which can live in the region $\{p_E(x, \xi) \le 0\}$ is approximately (up to some universal multiplicative constant) the volume of this region divided by $(2\pi h)^n$.

**Lieb–Thirring inequalities and Scott's conjecture** In the case of regular potentials, we have seen that the quantity $h^n N_h^s(E)$ was asymptotically equal as $h \to 0$ to $L^{\rm cl}_{s,n}(\int_{V(x)\le E} (E - V(x))^{s+n/2}\, dx)$. For other questions occurring in atomic physics (*see* Stability of Matter), one is more interested in the existence of universal constants $M_{s,n}$ such that

$$h^n N_h^s(E) \le M_{s,n} \left( \int_{V(x)\le E} (E - V(x))^{s+n/2}\, dx \right)$$

for any $V$ and any $h$.

The best $M_{s,n}$ (which exists if $s + n/2 > 0$) is denoted by $L_{s,n}$ (for $s = 0$; this is called the Cwickel–Lieb–Rozenblium inequality). The semiclassical result gives the inequality $L_{s,n} \ge L^{\rm cl}_{s,n}$.

A still open question is the so-called Lieb–Thirring conjecture: do we have $L_{1,3} = L^{\rm cl}_{1,3}$? This is related to the question of the stability of the matter (*see* Stability of Matter). The last results in this direction have been obtained quite recently by A Laptev and T Weidl, who show, for example, the equality for $s \ge 3/2$.

The control, when $s = 1$, of a second term (for more singular potentials) for $N_h^s(E)$ was the object of the Scott conjecture, which was solved recently in many important cases by Hughes, Siedentop–Weikard, Ivrii–Sigal, and Feffermann–Secco (see Ivrii (1998), Stability of Matter, and references therein).

**Localization of the eigenfunctions** The localization property was already observed on the specific case of the harmonic oscillator. But this was a consequence

of an explicit description of the eigenfunctions. This is quite important to have a good description of the decay of the eigenfunctions (as $h \to 0$) outside the classically permitted region without having to know an explicit formula. Various approaches can be used.

The first one fits very well in the case of the Schrödinger operator (more generally to $h$-pseudodifferential operators with symbols admitting holomorphic extensions in the $\xi$ variable) and gives exponential decay. This is based on the so-called Agmon estimates (developed in the semiclassical context by Helffer–Sjöstrand and Simon). We shall not say more about this approach, which is the starting point of the analysis of the tunneling (see Helffer (1988), Dimassi and Sjöstrand (1999), and Martinez (2002)).

The second one is an elementary application of the $h$-pseudodifferential formalism which will be described later and leads, for example, to the following statement. Let $E$ in $I$ and let $(\lambda(h_j), \phi_{(h_j)}(x))$ be a sequence of spectral pairs in $I \times L^2(\mathbb{R}^n)$, where $h_j \to 0$ as $j \to +\infty, \lambda(h_j) \to E$, and $x \mapsto \phi_{(h_j)}(x)$ is an $L^2$-normalized eigenfunction associated with $\lambda(h_j)$. Let $\Omega$ be a relatively compact set in $\mathbb{R}^n$ such that

$$V^{-1}(]-\infty, E]) \cap \bar{\Omega} = \emptyset$$

Then, there exists, for all integer $N$, a constant $C_{N,\Omega}$ such that

$$\|\phi_{(h_j)}\|_{L^2(\Omega)} \leq C_{N,\Omega} \cdot h_j^N$$

A third one uses the notion of frequency set and will be discussed later (see also the book of Martinez (2002) for what can be done with the Fourier–Bros–Iagolnitzer transform as developed by J Sjöstrand).

## Brief Introduction to the *h*-Pseudodifferential Calculus

For fixed $h$, the pseudodifferential calculus has a long story starting in its modern form in the 1960s. A rather achieved version of the calculus is presented in Hörmander (1984). We will emphasize here on the semiclassical aspect of the calculus, that is, on the dependence of the calculus on the parameter $h > 0$.

### *h*-Pseudodifferential Calculus

**Basic calculus: the class $S^0$** We shall mainly discuss the most simple one called the $S^0$ calculus. Let us first say that the $S^0$ calculus is sufficient once we have suitably (micro)-localized the problem (e.g., by the functional calculus). Note that it is also sufficient for the local analysis of many problems occurring on compact manifolds.

This class of symbols $p$ is simply defined by the conditions:

$$|\partial_x^\alpha \partial_\xi^\beta p(x, \xi)| \leq C_{\alpha,\beta} \qquad [7]$$

for all $(\alpha, \beta) \in \mathbb{N}^n \times \mathbb{N}^n$. The symbols can possibly be $h$-dependent. With this symbol, one can associate an $h$-pseudodifferential operator by [3]. This operator is a continuous operator on $\mathcal{S}(\mathbb{R}^n)$ but can also be defined by duality on $\mathcal{S}'(\mathbb{R}^n)$.

The first basic analytical result is the Calderon–Vaillancourt theorem (see Hörmander (1984)) establishing the $L^2$-continuity. We also mention that if $p$ is in $L^2(\mathbb{R}^{2n})$, the associated operator is Hilbert–Schmidt. One can also give conditions on $p$ implying the trace-class property (replace the uniform control in [7] by a control in $L^1$).

The second important property is the existence of a calculus. If $a$ is in $S^0$ and $b$ is in $S^0$ then the composition $a^{\mathrm{w}}(x, hD_x) \circ b^{\mathrm{w}}(x, hD_x)$ of the two operators is a pseudodifferential operator associated with an $h$-dependent symbol $c$ in $S^0$:

$$a^{\mathrm{w}}(x, hD_x) \circ b^{\mathrm{w}}(x, hD_x) = c^{\mathrm{w}}(x, hD_x; h)$$

We see here that we immediately meet symbols admitting expansions in powers of $h$, which we shall call regular symbols, in the sense that they admit expansions of the type

$$a(x, \xi; h) \sim \sum_j a_j(x, \xi) h^j$$

$$b(x, \xi; h) \sim \sum_j b_j(x, \xi) h^j$$

In this case the Weyl symbol $c$ of the composition has a similar expansion:

$$c(x, \xi; h) \sim \left[ \exp\left( \frac{\mathrm{i}h}{2} (D_x \cdot D_\eta - D_y \cdot D_\xi) \right) \times (a(x, \xi; h) \cdot b(y, \eta; h)) \right]_{x=y;\ \xi=\eta}$$

The symbol $a_0$ is called the principal symbol. At the level of principal symbols, the rule is simply that the principal symbol of $a^{\mathrm{w}} \circ b^{\mathrm{w}}$ is the product of the principal symbols of $a^{\mathrm{w}}$ and $b^{\mathrm{w}}$: $c_0 = a_0 \cdot b_0$. Another important property is the following correspondence between commutator of two operators and Poisson brackets. The principal symbol of the commutator $(1/h)(a^{\mathrm{w}} \circ b^{\mathrm{w}} - b^{\mathrm{w}} \circ a^{\mathrm{w}})$ is $(1/\mathrm{i})\{a_0, b_0\}$, where $\{f, g\}$ is the Poisson bracket of $f$ and $g$:

$$\{f, g\}(x, \xi) = H_f g = \sum_j \left( \partial_{\xi_j} f \cdot \partial_{x_j} g - \partial_{x_j} f \cdot \partial_{\xi_j} g \right)$$

**About global classes** The class $S^0$ is far from being sufficient for analyzing the global spectral problem and we refer the reader to Hörmander (1984) or Robert (1987) for an extensive presentation of the theory and for the discussion of other quantizations. Our initial operators (think of the harmonic oscillator) do not belong to these classes of pseudodifferential operators. We are consequently obliged to construct more general classes including these examples in order to realize this localization. Once such a class is introduced, one of the main points to consider is the existence of a quasi-inverse (or parametrix) for a suitably defined elliptic operator of positive order. Following Beals–Feffermann (see also the most general Hörmander calculus in Hörmander (1984) and references therein), we introduce a scale function (possibly $h$-dependent; typically, $m(x,\xi;h) = h^{\nu} m_0(x,\xi)$) $(x,\xi) \mapsto m(x,\xi;h)$ and $C^\infty$ strictly positive weight functions $\phi$ and $\Phi$ such that $\phi \cdot \Phi \geq 1$. All these functions are strictly positive and should satisfy additional conditions on their variation and growth. The class of symbols $S^{\mathrm{reg}}(m,\phi,\Phi)$ is defined by

$$|D_x^\alpha D_\xi^\beta p(x,\xi;h)| \leq C_{\alpha,\beta}\, m(x,\xi;h)\phi(x,\xi)^{-|\alpha|}\Phi(x,\xi)^{-|\beta|}$$

These apparently complicated estimates permit actually the control of the variation of the symbol in reference balls defined by

$$\phi^{-2}(x_0,\xi_0)|x-x_0|^2 + \Phi^{-2}(x_0,\xi_0)|\xi-\xi_0|^2 \leq c$$

**Elliptic theory** As noted above, the main point is to have a large class of invertible operators, such that the inverses are also in the class. This is what we call an elliptic theory and the typical statement is:

**Theorem 2** *Let P be an h-pseudodifferential operator associated with a symbol p in* $S^{\mathrm{reg}}(m,\phi,\Phi)$. *We assume that it is elliptic in the sense that* $1/p$ *belongs to* $S^{\mathrm{reg}}(1/m,\phi,\Phi)$. *Then there exists an h-pseudodifferential operator Q with symbol in* $S^{\mathrm{reg}}(1/m,\phi,\Phi)$, *such that*

$$QP = I + R; \qquad PQ = I + S$$

*The remainders R and S are pseudodifferential operators with symbols in*

$$\bigcap_N S\left(\left(\frac{h}{\Phi\cdot\phi}\right)^N, \phi, \Phi\right)$$

These remainders are called "regularizing." Note that this notion depends strongly on the choice of the class of pseudodifferential operators! When $\phi = \Phi = 1$, we are just inverting modulo a remainder whose norm in $\mathcal{L}(L^2)$ is $\mathcal{O}(h^\infty)$ (or simply $\mathcal{O}(h)$ at the first step). With other weights like $\phi = \Phi = \sqrt{1+|x|^2+|\xi|^2}$, we invert $P$ modulo a remainder, which has, in addition, a distribution kernel in the Schwartz space $\mathcal{S}(\mathbb{R}^n \times \mathbb{R}^n)$. The invertibility modulo a compact operator (which implies the Fredholm property) is a consequence of the assumption

$$\lim_{|x|+|\xi|\to+\infty} \phi(x,\xi)\Phi(x,\xi) = +\infty$$

The proof is rather easy, once the formalism of composition and the notion of principal symbol have been understood. One can indeed start from the operator $Q_0$ of symbol $1/p$ and observe that $Q_0P = I + R_1$ holds, with $R_1$ in $\mathrm{Op}^{\mathrm{w}}(S((h/\Phi\cdot\phi),\phi,\Phi))$. The operator $(I+R_1)^{-1}Q_0 \sim (\sum_{j\geq 0}(-1)^j R_1^j)Q_0$ gives essentially the solution.

## Essential Self-Adjointness and Semiboundedness

We now sketch two applications of this calculus in spectral theory. We shall usually consider in our applications an $h$-pseudodifferential operator $P$, whose Weyl symbol $p$ is regular, that is, admitting an asymptotic expansion:

$$\text{(H0)} \quad p(x,\xi;h) \sim \sum_{j\geq 0} h^j p_j(x,\xi)$$

(We refer to Robert (1987), Hörmander (1984), and Dimassi and Sjöstrand (1999) for a more precise formulation). Moreover, we assume that

$$\text{(H1)} \quad (x,\xi) \mapsto p(x,\xi;h) \in \mathbb{R}$$

This implies, as can be immediately seen from [3], that $p^{\mathrm{w}}$ is symmetric (= formally self-adjoint):

$$\langle p^{\mathrm{w}}u, v\rangle_{L^2} = \langle u, p^{\mathrm{w}}v\rangle_{L^2}, \quad \forall u,v \in \mathcal{S}(\mathbb{R}^n)$$

The third assumption is that the principal symbol is bounded from below (and there is no restriction to assume that it is positive)

$$\text{(H2)} \quad p_0(x,\xi) \geq 0$$

This assumption implies that the operator itself is bounded from below. This result belongs to the family of the so-called Garding inequalities. More precisely, the assumption (there are other quantizations, e.g., the anti-Wick quantization, for which this result becomes trivial, the difference between the two quantizations being $\mathcal{O}(h)$) will basically give, if $m \geq 1$, the existence of a constant $C$ such that, for any $u \in \mathcal{S}(\mathbb{R}^n)$,

$$\langle Pu, u\rangle_{L^2\times L^2} \geq -C\, h||u||^2$$

Everything is proved if $m(x,\xi)=(p_0+1)$ is a scale function, if $p_j$ and their derivatives are controlled by $(p_0+1)$:

$$\text{(H3)}\quad |\partial_x^\alpha \partial_\xi^\beta p_j(x,\xi)| \le C_{\alpha,\beta,j}(p_0+1)\phi(x,\xi)^{-j-|\alpha|} \times \Phi(x,\xi)^{-j-|\beta|}$$

for all $(\alpha,\beta)\in\mathbb{N}^n\times\mathbb{N}^n$, and if there is a suitable control of the family $(N\in\mathbb{N})$ of symbols

$$\left(\frac{\phi\Phi}{(p_0+1)h}\right)^{(N+1)}\left(p-\sum_{j=0}^{N} p_j h^j\right)$$

Under these assumptions, the main result is that $P$ is, for $h$ small enough, essentially self-adjoint. This means that the operator which was initially defined on $\mathcal{S}(\mathbb{R}^n)$ by the pseudodifferential operator with symbol $p$ admits a unique self-adjoint extension.

### The Functional Calculus

It is well known by the spectral theorem for a self-adjoint operator $P$ that a functional calculus exists for Borel functions. What is important here is to find a class of functions (actually essentially $C_0^\infty$) such that $f(P)$ is a pseudodifferential operator in the same class as $P$ with simple rules of computation for the principal symbol.

We are starting from the general formula (see Dimassi and Sjöstrand (1999))

$$f(P) = -\pi^{-1}\lim_{\epsilon\to 0^+}\iint_{|\mathrm{Im}\,z|\ge\epsilon}\frac{\partial\tilde{f}}{\partial\bar{z}}(x,y)(z-P)^{-1}\,\mathrm{d}x\,\mathrm{d}y$$

which is true for any self-adjoint operator and any $f$ in $C_0^\infty(\mathbb{R})$. Here the function $(x,y)\mapsto\tilde{f}(x,y)$ (note that $z=x+\mathrm{i}y$) is a compactly supported, almost analytic extension of $f$ to C. This means that $\tilde{f}=f$ on $\mathbb{R}$ and that for any $N\in\mathbb{N}$ there exists a constant $C_N$ such that

$$\left|\frac{\partial\tilde{f}}{\partial\bar{z}}(z)\right|\le C_N\left|\mathrm{Im}\,z\right|^N$$

The main result due to Helffer–Robert (see also Dimassi and Sjöstrand (1999) and references therein) is that, for $P$ an $h$-regular pseudodifferential operator satisfying (H0)–(H3) and $f$ in $C_0^\infty(\mathbb{R})$, the operator $f(P)$ is an $h$-pseudodifferential operator, whose Weyl symbol $p_f(x,\xi;h)$ admits a formal expansion in powers of $h$:

$$p_f(x,\xi;h)\sim\sum_{j\ge 0}h^j p_{f,j}(x,\xi)$$

with

$$p_{f,0}=f(p_0)$$
$$p_{f,1}=p_1\cdot f'(p_0)$$
$$p_{f,j}=\sum_{k=1}^{2j-1}(-1)^k(k!)^{-1}d_{j,k}f^{(k)}(p_0),\quad\forall j\ge 2$$

where the $d_{j,k}$ are universal polynomial functions of the symbols $\partial_x^\alpha\partial_\xi^\beta p_\ell$, with $|\alpha|+|\beta|+\ell\le j$.

The main point in the proof is that we can construct, for $\mathrm{Im}\,z\ne 0$, a parametrix (= approximate inverse) for $(P-z)$ with a nice control as $\mathrm{Im}\,z\to 0$. The constants controlling the estimates on the symbols are exploding as $\mathrm{Im}\,z\to 0$ but the choice of the almost analytic extension of $f$ absorbs any negative power of $|\mathrm{Im}\,z|$.

As a consequence, we get that if, for some interval $I$ and some $\epsilon_0>0$,

$$\text{(H4)}\quad p_0^{-1}(I+[-\epsilon_0,\epsilon_0])\text{ is compact}$$

then the spectrum is, for $h$ small enough, discrete in $I$.

In particular, we get that, if $p_0(x,\xi)\to+\infty$ as $|x|+|\xi|\to+\infty$, then the spectrum of $P_h$ is discrete ($P_h$ has compact resolvent). Under the assumption (H4), we get more precisely the following theorem.

**Theorem 3** *Let $P$ be an $h$-regular pseudodifferential operator satisfying (H0)–(H4), with $I=[E_1,E_2]$, then, for any $g$ in $C_0^\infty([E_1,E_2])$, we have the following expansion in powers of $h$:*

$$\mathrm{tr}[g(P(h))]\sim h^{-n}\sum_{j\ge 0}h^j T_j(g),\quad\text{as } h\to 0$$

*where $g\mapsto T_j(g)$ are distributions in $\mathcal{D}'(]E_1,E_2[)$. In particular, we have*

$$T_0(g)=(2\pi)^{-n}\iint g(p_0(x,\xi))\,\mathrm{d}x\,\mathrm{d}\xi$$
$$T_1(g)=(2\pi)^{-n}\iint g'(p_0(x,\xi))p_1(x,\xi)\,\mathrm{d}x\,\mathrm{d}\xi$$

This theorem is just obtained by integration of the preceding one, because in these cases the trace of a trace-class pseudo-differential operator $\mathrm{Op}^{\mathrm{w}}(a)$ is given by the integral of the symbol $a$ over $\mathbb{R}^{2n}=\mathbb{R}_x^n\times\mathbb{R}_\xi^n$. According to [3], the distribution kernel is given by the oscillatory integral:

$$K(x,y;h)=(2\pi h)^{-n}\int_{\mathbb{R}^n}\exp\left(\frac{\mathrm{i}}{h}(x-y)\cdot\xi\right)\times a\left(\frac{x+y}{2},\xi;h\right)\mathrm{d}\xi\qquad[8]$$

and the trace of $\mathrm{Op}^{\mathrm{w}}(a)$ is the integral over $\mathbb{R}^n$ of the restriction to the diagonal of the distribution kernel:

$$K(x,x) = (2\pi h)^{-n} \int_{\mathbb{R}^n} a(x,\xi;h)\,\mathrm{d}\xi$$

Of course, one could think of using the theorem with $g$, the characteristic function of an interval, in order to get, for example, the behavior of the counting function attached to this interval. This is of course not directly possible and this will be obtained only through Tauberian theorems (Hörmander (1968), (1984), Ivrii (1998)) and at the price of additional errors.

Let us, however, remark that, if the function $g$ is not regular, then the length of the expansion depends on the regularity of $g$. So it will not be surprising that, by looking at the Riesz means, we shall get a better expansion when $s$ is large.

Anyway, one basic interest of functional calculus is to permit a localization in the energy of the operator. For a general $h$-pseudodifferential operator, it could be difficult to approximate an operator like $\exp(-\mathrm{i}tP/h)$ by suitable Fourier integral operators but approximate $\exp(-\mathrm{i}tP/h)f(P)$ for suitable compactly supported $f$ could be easier.

Another interest is that for suitable $f$ (possibly $h$-dependent) the operator $f(P)$ could have better properties than the initial operator. This idea will, for example, be applied for the theorem concerning clustering. It appears, in particular, very powerful in dimension 1, where we can in some interval of energy find a function $t \mapsto f(t;h)$ admitting an expansion in powers of $h$ such that $f(P;h)$ has the spectrum of the harmonic oscillator. This is a way to get the Bohr–Sommerfeld conditions (see Helffer–Robert (1987), together with Maslov (1972), Leray (1981), or the thesis of A Voros in 1977), which reads:

$$f(\lambda_n(h);h) \sim (2n+1)h \quad \text{modulo } \mathcal{O}(h^\infty)$$

## *h*-Fourier Integral Operators and Evolution Operators

### Classical Mechanics

Let us come back to the Hamilton equations [1]. The local existence of solutions is well known. If, in addition, we assume (H4), the energy conservation law implies global existence for these solutions, if the initial data $(y,\eta)$ belong to $p^{-1}(I)$.

We recall that $(y,\eta) \mapsto \phi^t(y,\eta) = (x(t,y,\eta),\xi(t,y,\eta))$ defines for any $t$ a canonical transformation, that is, a diffeomorphism respecting the symplectic 2-form:

$$\sigma = \sum_j \mathrm{d}\xi_j \wedge \mathrm{d}x_j$$

We shall denote by $\Lambda^t$ the graph of $\phi^t$ which is a Lagrangian submanifold (which means that at each point $m$ of the manifold the restriction of the symplectic two-form to $T_m\Lambda^t$ is 0) for the 2-form on $\mathbb{R}^{2n} \times \mathbb{R}^{2n}$: $\sum_j \mathrm{d}\eta_j \wedge \mathrm{d}y_j - \sum_j \mathrm{d}\xi_j \wedge \mathrm{d}x_j$.

When the projection $(y,\eta,x,\xi) \mapsto (\eta,x)$ gives a local system of coordinates for $\Lambda_t$ (and this will always be the case for $(\eta,x)$ in a compact set and $t$ small enough), one easily finds, using the Lagrangian character of $\Lambda^t$, a function $(\eta,x) \mapsto S_t(x,\eta)$ such that

$$\Lambda^t = \{y,\eta,x,\xi \mid y = \partial_\eta S_t,\ \xi = \partial_x S_t\}$$

This function is only defined modulo an arbitrary function of $t$. In order to get a more natural choice, we consider the Lagrangian submanifold in $\mathbb{R}^{2n} \times \mathbb{R}^{2n} \times \mathbb{R}^2$ defined as

$$\Lambda = \{y,\eta,x,\xi,t,\tau | (x,\xi) = \phi^t(y,\eta),\ \tau = -p_0(x,\xi)\} \quad [9]$$

The parametrization of $\Lambda$, by its projection $(y,\eta,x,\xi,t,\tau) \mapsto (\eta,x,t)$, will now give a natural function $(\eta,x,t) \mapsto S(t,x,\eta) = S_t(x,\eta)$ describing $\Lambda$ by

$$\Lambda = \{y,\eta,x,\xi,t,\tau | \xi = \partial_x S,\ y = \partial_\eta S,\ \tau = \partial_t S\} \quad [10]$$

We observe that we can choose

$$S(0,x,\eta) = x \cdot \eta \quad [11]$$

and that $S$ is automatically a solution of the Hamilton–Jacobi equation

$$(\partial_t S)(t,x,\eta) + p_0(x,\partial_x S(t,x,\eta)) = 0 \quad [12]$$

also called the eiconal equation.

We also observe the following property (by comparison of [9] and [10]):

$$\phi^t(\partial_\eta S(t,x,\eta),\eta) = (x,\partial_x S(t,x,\eta))$$

We have actually an explicit expression of $S(t,x,\eta)$ in term of the inverse $y(t,x,\eta)$ of the map $y \mapsto x(t,y,\eta)$:

$$\begin{aligned} S(t,x,\eta) &= y(t,x,\eta)\cdot\eta \\ &\quad + \int_0^t \Big[\sum_i \xi_i(s,y,\eta)\cdot(\partial_{\xi_i}p)(x(s,y,\eta),\xi(s,y,\eta)) \\ &\quad - p(y,\eta)\Big]\,\mathrm{d}s_{/y=y(t,x,\eta)} \end{aligned}$$

For the harmonic oscillator, easy computations give

$$p(x,\xi) = \tfrac{1}{2}(\xi^2 + x^2), \qquad H_p = (\xi,-x)$$
$$\phi^t(y,\eta) = (y\cos t + \eta\sin t,\ -y\sin t + \eta\cos t)$$

and

$$S(t,x,\eta) = -\tfrac{1}{2}(x^2+\eta^2)\cdot(\tan t) + \frac{x\cdot\eta}{\cos t}$$

### Fourier Integral Operators

We have already given in [8] the distribution kernel of an $h$-pseudodifferential operator. It appears useful to generalize this point of view by considering more generally objects defined similarly as

$$K(x,y;h) = (2\pi h)^{-r} \int_{\mathbb{R}^N} \exp\left(\frac{\mathrm{i}}{h}\phi(x,y,\theta)\right) a(x,y,\theta;h)\,\mathrm{d}\theta$$

There are a lot of examples entering in this framework. The representation of the metaplectic group in $L^2(\mathbb{R}^n)$ appears to be in this class, with the specificity that the phase is quadratic (Guillemin and Sternberg (1977)). A quite elementary case corresponds to the case when $N=0$ and $\phi(x,y)=x\cdot y$. No $\theta$ variable is present and so no integration appears with respect to $\theta$. When $a=1$, this defines essentially the Fourier transform. Under suitable conditions on $\phi$ and $a$, one can show that the associated operators are continuous on $\mathcal{S}(\mathbb{R}^n)$ (this is, of course, the case for the Fourier transform). This was done by Asada and Fujiwara, who transpose the theory developed by Hörmander (1971) in this context, and we should also mention the older (but more formal) work by Maslov (1972) (see also Leray (1981)). We actually do not need it in the semiclassical context because the case when the amplitude is with compact support is sufficient.

The basic object is first to look, thinking of the stationary-phase theorem, which gives the main contribution as $h \to 0$ in this "formal integral" (*see* Stationary Phase Approximation), at the critical set $\mathcal{C}_\phi$:

$$\mathcal{C}_\phi = \{(x,y,\theta) \in \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^N | (\partial_\theta \phi)(x,y,\theta) = 0\}$$

In the case of a pseudodifferential operator, we find that it is included in $\{x=y\}$. Then we associate the canonical object, which is a Lagrangian submanifold called $\Lambda_\phi$ and defined as

$$\Lambda_\phi = \{(x,\xi,y,\eta) | \exists\theta \text{ s.t. } \xi = \nabla_x\phi(x,y,\theta),$$
$$\eta = -\nabla_y\phi(x,y,\theta), \nabla_\theta\phi(x,y,\theta) = 0\}$$

The assumptions on $\phi$ (which are omitted here) are given in order to get that $\Lambda_\phi$ is a regular manifold at least on the support of $a$. The associated operators are called Fourier integral operators (FIOs). L. Hörmander (1971, 1984) has developed a general and more intrinsic machinery but with a homogeneity condition on the phase which is irrelevant in the semiclassical context. This theory permits also the reduction to normal forms for Hamiltonians in continuation of what can be done in classical mechanics.

### Quantum Evolution

We just sketch how one approximates the operator $\exp(-\mathrm{i}tP/h)$ by an FIO. The formal construction is probably rather old (Maslov 1972, Fedoryuk and Maslov 1981) but the rigorous approach with estimates of the remainders was first considered by J Chazarain with rather strong assumptions. It has been later realized that we need only a local approximation of this operator and everything becomes easier.

The first approach followed by Helffer–Robert (see Robert (1987)) is to localize in energy, within the functional calculus associated to the operator $P$. If $I$ is an interval and $\chi$ is with compact support in $I$, it appears to be easier to approximate $\exp(-\mathrm{i}tP/h)\chi(P)$ when $P$ satisfies (H4) in a neighborhood of $I$.

We do not need any more assumptions at $\infty$ and the composition by $\chi(P)$ localizes the construction.

Although this construction is simple because we remain within a functional calculus which involves only functions of $P$, it is not always sufficient to localize in energy. We have then to localize through more general $h$-pseudodifferential operators and consider $\exp(-\mathrm{i}tP/h)a^{\mathrm{w}}(x,hD_x)$, where $a$ is a symbol with compact support. We shall quickly develop the first approach. The result is that one can approximate $U_\chi(t) := \chi(P)\exp(-\mathrm{i}tP/h)$ by a Fourier integral operator of the form

$$K_\chi(t,x,y;h) = (2\pi h)^{-n} \int^{\mathrm{osc}} \exp\left(-\frac{\mathrm{i}}{h}(S(t,x,\eta) - y\cdot\eta)\right)$$
$$\times\, d_\chi(t,x,\eta;h)\,\mathrm{d}\eta$$

with $d_\chi \sim \sum_j d_{\chi,j}h^j$, in order to have

$$\left\| \chi(P)\exp\left(-\frac{\mathrm{i}tP}{h}\right) - K_\chi(t) \right\|_{\mathcal{L}(L^2)} = \mathcal{O}(h^\infty)$$

Writing that $U_\chi(t)$ is a solution of $(hD_t + P)U_\chi = 0$, $(U_\chi)(0) = \chi(P)$, and expanding in powers of $h$, one gets a sequence of equations permitting to determine recursively the symbols. The first one was analyzed in [12] and reads, in the case when $P = -h^2\Delta + V$:

$$(\partial_t S)(t,x,\eta) + |\nabla_x S(t,x,\eta)|^2 + V(x) = 0$$

with the initial condition $S(0,x,\eta) = x\cdot\eta$.

This has been solved for $t$ small enough. The other equations are called transport equations. The first one is, for $a(t,x,\eta) = d_{\chi,0}(t,x,\eta)$,

$$\partial_t a + (\partial_\xi p_0)(x,\partial_x S(t,x,\eta))\cdot\partial_x a + ca = f$$

with initial condition $a(0,x,\eta) = \chi(p_0(x,\eta))$.

This type of equation is easily solved by integration along the integral curves of the vector field $\partial_t + (\partial_\xi p_0)(x,\partial_x S(t,x,\eta))\cdot\partial_x$.

## Applications

### The Frequency Set

One has already met the question of localization of the eigenfunctions. It appears important to give this localization, not only in position (in domain of $\mathbb{R}^\nu$) but directly in the phase space. This can be described by the notion of frequency set attached to a bounded family $u_h$ of functions in $L^2(\mathbb{R}^\nu)$ (or more generally of distributions in $\mathcal{S}'(\mathbb{R}^\nu)$). Here $h$ belongs to an interval $(0, h_0]$ or more generally to a subset of $\mathbb{R}^+$ having 0 as accumulation point.

**Definition 4** We shall say that $(x_0, \xi_0) \in \mathbb{R}^\nu \times \mathbb{R}^\nu$ does not belong to the frequency set of the family $u_h$ and write $(x_0, \xi_0) \notin \mathrm{FS}(u_h)$, if there exists a compactly supported function $\phi$ equal to 1 in a neighborhood of $x_0$ and a neighborhood $\mathcal{V}$ of $\xi_0$ in which the $h$-Fourier transform of $u_h$ satisfies, as $h \to 0$,

$$\int \exp\left(-\frac{\mathrm{i}x \cdot \xi}{h}\right) \phi(x) u_h(x)\, \mathrm{d}x = \mathcal{O}(h^\infty) \text{ in } \mathcal{V}$$

For example, the frequency set $\mathrm{FS}(u_h)$ of $u_h(x) = \chi(x) \exp(\mathrm{i}\,\theta(x)/h)$ with compactly supported $\chi$ is contained in $\{(x, \xi) \mid x \in \operatorname{supp} \chi, \xi = \nabla_x \theta(x)\}$, and the frequency set of the coherent state,

$$x \mapsto \Psi_{y,\eta,h}(x) = h^{-\nu/4} \cdot \exp\left(\frac{\mathrm{i}(x-y) \cdot \eta}{h}\right) \times \exp\left(-\frac{(x-y)^2}{h}\right)$$

is reduced to a point $(y, \eta)$.

In this semiclassical context, this notion seems to have been introduced by Guillemin and Sternberg (1977) and is further discussed in the book of Robert (1987) (see references therein). This is the semiclassical analog of the well-known notion of wave front set of a distribution introduced by Hörmander (1984) in the $C^\infty$-category for describing the singularities of a distribution, but note that a major difference is that the frequency set is attached to a family. If $P$ is an $h$-pseudodifferential operator with symbol in $S^0$, it is possible, as a consequence of the elliptic theory, to prove that: $\mathrm{FS}(Pu_{(h)}) \subset \mathrm{FS}(u_{(h)})$. For an FIO $F$ attached to a canonical relation $\kappa$, we get similarly: $\mathrm{FS}(Fu_{(h)}) \subset \kappa(\mathrm{FS}(u_{(h)}))$.

We also get a microlocal version of the localization result for the eigenfunctions mentioned in the first section (using again the parametrix construction).

**Theorem 5** *Let $E$ be in $I$ and let $(\lambda(h_j), \phi_{(h_j)}(x))$ be a sequence in $I \times L^2(\mathbb{R}^n)$, where $\lambda(h_j) \to E$ and $h_j \to 0$ as $j \to \infty$, $x \mapsto \phi_{(h_j)}(x)$ is an associated eigenfunction to $\lambda(h_j)$ with norm 1. Then*

$$\mathrm{FS}(\phi_{(h_j)}) \subset p_0^{-1}(E)$$

*Moreover, the frequency set of the family $\phi_{(h_j)}$ is invariant under the Hamiltonian flow $\phi^t$.*

The last statement in the above theorem is the analog of the theorem on the propagation of singularities for the solution of a partial differential equation (PDE) (see Hörmander (1984)) and is a consequence of the Egorov theorem, which will be presented in the next subsection.

Another remarkable property is that (see, e.g., the report on the lecture of T Paul in Rauch and Simon (1997), say, in the case of dimension 1, when $P$ is a harmonic oscillator, then $\exp(-\mathrm{i}t/hP)\psi_{y,\eta;h}$ is a coherent state attached to $\phi^t(y, \eta)$.

### Egorov's Theorem

Egorov's theorem plays a central role in the classical theory of PDE by permitting to reduce the study of general differential operators to the study of simpler model operators, the simplest one being $\partial/\partial x_n$ (see Hörmander (1984)). We use it here in a simple form, given in the semiclassical context by Robert (1987), and which will play an important role in the study of ergodic situations (*see* Quantum Ergodicity and Mixing of Eigenfunctions, and references therein). The theorem is the following:

**Theorem 6** *Let $P$ satisfy assumptions (H0)–(H3). For all a's in $S^0$ with compact support and all $t \in \mathbb{R}$, we have*

$$\left\| \exp\left(-\mathrm{i}\frac{t}{h}P\right) a^{\mathrm{w}}(x, hD_x) \exp\left(\mathrm{i}\frac{t}{h}P\right) - a_t^{\mathrm{w}}(x, hD_x) \right\|_{\mathcal{L}(L^2)} = \mathcal{O}(h)$$

*where*

$$a_t(x, \xi) = a(\phi^t(x, \xi))$$

*and $\phi^t$ is the flow of $H_{p_0}$, where $p_0$ is the principal symbol of $P$.*

The proof is based on the study of the operator $\exp(-\mathrm{i}(t/h)P)\, a^{\mathrm{w}}(x, hD_x) \exp(\mathrm{i}(t/h)P)$, which appears as the composition of three FIOs. But the Lagrangian manifold associated with this composition is the graph of the identity, and this is consequently a pseudodifferential operator whose "principal" symbol can be computed modulo $\mathcal{O}(h)$ as $a(\phi^t(x, \xi))$. As an immediate consequence, $FS(\exp(-\mathrm{i}tP/h)u_h) = \phi^t(FS(u_h))$.

### The Poisson Relation

We start from the harmonic oscillator

$$H(h) = \frac{1}{2}\left(-h^2\frac{d^2}{dx^2} + x^2\right)$$

Its spectrum is given by $(n+1/2)h$ $(n \geq 0)$. Its symbol is $a_0(x,\xi) = (1/2)(\xi^2 + x^2)$ and the corresponding flow, for any strictly positive level $E$, is periodic with primitive period $2\pi$. The quantity we are interested in is

$$S_h^\chi(t) := \sum_{j\in\mathbb{N}} \chi\left(\left(j+\tfrac{1}{2}\right)h\right)\exp\left(-it\left(j+\tfrac{1}{2}\right)\right)$$

Using the classical Poisson relation,

$$\sum_{k\in\mathbb{Z}} \hat{f}(k)\exp(ikx) = (2\pi)\cdot\sum_{k\in\mathbb{Z}} f(x+2k\pi)$$

one shows rather easily that the frequency set of $S_\chi$ is

$$\text{FS}\ (S_h^\chi) = \{(2k\pi,\tau)|\tau > 0,\ \tau \in \text{supp}\ \chi, k \in \mathbb{Z}\} \cup (\mathbb{R}\times\{0\}$$

This admits the following generalization, initiated in this context by Chazarain.

**Theorem 7** *Let $P$ satisfy* (H0)–(H4). *Let $\chi$ be a function with compact support in $I$ and let $t \mapsto f_\chi(t;h)$ be the family of distributions defined by*

$$f_\chi(t;h) = \text{tr}\left(\exp\left(-\frac{itP}{h}\right)\chi(P)\right)$$

*Then* $\text{FS}(f_\chi)$ *is contained in*

$$\{(t,\tau)|\tau \in \text{supp}\ (\chi) \text{ and } \exists(x,\xi) \text{ s.t. } p_0(x,\xi) = \tau, \phi^t(x,\xi) = (x,\xi)\}$$

According to the definition, we have to study

$$\int \exp\left(-\frac{it\tau}{h}\right)\theta(t) f_\chi(t;h)\mathrm{d}t$$

This takes the form

$$\int c(t,x,\eta)\exp\frac{i}{h}(-t\tau + S(t,x,\eta) - x\eta)\mathrm{d}t\,\mathrm{d}x\,\mathrm{d}\eta$$

and can be analyzed by a nonstationary-phase theorem, in order to determine for which value of $\tau$ the quantity is $\mathcal{O}(h^\infty)$.

### Gutzwiller's Formula

The Gutzwiller formula was established formally by Gutzwiller (1971). It then appears in the context of high-energy spectral asymptotics in contributions of Colin de Verdière, Chazarain, and Duistermaat and Guillemin (see Duistermaat and Guillemin (1975), Hörmander (1984), Guillemin and Sternberg (1977); see also Semi-Classical Spectra and Closed Orbits and Quantum Ergodicity and Mixing of Eigenfunctions). In the semiclassical context, the simplest statement (cf. Chazarain, Helffer–Robert, Guillemin–Uribe, Meinrencken, Paul–Uribe, Dozias, Combescure–Ralston–Robert – see Robert (1987), Rauch and Simon (1997), Dimassi and Sjöstrand (1999), and in the recent article by Combescure *et al.* (1999) for techniques involving coherent states) can be presented in the following way. For a noncritical $E$, we introduce the energy surface $W_E = \{w \in T^*\mathbb{R}^n \,|\, p_0(w) = E\}$. Let $P(h)$ an $h$-pseudodifferential operator satisfying (H0)–(H4), with $I = \{E\}$. We also assume that

(Cl) The restriction of the flow $\phi^t_{p_0}$ to $W_E$ is clean. (A flow $\phi^t$, associated with a $C^\infty$-vector field $X$ on a manifold $W$, is called clean if the two following properties are satisfied:
- the set $\Gamma = \{(t,w) \in \mathbb{R}\times W \,|\, \phi^t(w) = w\}$ is a submanifold of $\mathbb{R}\times W$;
- in each point $\gamma = (t,w)$ of $\Gamma$, the tangent space to $\Gamma$ is given by $T_\gamma\Gamma = \{(\tau,v) \in \mathbb{R}\times T_wW \,|\, \tau X(w) + (D\phi^t)(w)\cdot v = v\}$.)

Then there exists a sequence of distributions $\gamma_k \in \mathcal{D}'(\mathbb{R})$, such that, for all $\phi \in \mathcal{S}(\mathbb{R})$ with compactly supported Fourier transform, we have the asymptotic expansion in powers of $h$:

$$\sum_{\lambda_j(h)\in[E-\epsilon_0/2,E+\epsilon_0/2]} \phi(h^{-1}(\lambda_j(h)-E)) \sim \sum_{j=0}^{\infty}\gamma_j(\hat{\phi})h^{-n+1+j} \qquad [13]$$

Moreover, the supports of the distributions are contained in the set of the periods of the periodic trajectories of the flow contained in $W_E$.

Actually, the proof gives more information on the structure of the different distributions. Let us just write the formula for $\gamma_0$:

$$\gamma_0 = (\pi)^{-n/2}\left(\frac{d}{d\lambda}\int_{p(x,\xi)\leq\lambda} dx d\xi\right)_{\lambda=E}\delta_0$$

where $\delta_0$ is the Dirac measure at 0.

### Clustering of Eigenvalues

We shall mention one typical result due to Chazarain–Helffer–Robert in this context, but inspired by previous results obtained for the Laplacian on compact manifolds (*see* Semi-Classical Spectra and Closed Orbits, Quantum Ergodicity and Mixing of Eigenfunctions and references therein, including Chazarain, Duistermaat–Guillemin, and Colin de Verdière).

Clustering means that the spectrum is concentrated around a specific sequence tending to $\infty$. This was observed in the case of the Laplacian on the sphere $S^{n-1}$ by explicit computations. Here we assume that, with $I = [E_1, E_2]$, the conditions (H0)–(H4) are satisfied and that

- (H5) $[E_1, E_2]$ does not meet the set of critical values of $p_0$.
- (H6) $\forall E \in [E_1 - \epsilon, E_2 + \epsilon]$, $W_E$ is connected.
- (H7) $\forall E \in [E_1 - \epsilon, E_2 + \epsilon]$, the Hamiltonian flow associated with $p_0$ is periodic, with period $T(E) > 0$, on $W_E$ (with $T(E)$ bounded).
- (H8) $\forall E \in [E_1 - \epsilon, E_2 + \epsilon]$, the subprincipal $p_1$ vanishes on $W_E$.

Then, under these conditions, one first observes that for a suitable $C^\infty$-function $f$ defined in a neighborhood of $[E_1, E_2]$, the period of the Hamiltonian flow associated with $f(p_0)$ can be chosen as constant and equal to $2\pi$. Extending the function $f$ suitably, one can then state the following result of Chazarain–Helffer–Robert:

**Theorem 8** *There exists $h_0$ and $C$ such that, for $0 < h \leq h_0$,*

$$\sigma(f(P(h))) \cap [E_1, E_2] \subset \bigcup_{k \in \mathbb{Z}} I_k(h)$$

*where*

$$I_k(h) = \left[ -\frac{S}{2\pi} - \frac{h}{4}\mu + kh - Ch^2, -\frac{S}{2\pi} - \frac{h}{4}\mu + kh + Ch^2 \right]$$

$$S = \int_\gamma \xi \, dx - 2\pi E$$

*for some (hence for any) periodic trajectory $\gamma$ of period $2\pi$, and $\mu$ is the Maslov index of this trajectory.*

Moreover, one can compute the multiplicity, in each of the intervals $I_k$. The property remains true (e.g., Dozias proved this (see Rauch and Simon (1997)) in the case when the assumption is made only for one energy $E$, but in intervals $[E - ah, E + ah]$, where $a$ can be large but $h$ is small enough.

**Remark 1** These results appear first in the context of high energy for Laplacians on compact manifolds. After illuminating contributions by physicists like Balian–Bloch, the main ideas (see the presentation in Semi-Classical Spectra and Closed Orbits) appear in the works of Colin de Verdière, Chazarain, Duistermaat–Guillemin (1975), and Weinstein (see also Hörmander (1984) and Quantum Ergodicity and Mixing of Eigenfunctions). The proof given in the semiclassical context is actually more general (it contains the case of the Laplacian on a Riemannian manifold) and shows that the results are true for general Hamiltonians.

**Remark 2** (the case of dimension 1). In this particular case, the flow is periodic and the above theorems gives the localization of the problem predicted by the Bohr–Sommerfeld relations and the computation of the multiplicity gives $n_k(h) = 1$ for $h$ small enough. This point of view was developed by Helffer–Robert (1987) (*see* Semi-Classical Spectra and Closed Orbits).

Similar properties have been extended to the case of integrable systems by Colin de Verdière in the high-energy context and in the semiclassical context by Charbonnel and Ivrii (see Ivrii (1998), Dimassi and Sjöstrand (1999), and references therein).

**Remark 3** Another interesting application of semi-classical analysis concerns the Schnirelman theorem treating the case when the flow is ergodic. We refer the reader to Quantum Ergodicity and Mixing of Eigenfunctions for references and to Helffer–Martinez–Robert (see Rauch and Simon (1997) for references) for the specific statement for general Hamiltonians in semiclassical analysis.

## Conclusions and Suggestions for Further Reading

In this brief survey we have tried to present some of the foundational techniques appearing in the "mathematical" semiclassical analysis. Of course, this is very limited, and semiclassical methods go far beyond the verification of the correspondence principle. One can refer to semiclassical analysis for many other problems where the same analysis (with a small parameter $h$) is relevant but where $h$ is no more the Planck constant. This could be a flux (Harper's equation) or the inverse of a flux, the inverse of a mass (Born–Oppenheimer's approximation), of an energy, or of a number of particles. We have not developed this point of view here.

The books given in the bibliography will allow the reader to discover other fields. The books by Robert (1987), Helffer (1988) and Dimassi and Sjöstrand (1999) present the basic statements of the theory. The book by Martinez (2002) is more "microlocal" in spirit. The lectures published in Rauch and Simon (1997) give a rather good idea of the state of art in the middle of the 1990s, and we also refer the reader to other articles in this encyclopedia for the presentation of the resonances (*see* Resonances), spectral problems connected with ergodicity (*see* Quantum Ergodicity and Mixing of Eigenfunctions), Kolmogorov–Arnol'd–Moser theory (*see* Normal Forms and Semi-Classical Approximation), and trace formulas (*see* Semi-Classical Spectra and Closed Orbits). The book by Ivrii (1998) gives the

most sophisticated theorems on the counting functions (including boundaries, singularities, ...) but is only written for specialists.

# Hubbard Model

**H Tasaki**, Gakushuin University, Tokyo, Japan

## Definitions

The Hubbard model is a standard theoretical model for strongly interacting electrons in a solid. It is a minimum model which takes into account both quantum many-body effects and strong nonlinear interaction between electrons. Here we review rigorous results on the Hubbard model, placing main emphasis on magnetic properties of the ground states.

Let the lattice $\Lambda$ be a finite set whose elements $x, y, \ldots \in \Lambda$ are called sites. Physically speaking, each site corresponds to an atomic site in a crystal. The Hubbard model is based on the simplest tight-binding description of electrons (Figure 1), where a single state is associated with each site.

For each $x \in \Lambda$ and $\sigma \in \{\uparrow, \downarrow\}$, we define the creation and the annihilation operators $c^\dagger_{x,\sigma}$ and $c_{x,\sigma}$, respectively, for an electron at site $x$ with spin $\sigma$. ($A^\dagger$ is the adjoint or the Hermitian conjugate of $A$.) These operators satisfy the canonical anti-commutation relations

$$\begin{aligned} \left\{c^\dagger_{x,\sigma}, c_{y,\tau}\right\} &= \delta_{x,y}\,\delta_{\sigma,\tau} \\ \left\{c^\dagger_{x,\sigma}, c^\dagger_{y,\tau}\right\} &= \{c_{x,\sigma}, c_{y,\tau}\} = 0 \end{aligned} \qquad [1]$$

for any $x, y \in \Lambda$ and $\sigma, \tau = \uparrow, \downarrow$, where $\{A, B\} = AB + BA$. The number operator is defined by

$$n_{x,\sigma} = c^\dagger_{x,\sigma}\, c_{x,\sigma} \qquad [2]$$

which has eigenvalues 0 and 1.

The Hilbert space of the model is constructed as follows. Let $\Phi_{\text{vac}}$ be a normalized vector state which satisfies $c_{x,\sigma}\Phi_{\text{vac}} = 0$ for any $x \in \Lambda$ and $\sigma = \uparrow, \downarrow$. Physically, $\Phi_{\text{vac}}$ corresponds to a state where there are no electrons in the system. For arbitrary subsets $\Lambda_\uparrow, \Lambda_\downarrow \subset \Lambda$, we define

$$\Phi_{\Lambda_\uparrow,\Lambda_\downarrow} = \left(\prod_{x\in\Lambda_\uparrow} c^\dagger_{x,\uparrow}\right)\left(\prod_{x\in\Lambda_\downarrow} c^\dagger_{x,\downarrow}\right)\Phi_{\text{vac}} \qquad [3]$$

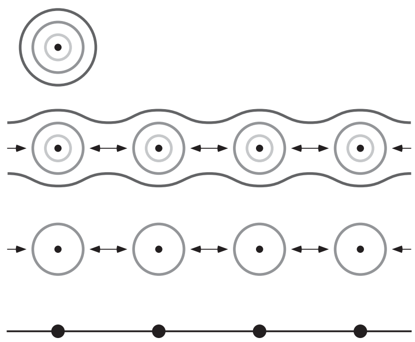

**Figure 1** A highly schematic figure which explains the philosophy of tight-binding description. (a) A single atom which has multiple electrons in different orbits. (b) When atoms come together to form a solid, electrons in the black orbits become itinerant, while those in the light gray orbits are still localized at the original atomic sites. Electrons in the gray orbits are mostly localized around the atomic sites, but tunnel to nearby gray orbits with nonnegligible probabilities. (c) We only consider electrons in the gray orbits, which are expected to play essential roles in determining various aspects of low-energy physics of the system. (d) If the gray orbit is nondegenerate, we get a lattice model in which electrons live on lattice sites and hop from one site to another. In a simplified treatment of a metal, the black and the gray orbits correspond to the 4*s* and the 3*d* bands, respectively.

in which sites in $\Lambda_\uparrow$ are occupied by up-spin electrons and sites in $\Lambda_\downarrow$ by down-spin electrons. We fix the electron number $N_e$, which is an integer satisfying $0 < N_e \le 2|\Lambda|$. (We denote by $|S|$ the number of elements in a set $S$.) The Hilbert space for the system with $N_e$ electrons is spanned by the basis states [3] with all subsets $\Lambda_\uparrow$ and $\Lambda_\downarrow$ such that $|\Lambda_\uparrow| + |\Lambda_\downarrow| = N_e$.

We define total spin operators $\hat{S}_{\text{tot}} = (\hat{S}^{(1)}_{\text{tot}}, \hat{S}^{(2)}_{\text{tot}}, \hat{S}^{(3)}_{\text{tot}})$ by

$$\hat{S}^{(\alpha)}_{\text{tot}} = \frac{1}{2} \sum_{\substack{x\in\Lambda \\ \sigma,\tau=\uparrow,\downarrow}} c^\dagger_{x,\sigma} (p^{(\alpha)})_{\sigma,\tau}\, c_{x,\tau} \qquad [4]$$

for $\alpha = 1, 2$, and 3. Here $p^{(\alpha)}$ are the Pauli matrices

$$p^{(1)} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad p^{(2)} = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}, \quad p^{(3)} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad [5]$$

The operators $\hat{S}_{\text{tot}}$ are the generators of global SU(2) rotations of the spin space. As usual, we denote the eigenvalue of $(\hat{S}_{\text{tot}})^2$ as $S_{\text{tot}}(S_{\text{tot}}+1)$. The maximum possible value of $S_{\text{tot}}$ is $S_{\max} = N_e/2$ when $N_e \le |\Lambda|$, and $S_{\max} = |\Lambda| - (N_e/2)$ when $N_e \ge |\Lambda|$.

The most general Hamiltonian of the Hubbard model is

$$H = -\sum_{\substack{x,y\in\Lambda \\ \sigma=\uparrow,\downarrow}} t_{x,y}\, c^\dagger_{x,\sigma} c_{y,\sigma} + \sum_{x\in\Lambda} U_x\, n_{x,\uparrow} n_{x,\downarrow} \qquad [6]$$

Here the first term describes quantum-mechanical motion of electrons which hop around the lattice according to the amplitude $t_{x,y} = t_{y,x} \in \mathbb{R}$. Usually, $t_{x,y}$ is nonnegligible only when the two sites $x$ and $y$ are close to each other. The second term represents nonlinear interaction between electrons. There is an increase in energy by $U_x \in \mathbb{R}$ when the site $x$ is occupied by both up-spin electron and down-spin electron. We usually set $U_x > 0$ to mimic (screened) Coulomb interaction between electrons.

The Hamiltonian $H$ commutes with the total spin operator $\hat{S}^{(\alpha)}_{\text{tot}}$ for $\alpha = 1$, 2, and 3. One can thus investigate simultaneous eigenstates of $(\hat{S}_{\text{tot}})^2$ and $H$. For $S_{\text{tot}}$ in the allowed range, we denote by $E_{\min}(S_{\text{tot}})$ the lowest possible energy among the states which satisfy $(\hat{S}_{\text{tot}})^2\Phi = S_{\text{tot}}(S_{\text{tot}}+1)\Phi$.

## Wave–Particle Dualism in the Hubbard Model

It is illuminating to examine the eigenstates of the Hamiltonian [6] for the following two special cases.

First suppose that one has $U_x = 0$ for all $x \in \Lambda$, that is, the model has no interactions. For $i = 1, 2, \ldots, |\Lambda|$, let $\psi^{(i)} = (\psi^{(i)}_x)_{x\in\Lambda} \in \mathbb{C}^\Lambda$ be the single-electron eigenstate, which is the solution of the Schrödinger equation

$$-\sum_{y\in\Lambda} t_{x,y}\, \psi^{(i)}_y = \epsilon_i \psi^{(i)}_x \quad \text{for any } x \in \Lambda \qquad [7]$$

We order the energy eigenvalues as $\epsilon_i \le \epsilon_{i+1}$. By defining the corresponding creation operator by $a^\dagger_{i,\sigma} = \sum_{x\in\Lambda} \psi^{(i)}_x c^\dagger_{x,\sigma}$, we see that, for any subsets $I_\uparrow, I_\downarrow \in \{1, 2, \ldots, |\Lambda|\}$ such that $|I_\uparrow| + |I_\downarrow| = N_e$, the state

$$\Psi_{I_\uparrow, I_\downarrow} = \left(\prod_{i\in I_\uparrow} a^\dagger_{i,\uparrow}\right)\left(\prod_{i\in I_\downarrow} a^\dagger_{i,\uparrow}\right)\Phi_{\text{vac}} \qquad [8]$$

is an eigenstate of $H$ (with $U_x = 0$) with the eigenvalue $E = \sum_{i\in I_\uparrow} \epsilon_i + \sum_{i\in I_\downarrow} \epsilon_i$. The ground states are obtained by choosing $I_\uparrow, I_\downarrow$ which minimize $E$. In particular, when $N_e$ is even and the single-electron eigenenergies $\epsilon_i$ are nondegenerate, the ground state is unique and written as

$$\Phi_{\text{GS}} = \left(\prod_{i=1}^{N_e/2} a^\dagger_{i,\uparrow} a^\dagger_{i,\downarrow}\right)\Phi_{\text{vac}} \qquad [9]$$

The fact that this ground state has the minimum possible spin $S_{\text{tot}} = 0$ is known as Pauli paramagnetism.

We have seen that the Hamiltonian $H$ with $U_x = 0$ can be diagonalized by using single-electron

eigenstates $\psi^{(i)}$. When $(t_{x,y})$ has a translation invariance, each $\psi^{(i)}$ behaves as a "wave." We can say that the noninteracting models can be understood in terms of the wave picture of electrons.

Next suppose that $t_{x,y}=0$ for all $x,y\in\Lambda$, that is, the electrons do not hop. Then the Hamiltonian [6] is readily diagonalized in terms of the basis state [3], where the corresponding eigenvalue is simply $E=\sum_{x\in\Lambda_\uparrow\cap\Lambda_\downarrow}U_x$. In this case, the model is best understood in the particle picture of electrons.

We thus see that the wave–particle dualism manifests itself in the Hubbard model in an essential manner. When both the first and the second terms in the Hamiltonian [6] are present, there takes place a "competition" between wave-like nature and particle-like nature of electrons. The competition generates rich nontrivial phenomena including antiferromagnetism, ferromagnetism, metal–insulator transition, and (probably) superconductivity. To investigate these phenomena is a major motivation in the study of the Hubbard model.

## One-Dimensional Model

The Hubbard model defined on a simple one-dimensional lattice is easier to study. But it does not exhibit truly nontrivial behavior as the following classical theorem of Lieb and Mattis suggests.

**Theorem 1** *Consider a Hubbard model on a one-dimensional lattice* $\Lambda=\{1,2,\ldots,N\}$ *with open boundary conditions. We assume that* $t_{x,y}\neq 0$ *if* $|x-y|=1$, *and* $t_{x,y}=0$ *if* $|x-y|>1$. $t_{x,x}\in\mathbb{R}$ *and* $U_x\in\mathbb{R}$ *are arbitrary. Then one has* $E_{\min}(S_{\text{tot}})<E_{\min}(S_{\text{tot}}+1)$ *for any* $S_{\text{tot}}=0,1,\ldots,S_{\max}-1$ *(or* $S_{\text{tot}}=1/2,3/2,\ldots,S_{\max}-1$*).*

As a consequence, one finds that the ground states always have $S_{\text{tot}}=0$ (or $S_{\text{tot}}=1/2$) as in the noninteracting models.

The translation invariant model with $t_{x,y}=t$ if $|x-y|=1$, $t_{x,y}=0$ if $|x-y|\neq 1$, and $U_x=U$ can be solved by using the Bethe ansatz, as was first shown by Lieb and Wu. It was found that the model is insulating for all $U>0$, and there is no metal–insulator transition. (A metal–insulator transition is expected to take place in higher dimensions.) Earlier works on the Bethe ansatz were based on the assumption that the Bethe ansatz equation gives the true ground states. Recently, the existence and the uniqueness of the Bethe ansatz solution for the ground state of a finite system was proved by Goldbaum.

## Half-Filled Systems

The system in which the electron number $N_e$ is identical to the number of sites $|\Lambda|$ is said to be half-filled. Many (but not all) physical systems can be modeled as a half-filled Hubbard model.

Based on a heuristic perturbation theory, low-energy properties of half-filled models with large $U$ are expected to be similar to those of Heisenberg antiferromagnetic spin systems. There is no electrical conduction, and the spin degrees of freedom may show antiferromagnetic long-range order in the ground states.

This expectation is partly justified by the following theorem due to Lieb. A Hubbard model is said to be bipartite if the lattice $\Lambda$ can be decomposed into a disjoint union of two sublattices as $\Lambda=A\cup B$ (with $A\cap B=\emptyset$), and it holds that $t_{x,y}=0$ whenever $x,y\in A$ or $x,y\in B$. In other words, only hopping between different sublattices is allowed.

**Theorem 2** *Consider a bipartite Hubbard model. We assume* $|\Lambda|$ *is even, and the whole* $\Lambda$ *is connected through nonvanishing* $t_{x,y}$. *We also assume* $U_x=U>0$ *for any* $x\in\Lambda$. *Then the ground states of the model are nondegenerate apart from the trivial spin degeneracy, and have total spin* $S_{\text{tot}}=||A|-|B||/2$. *It also holds that* $E_{\min}(S_{\text{tot}})<E_{\min}(S_{\text{tot}}+1)$ *for any* $S_{\text{tot}}\geq ||A|-|B||/2$.

The theorem implies that, as far as the total spin is concerned, the half-filled Hubbard model behaves exactly as the Heisenberg antiferromagnet. But the existence of antiferromagnetic ordering has not been proved in any version of the Hubbard model.

To see another implication of Theorem 2, take the so-called CuO lattice in Figure 2. Here the $A$ and $B$ sublattices consist of black and white sites, respectively. One has $|A|=|\Lambda|/3$ and $|B|=2|\Lambda|/3$. Then the theorem implies that the ground state of the corresponding Hubbard model has total spin

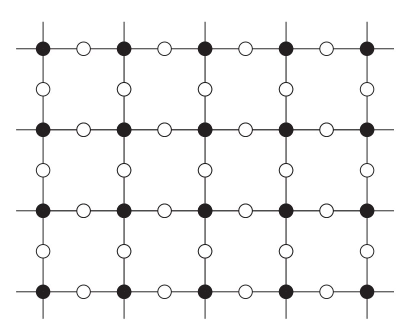

**Figure 2** An example (the so-called CuO lattice) of a bipartite lattice in which the numbers of sites in two sublattices are different. Lieb's theorem implies that the half-filled Hubbard model defined on this lattice exhibits ferrimagnetism.

$S_{tot} = ||A| - |B||/2 = |\Lambda|/6$. Since the total spin magnetic moment of the system is proportional to the number of sites $|\Lambda|$, we conclude that the model exhibits ferrimagnetism, a weaker version of ferromagnetism.

Another interesting result for the half-filled models is the following uniform density theorem by Lieb, Loss, and McCann.

**Theorem 3** *Consider a bipartite Hubbard model. $t_{x,y} \in \mathbb{R}$, $U_x \in \mathbb{R}$ are arbitrary. Suppose that the ground states are n-fold degenerate, and let $\Phi_{GS}^{(i)}$ $(i = 1, \dots, n)$ be mutually orthogonal normalized ground states. Define the correlation function by $\rho(x, y) = n^{-1} \sum_{i=1}^{n} \left\langle \Phi_{GS}^{(i)}, (c_{x,\uparrow}^{\dagger} c_{y,\uparrow} + c_{x,\downarrow}^{\dagger} c_{y,\downarrow})\, \Phi_{GS}^{(i)} \right\rangle$. ($\langle \cdot,\cdot \rangle$ is the inner product.) Then for any $x, y \in A$ or $x, y \in B$, one has $\rho(x, y) = \delta_{x,y}$.*

It is interesting that the density $\rho(x, x)$ in the ground state is always unity though the hopping matrix and interactions can be highly nonuniform.

## Ferromagnetism

Ferromagnetism is an interesting phenomenon in which the majority of the spins in the system align in the same direction. One of the original motivations to study the Hubbard model was to understand the origin of ferromagnetism in an idealized situation. Let us recall that neither the hopping term nor the interaction term in the Hamiltonian [6] favors ferromagnetism (or any other magnetic order). One must deal with the interplay between the two terms to have ferromagnetism. Here we review three rigorous examples of saturated ferromagnetism in the Hubbard model. Saturated ferromagnetism is the strongest form of ferromagnetism where the ground state has $S_{tot} = S_{max}$.

The first example is due to Nagaoka and Thouless.

**Theorem 4** *Take an arbitrary finite lattice $\Lambda$, and let $N_e = |\Lambda| - 1$. Assume that $t_{x,y} \le 0$ for any $x \ne y$, and let $U_x \to \infty$ for all $x \in \Lambda$. (Taking the limit $U_x \to \infty$ is equivalent to inhibiting x from being occupied by two electrons.) Then among the ground states of the model, there exist states with total spin $S_{tot} = S_{max} (= N_e/2)$. If the system further satisfies the connectivity condition (see below), then the ground states have $S_{tot} = S_{max} (= N_e/2)$ and are nondegenerate apart from the trivial spin degeneracy.*

The connectivity condition is a simple condition which holds in most of the lattices in two or higher dimensions, including the square lattice, the triangular lattice, or the cubic lattice. To be precise the condition requires that "by starting from any electron configuration on the lattice and by moving around the hole along nonvanishing $t_{x,y}$, one can get any other electron configuration."

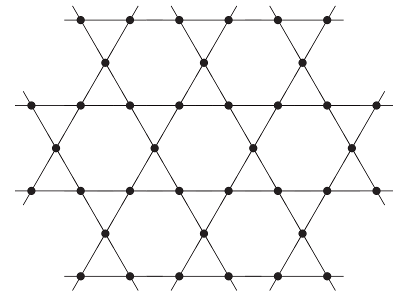

**Figure 3** The Hubbard model on the kagomé lattice is a typical example which exhibits flat-band ferromagnetism.

The requirements that $U_x \to \infty$ and $N_e = |\Lambda| - 1$ are indeed rather pathological. We still do not know if the ferromagnetism extends to more realistic situations. Heuristic studies indicate that the issue is highly delicate.

A completely different class of rigorous examples of ferromagnetism was found by Mielke. Take, for example, the kagomé lattice of Figure 3, and define a Hubbard model by setting $t_{x,y} = t < 0$ when $x$ and $y$ are neighboring, $t_{x,y} = 0$ otherwise, and $U_x = U \ge 0$ for any $x \in \Lambda$. Then the corresponding single-electron Schrödinger equation [7] has a peculiar feature that its ground states are $\{(|\Lambda|/3) + 1\}$-fold degenerate. This huge degeneracy corresponds to the fact that the lowest-energy band of the model is completely dispersionless (or flat).

**Theorem 5** *Consider the Hubbard model on the kagomé lattice with $N_e = (|\Lambda|/3) + 1$. For any $U > 0$, the ground states have $S_{tot} = S_{max} (= N_e/2)$ and are nondegenerate apart from the trivial spin degeneracy.*

There are similar examples in higher dimensions. Ferromagnetism observed in these models is called flat-band ferromagnetism.

The above examples of ferromagnetism have either singular interaction $(U_x \to \infty)$ or singular dispersion relation (highly degenerate single-electron ground states). Tasaki found a class of Hubbard models which are free from such singularities, and exhibit ferromagnetism.

For simplicity, we concentrate on the simplest model in one dimension. There are similar examples in higher dimensions. Take the one-dimensional lattice $\Lambda = \{1, 2, \dots, N\}$ with $N$ sites (where $N$ is an even integer), and impose a periodic boundary condition by identifying the site $N + 1$ with the site 1. The hopping matrix is defined by setting $t_{x,x+1} = t_{x+1,x} = -t'$ for any $x \in \Lambda$, $t_{x,x+2} = t_{x+2,x} = -t$ for even $x$, $t_{x,x+2} = t_{x+2,x} = s$ for odd $x$, and $t_{x,y} = 0$

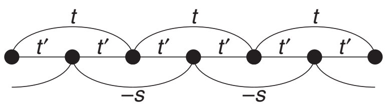

**Figure 4** An example of nonsingular Hubbard model which exhibits saturated ferromagnetism.

otherwise. Here $t > 0$ and $s > 0$ are independent parameters, but the parameter $t'$ is determined as $t' = \sqrt{2}(t + s)$.

As can be seen from Figure 4, electrons are allowed to hop to next-nearest neighbors. Thus, Theorem 1 does not apply. The single-electron ground states are not degenerate unless $s = 0$. We set $U_x = U > 0$ for any $x \in \Lambda$, and fix the electron number as $N_e = N/2$. In terms of filling factor, this corresponds to the quarter filling.

**Theorem 6** *Suppose that the two dimensionless parameters t/s and U/s are sufficiently large. Then the ground states have* $S_{tot} = S_{max}(= N/4)$ *and are nondegenerate apart from the trivial spin degeneracy.*

The theorem is valid, for example, when $t/s \geq 4.5$ if $U/s = 50$, and $t/s \geq 2.6$ if $U/s = 100$. It is crucial that the statement of the theorem is valid only when the interaction $U$ is sufficiently large. In the same model, it is also proved that low-lying excitation above the ground state has a normal dispersion relation of a spin-wave excitation.

We would like to point out that one can learn more details about the Hubbard model and further rigorous results from the review articles (Lieb 1995, Tasaki 1998a, Tasaki 1998b). One can also find references for most of the results discussed here in these review articles, especially in Lieb (1995).

As for the latest results which are not included in the above reviews, see recent publications, for example, Lieb and Wu (2003), Tasaki (2003), and Goldbaum (2005), and references therein.

# Hyperbolic Billiards

**Maciej P Wojtkowski**, University of Arizona, Tucson, AZ, USA and Institute of Mathematics PAN, Warsaw, Poland

## Introduction

Billiards are a class of dynamical systems with appealingly simple description. A point particle moves with constant velocity in a box of arbitrary dimension (the billiard table) and reflects elastically from the boundary (the component of velocity perpendicular to the boundary is reversed and the parallel component is preserved). Mathematically, it is a class of Hamiltonian systems with collisions defined by symplectic maps on the boundary of the phase space. The billiard dynamics defines a one-parameter group of maps $\Phi^t$ of the phase space which preserve the Lebesgue measure, and are in general only measurable due to discontinuities. The boundaries of the box are made up of pieces, concave, convex, and flat. Discontinuities occur at the orbits tangent to concave pieces of the boundary of the box. The orbits hitting two adjacent pieces ("corners") cannot be naturally

continued, which is another source of discontinuities. These singularities are not too severe so that the flow has well-defined Lyapunov exponents and Pesin structural theory is applicable (Katok and Strelcyn 1986). A billiard system is called hyperbolic if it has nonzero Lyapunov exponents on a subset of positive Lebesgue measure, and completely hyperbolic if all of its Lyapunov exponents are nonzero almost everywhere, except for one zero exponent in the direction of the flow.

Billiards in smooth strictly convex domains have no singularities, but no such examples are known to be hyperbolic.

In general, billiards exhibit mixed behavior just like other Hamiltonian systems; there are invariant tori intertwined with "chaotic sea." In hyperbolic billiards, stable behavior is excluded by the choice of the pieces in the boundary of the box, arbitrary concave pieces and special convex ones, and their particular placement. Thus, hyperbolicity is achieved by design, as in optical instruments.

It was established by Turaev and Rom-Kedar (1998) that complete hyperbolicity may be lost under generic singular perturbation of the billiard system to a smooth Hamiltonian system.

Hyperbolicity is the universal mechanism for random behavior in deterministic dynamical systems. Under suitable additional assumptions, it leads to ergodicity, mixing, $K$-property, Bernoulli property, decay of correlations, central-limit theorem, and other stochastic properties. Hyperbolic billiards provide a natural class of examples for which these properties were studied. In this article we restrict ourselves to hyperbolicity itself.

The most prominent example of a hyperbolic billiard is the gas of hard spheres. This way of looking at the system was developed in the groundbreaking papers of Sinai (see Chernov and Sinai (1987) for an exhaustive list of references). The collection of papers (Szász 2000) contains more up-to-date information. Another source on hyperbolic billiards is the book by Chernov and Markarian (2005). The books by Kozlov and Treschev (1990), and by Tabachnikov (1995) provide broad surveys of billiards from different perspectives.

## Jacobi Fields and Monotonicity

The key to understanding hyperbolicity in billiards lies in two essentially equivalent descriptions of infinitesimal families of trajectories. The basic notion is that of a Jacobi field along a billiard trajectory. Let $\gamma(t,u)$ be a family of billiard trajectories, where $t$ is time and $u$ is a parameter, $|u| < \epsilon$. A Jacobi field along $\gamma(t,0)$ is defined by $J(t) = \partial\gamma/\partial u_{|u=0}$.

Jacobi fields form a finite-dimensional vector space which can be identified with the tangent to the phase space at points along the trajectory. They contain the same information as the derivatives of the billiard flow $D\Phi^t$. In particular, the Lyapunov exponents are the exponential rates of growth of Jacobi fields.

Jacobi fields split naturally into parallel and perpendicular components to the trajectory, each of them a Jacobi field in its own right. The parallel Jacobi field carries the zero Lyapunov exponent. In the rest we discuss only the perpendicular Jacobi fields. Between collisions the Jacobi fields satisfy the differential equation $J'' = 0$, hence $J(t) = J(0) + tJ'(0)$. At a collision a Jacobi field undergoes a change by the map

$$\begin{aligned} J(t_c^+) &= \mathcal{R}J(t_c^-) \\ J'(t_c^+) &= \mathcal{R}J'(t_c^-) + \mathcal{P}^*\mathcal{K}\mathcal{P}J(t_c^+) \end{aligned} \qquad [1]$$

where $J(t_c^-)$ and $J(t_c^+)$ are Jacobi fields immediately before and after collision, $\mathcal{K}$ is the shape operator of the piece of the boundary ($\mathcal{K} = \nabla n, n$ is the inside unit normal to the boundary), and $\mathcal{P}$ is the projection along the velocity vector from the hyperplane perpendicular to the orbit to the hyperplane tangent to the boundary. Finally, $\mathcal{R}$ is the orthogonal reflection in the hyperplane tangent to the boundary.

Perpendicular Jacobi fields at a point of a trajectory can be identified with a subspace of the tangent to the phase space, the subspace perpendicular to the phase trajectory. To measure the growth/decay of Jacobi fields, we introduce a quadratic form on the tangent spaces, or equivalently on Jacobi fields, $\mathcal{Q}(J, J') = <J, J'>$ . Evaluation of $\mathcal{Q}$ on a Jacobi field is a function of time $\mathcal{Q}(t)$. Between collisions we have $\mathcal{Q}(t_2) \geq \mathcal{Q}(t_1)$ for $t_2 \geq t_1$ (monotonicity). By [1] the monotonicity at the collisions, that is, $\mathcal{Q}(t_c^+) \geq \mathcal{Q}(t_c^-)$ is equivalent to the positive semidefiniteness of the shape operator $\mathcal{K} \geq 0$, it holds for concave pieces of the boundary. If $\mathcal{K} > 0$ at a point of collision with the boundary, then for $(J, J') \neq (0,0)$, we have $\mathcal{Q}(t_2) > \mathcal{Q}(t_1)$ (strict monotonicity), assuming that the collision occurred between time $t_1$ and $t_2$.

In billiards with concave pieces of the boundary, where $\mathcal{K} \geq 0, \mathcal{K} \neq 0$, strict monotonicity may still occur after sufficiently many reflections (eventual strict monotonicity, or ESM). Such billiards are called semidispersing, and the gas of hard spheres is an example.

The role of monotonicity is revealed in the following:

**Theorem 1** (Wojtkowski 1991). *If a system is eventually strictly monotone (ESM), except on a set of orbits of zero measure, then it is completely hyperbolic.*

The theorem applies to billiard systems. It can be generalized and applied to other systems, not even Hamiltonian (see Wojtkowski (2001) for precise formulations, references and the history of this idea).

The difficulty in applying the above theorem to the gas of hard spheres lies in the gap between monotonicity and strict monotonicity. There are many orbits on which strict monotonicity is never attained (parabolic orbits). Establishing that the family of parabolic orbits has measure zero (or better yet codimension 2) is a formidable task. It was brought to conclusion in the work of Simányi (2002).

## Wave Fronts and Monotonicity

There is a geometric formulation of monotonicity (which historically preceded the one given above). Let us consider a local wave front, that is, a local hypersurface $W(0)$ perpendicular to a trajectory $\gamma(t)$ at $t=0$. Let us consider further all billiard trajectories perpendicular to $W(0)$. The points on these trajectories at time $t$ form a local hypersurface $W(t)$ perpendicular again to the trajectory (warning: at exceptional moments of time the wave front $W(t)$ may be singular). Infinitesimally wave fronts are described by the shape operator $U=\nabla n$, where $n$ is the unit normal field. $U$ is a symmetric operator on the hyperplane tangent to the wave front (and perpendicular to the trajectory $\gamma(t)$. The evolution of infinitesimal wave fronts is described by the formulas

$$\begin{aligned} U(t) &= (tI + U(0)^{-1})^{-1} \quad \text{without collisions} \\ U(t_c^+) &= \mathcal{R}U(t_c^-)\mathcal{R} + \mathcal{P}^*\mathcal{K}\mathcal{P} \quad \text{at a collision} \end{aligned} \qquad [2]$$

It follows that between collisions a wave front that is initially convex (i.e., diverging, or $U>0$) will stay convex. Moreover, any wave front after a sufficiently long run without collisions will become convex (after which the normal curvatures of the wave front will be decaying). The second part of [2] shows that after a reflection in a strictly concave boundary a convex wave front becomes strictly convex (and its normal curvatures increase). These properties are equivalent to (strict) monotonicity as formulated above. Indeed, in the language of Jacobi fields an infinitesimal wave front represents a linear subspace in the space of perpendicular Jacobi fields, that is, the tangent space. (Furthermore, it is a Lagrangian subspace with respect to the standard symplectic form.) We can follow individual Jacobi fields or whole subspaces of them. It explains the parallel of [1] and [2]. The form $\mathcal{Q}$ allows the introduction of positive and negative Jacobi fields and positive and negative Lagrangian subspaces. An infinitesimal convex wave front represents a positive Lagrangian subspace. Monotonicity is equivalent to the property that a positive Lagrangian subspace stays positive under the dynamics (it may appear that there is a loss of information in formulas [2] compared to [1], but actually they are equivalent due to the symplectic nature of the dynamics (Wojtkowski 2001).

## Design of Hyperbolic Billiards

In view of [2] it seems that a convex piece in the boundary ($K<0$) excludes monotonicity. There are two ways around this obstacle. First, we could change the quadratic form $\mathcal{Q}$ at the convex boundary. Second, we can treat convex pieces as "black boxes" and look only at incoming and outgoing trajectories. Although the second strategy seems more restrictive, all the examples constructed to date fit the black box scenario, and we will present it in more detail.

To understand this approach, let us consider a billiard table with flat pieces of the boundary and exactly one convex piece. A trajectory in such a billiard experiences visits to the convex piece separated by arbitrary long sequences of reflections in flat pieces, which do not affect the geometry of a wave front at all. Hence, whatever is the geometry of a wave front emerging from the curved piece it will become convex and very flat by the time it comes back to the curved piece of the boundary again. Hence, it follows, at least heuristically, that we must study the complete passage through the convex piece of the boundary, regarding its effect on convex, and especially flat, wave fronts.

Important difference between convex and concave pieces is that a trajectory has usually several consecutive reflections in the same convex piece; moreover, the number of such reflections is unbounded. A finite billiard trajectory is called "complete" if it contains reflections in one and the same piece of the boundary, and it is preceded and followed by reflections in other pieces.

**Definition** A complete trajectory is (strictly) $z$-monotone if for every nonzero Jacobi field the

value of the form $Q$ (increases) does not decrease between the point at the distance $z$ before the first reflection and the point at the distance $z$ after the last reflection.

A complete trajectory is parabolic if there is a nonzero Jacobi field $J$ such that $J'$ vanishes before the first and after the last reflection.

In the language of wave fronts, a complete trajectory is $z$-monotone if every diverging wave front at a distance at least $z$ from the first reflection becomes diverging after the last reflection at the distance $z$, or earlier.

It turns out that the only obstruction to monotonicity of complete trajectories is parabolicity. More precisely, if a complete trajectory is not parabolic then it is $z$-monotone for some $z > 0$.

It follows from Theorem 1 that we get a completely hyperbolic billiard if we put together curved pieces with no complete parabolic trajectories and some flat pieces, in such a way that for every two consecutive complete trajectories, being $z_1$- and $z_2$-monotone, respectively, the distance from the last reflection in the first trajectory to the first reflection in the second one is bigger than $z_1 + z_2$. Indeed, we can put together the midpoints of trajectories leaving one curved piece and hitting another one into the Poincaré section of the billiard flow and we obtain immediately ESM for the return map.

We can formulate somewhat informally two principles for the design of hyperbolic billiards.

1. *No parabolic trajectories* Convex pieces of the boundary cannot have complete parabolic trajectories.
2. *Separation* There must be enough separation (in space or in time through reflections in flat pieces) between strictly $z$-monotone trajectories according to the values of $z$.

All of the examples of hyperbolic billiards constructed up to now are designed according to these principles.

## Hyperbolic Billiards in Dimension 2

Checking the absence of parabolic trajectories is nontrivial due to the unbounded number of reflections in complete trajectories close to tangency. It was accomplished so far only in integrable, or near integrable examples, with the exception of convex scattering pieces described in the following.

Billiards in dimension 2 are understood best. First of all, there is yet another way of describing infinitesimal families of nearby trajectories. Every infinitesimal family of rays in the plane has a point of focusing (in linear approximation), possibly at infinity. This point of focusing contains the same information as the curvature of a wave front (it is the center of curvature, rather than curvature itself) and it has the advantage that it does not change between collisions. The focusing points before and after a reflection are related by the familiar mirror equation of the geometric optics:

$$-\frac{1}{f_0} + \frac{1}{f_1} = \frac{2}{d}$$

where $f_0, f_1$ are the signed distances of the points of focusing to the reflection point, $d = r\cos\theta$, $r$ being the radius of curvature of the boundary piece ($r > 0$ for a strictly convex piece), and $\theta$ the angle of incidence. The mirror equation is just the two dimensional version of [2].

It is instructive to consider an arc of a circle. A billiard in a disk is integrable due to its rotational symmetry. Let $J$ be a Jacobi field obtained by rotation of a trajectory. This family of trajectories ("the rotational family") is focused exactly in the middle between two consecutive reflections (that is where $J$ vanishes). It follows further from the mirror equation that a parallel family of orbits is focused at a distance $d/2$ after the reflection, and any family focusing somewhere between the parallel family and the rotational family will focus at a distance somewhere between $d/2$ and $d$, not only after the first reflection, but also after arbitrary long sequence of reflections.

Hence, any complete trajectory in an arc of a circle is $z$-monotone, where $2z$ is the length of a single segment of the trajectory and strictly $z'$-monotone for any $z' > z$. Two arcs of a circle separated by parallel segments form the stadium of Bunimovich (1979).

Lazutkin (1973) showed that billiards in smooth strictly convex domains are near integrable near the boundary. Donnay (1991) applied Lazutkin's coordinates to establish that for an arbitrary strictly convex arc the situation near the boundary is similar to that in a circle, that is, complete trajectories near tangency are $z$-monotone, where $z$ is of the order of the length of a single segment. In particular, no near tangent complete trajectory can be parabolic. Hence, this crucial calculation shows that if a strictly convex arc has no parabolic trajectories then any sufficiently small perturbation also has no parabolic trajectories. It follows further that any sufficiently small piece of a given strictly convex arc has no parabolic trajectories.

It turns out that in dimension 2, complete parabolic trajectories are also $z$-monotone for some

$z > 0$ (but clearly not strictly monotone) (Wojtkowski 2005). However, they are still an obstacle to complete hyperbolicity because in general nearby complete trajectories are $z$-monotone without a bound for the values of $z$, so that no separation of convex pieces is sufficient.

Integrability of the elliptic billiard allows one to establish strict monotonicity of trajectories in the semi-ellipse with endpoints on the longer axis, Wojtkowski 1986. Donnay (1991) showed that also the semi-ellipse with endpoints on the shorter axis has no parabolic trajectories provided that the eccentricity is less than $\sqrt{2}/2$. As the eccentricity goes to $\sqrt{2}/2$ the separation required to produce a hyperbolic billiard goes to infinity. Markarian *et al.* (1996) obtained explicitly the separation of the elliptic pieces needed for hyperbolicity, when the eccentricity is smaller than $\sqrt{2-\sqrt{2}}/2$.

It follows from the mirror equation that a trajectory with one reflection in a convex piece is always strictly $z$-monotone for $z > d$. Hence, if for any two consecutive reflections in convex pieces with respective values of $d$ equal to $d_1$ and $d_2$, the distance between reflections exceeds $d_1 + d_2$, then the billiard is completely hyperbolic. For one convex piece this condition, called convex scattering, turns out to be equivalent to $\mathrm{d}^2 r/\mathrm{d}s^2 < 0$, where $s$ is the arc length (Wojtkowski 1986). This leads to examples of hyperbolic billiards with one convex piece of the boundary, like the domain bounded by the cardioid.

Also, any complete trajectory in a convex scattering piece is strictly $z$-monotone for $z$ bigger than the maximum of the values of $d$ for the first and the last segment of the trajectory. This allows to find easily the explicit separation of convex scattering pieces guaranteeing hyperbolicity.

## Hyperbolic Billiards in Higher Dimensions

In higher dimensions, only two constructions of hyperbolic billiards with convex pieces in the boundary are known. The first construction by Bunimovich (1988), involves a piece of a sphere whose angular size, as seen from the center, does not exceed $\pi/2$ (Wojtkowski 1990, 2005, Bunimovich and Rehacek 1998). The second construction by Papenbrock (2000) uses two cylinders, at 90° with respect to each other to destroy integrability (Wojtkowski 2005). In both cases, the successful treatment is based on integrability of the billiard systems bounded by a sphere or a cylinder.

In both of these constructions, trajectories need to be cut into strictly monotone pieces of unbounded lengths. In the case of spherical caps, complete trajectories are $z$-monotone with unbounded value of $z$ and the geometry of the billiard table is used to separate them in time by sufficiently many reflections in flat pieces of the boundary (Wojtkowski 2005). In the case of cylinders, trajectories are cut by consecutive returns to a Poincaré section in the middle of the billiard table.

## Soft Billiards

The same ideas of monotonicity and strict monotonicity are applicable to soft billiards, where specular reflections are replaced by scatterers in which the point particle is subjected to the action of a spherically symmetric potential. As in ordinary billiards, we compare the wave fronts along trajectories before entering and after leaving scatterers. Again, in the absence of parabolic trajectories sufficient separation of the scatterers produces a completely hyperbolic system.

The conditions on the potential that guarantee the absence of parabolic trajectories were obtained by Donnay and Liverani (1991) in the two-dimensional case and by Bálint and Tóth (2006) in higher dimensions. The complete integrability of the motion of a point particle in a spherically symmetric potential is crucial in the derivation of these conditions (Wojtkowski 2005).

**B Hasselblatt**, Tufts University, Medford, MA, USA

## Introduction

### Division of Smooth Dynamical Systems

Linear maps can be elliptic (complex diagonalizable with all eigenvalues on the unit circle), parabolic (all eigenvalues on the unit circle but some Jordan blocks of size at least 2), or hyperbolic (no eigenvalues on the unit circle), and for differentiable dynamical systems, that is, smooth maps or flows, one can roughly make an analogous subdivision (see Hasselblatt and Katok 2002, p. 100f). The linear maps not covered by these alternatives are those with some eigenvalues on the unit circle and others off it; the corresponding class of "partially hyperbolic" dynamical systems is usually considered in the context of hyperbolic dynamical systems with a view to studying phenomena wherein the hyperbolic behavior dominates. Thus, elliptic dynamical systems are more or less similar to isometries, with orbit separation constant or at most oscillatory but without persistent growth. KAM theory deals with elliptic systems, establishing that much of the ellipticity in an integrable Hamiltonian system persists under perturbation. Parabolic systems may have polynomial orbit separation produced by a local "shear" phenomenon; billiards in polygonal domains are an example of this. Hyperbolic dynamical systems are characterized by exponential divergence of orbits. They are of interest because of the complexity of their orbit structure with respect to both topological and statistical behavior.

Specifically, the stretching (corresponding to eigenvalues outside the unit circle in the case of linear maps) combined with the folding necessitated by compactness of the phase space produces not only highly sensitive dependence of orbit asymptotics on initial conditions, but also a close intertwining of different behaviors. On the one hand, there is a dense set of periodic points, on the other hand, an abundance of dense orbits. While there are only finitely many periodic points of a given period, their number grows exponentially as a function of the period. The entropy of these systems is positive, which indicates that the overall complexity of the orbit structure grows exponentially as a function of the length of time for which it is being tracked. In effect, the behavior of orbits is so intricate as to be quasirandom, which makes it natural to use statistical methods to describe these systems.

### History of Hyperbolic Dynamical Systems

One strand of the history of hyperbolic dynamical systems leads back to the question of the stability of the solar system and to Poincaré, in whose prize memoir on the three-body problem the possibility of "homoclinic tangles" first presented itself. For Poincaré, this was important because the resulting complexity demonstrates that this system is not integrable. We describe below how hyperbolic dynamics arises in this situation (see Figure 3).

Another strand emerged about a decade later with Hadamard's study of geodesic flows (free particle motion) on negatively curved surfaces. Hadamard noted that these exhibit the kind of sensitive dependence on initial conditions as well as the pseudorandom behavior that are central features of hyperbolic dynamics. This subject was developed much further after the advent of ergodic theory, with the Boltzmann ergodic hypothesis as an important motivation: work by numerous mathematicians, principally Hedlund and Hopf, showed that free particle motion on a negatively curved surface provides examples of ergodic mechanical systems. More than two decades later, in the 1960s, Anosov and Sinai overcame a fundamental technical hurdle and established that this is indeed the case in arbitrary dimension. This was done in the more general context of a class of dynamical systems known now as Anosov systems, which were axiomatically defined and systematically studied for the first time during this period of research in Moscow.

A greater class of dynamical systems exhibiting chaotic behavior was introduced by Smale in his seminal 1967 paper under the name of Axiom-A systems. This class includes the hyperbolic dynamics arising from homoclinic tangles, see Figure 3 (*see* Homoclinic Phenomena). Smale's motivation was his program of classifying dynamical systems under topological conjugacy, and the consequent search for structurally stable systems. Today, Axiom-A (and Anosov) systems are valued as idealized models of chaos: while the conditions defining Axiom A are too stringent to include many real-life examples, it is recognized that they have features shared in various forms by most chaotic systems. Here, we concentrate on the discrete-time context to keep notations lighter.

Partial hyperbolicity was introduced in the 1970s and has proved that a limited amount of hyperbolicity in a dynamical system can produce much of the global complexity (such as ergodicity or the presence of dense orbits) exhibited by hyperbolic systems, and can do so in a robust way. Here one imposes uniform conditions, but expansion and contraction are not assumed to occur in all directions. Stable ergodicity has been an important subject of research in the last decade.

Nonuniform hyperbolicity weakens hyperbolicity by allowing the contraction and expansion rates to be nonuniform. This was motivated by examples of systems with hyperbolicity where expansion or contraction can be arbitrarily weak or absent in places, such as the Hénon attractor, and by situations where hyperbolicity coexists with singularities, such as for (semi)dispersing billiards (*see* Hyperbolic Billiards).

With respect to both uniformly and nonuniformly hyperbolic systems, dimension theory has been a subject of much interest (computations and estimates of the fractal dimension of attractors and hyperbolic sets, which is deeply connected to dynamical properties of the system).

A different weakening of hyperbolicity, the presence of a dominated splitting, has been of interest from the a viewpoint to stability and classification of diffeomorphisms.

The study of hyperbolic dynamics has always had interactions with other sciences and other areas of mathematics. In the natural and social sciences, this is the study of chaotic motions of just about any kind. Examples of applications in related areas of mathematics are geometric rigidity (an interaction with differential geometry) and rigidity of group actions.

## Uniformly Hyperbolic Dynamical Systems

### Definitions

Let $f$ be a smooth invertible map. A compact invariant set of $f$ is said to be "hyperbolic" if at every point in this set, the tangent space splits into a direct sum of two subspaces $E^{\mathrm{u}}$ and $E^{\mathrm{s}}$ with the property that these subspaces are invariant under the differential d$f$, that is, $\mathrm{d}f(x)E^{\mathrm{u}}(x)=E^{\mathrm{u}}(f(x))$, $\mathrm{d}f(x)E^{\mathrm{s}}(x)=E^{\mathrm{u}}(f(x))$, and that d$f$ expands vectors in $E^{\mathrm{u}}$ and contracts vectors in $E^{\mathrm{s}}$, that is, there are constants $0<\lambda<1<\mu, c>0$ such that if $v\in E^{\mathrm{s}}(x)$ for some $x$, then $\|\mathrm{d}f^n v\|\leq c\lambda^n\|v\|$ for $n=1,2,\ldots$, and if $v\in E^{\mathrm{u}}(x)$ for some $x$, then $\|\mathrm{d}f^{-n}v\|\leq c\mu^{-n}\|v\|$ for $n=1,2,\ldots$.

If $E^{\mathrm{u}}=\{0\}$ in the definition above, then the invariant set is made up of attracting fixed points or periodic orbits. Similarly, if $E^{\mathrm{s}}=\{0\}$, then the orbits are repelling. If neither subspace is trivial, then the behavior is locally "saddle-like," that is to say, relative to the orbit of a point $x$, most nearby orbits diverge exponentially fast in both forward and backward time. This is why hyperbolicity is a mathematical notion of chaos.

An Anosov diffeomorphism is a smooth invertible map of a compact manifold with the property that the entire space is a hyperbolic set.

Axiom A, which is a larger class, focuses on the part of the system that is not transient. More precisely, a point $x$ in the phase space is said to be "nonwandering" if every neighborhood $U$ of $x$ contains an orbit that returns to $U$. A map is said to satisfy Axiom A if its nonwandering set is hyperbolic and contains a dense set of periodic points.

Definitions in the continuous-time case are analogous: $f$ above is replaced by the time-$t$-maps of the flow, and the tangent spaces now decompose into $E^u \oplus E^0 \oplus E^s$ where $E^0$, which is one dimensional, represents the direction of the flow lines.

A geometric way of detecting (indeed, defining) hyperbolicity is via the cone criterion: at every point there is a cone that is mapped by the differential into the interior of the corresponding cone at the image point, and a "complementary" cone family behaves similarly for the inverse.

Many continuous structures associated with a hyperbolic dynamical system are, in fact, Hölder continuous. (For a function $g$ on a metric space this is defined as the existence of $C, \alpha > 0$ such that $d(g(x), g(y)) \leq Cd(x, y)^\alpha$ whenever $x, y$ are sufficiently close to each other.) In the present article, almost every assertion of continuity could be replaced by one of Hölder continuity. This notion is natural in this context because $x_n \to y$ exponentially fast implies that $g(x_n) \to g(y)$ exponentially fast if $g$ is Hölder continuous.

## Structure and Properties

### Stable and Unstable Manifolds, Local Product Structure

Anosov and Axiom-A systems are defined by the behavior of the differential. Corresponding to the linear structures left invariant by d$f$ are nonlinear structures, namely "stable manifolds" tangent to $E^s$ and "unstable manifolds" tangent to $E^u$.

Thus, associated with an Anosov map are two families of invariant manifolds, each one of which fills up the entire phase space; they are sometimes called the stable and unstable "foliations." The leaves of these foliations are transverse at each point, that is, they intersect at positive angles, forming a kind of (topological) coordinate system. The map $f$ expands distances along the leaves of one of these foliations and contracts distances along the leaves of the other. For Axiom-A systems, one has a similar local product structure or "coordinate system" at each point in the nonwandering set, but the picture is local, and there are gaps: the stable and unstable leaves do not necessarily fill out open sets in the phase space.

There is much interest in determining the fractal dimension (box-counting or Hausdorff, say) of hyperbolic sets. So far the best dimension estimates have been made for stable slices, that is, for the intersection of a stable leaf with the hyperbolic set, and for unstable slices. Because the local coordinate systems describing the local product structure are only known to be continuous, it is not known in general whether the sum of these stable and unstable dimensions gives the dimension of the hyperbolic set (we don't even know whether all stable slices have the same fractal dimension). The problem is that an $\alpha$-Hölder-continuous map can change dimensions by a factor of $\alpha$ or $1/\alpha$. But there is evidence to suggest that something like this "dimension product structure" may often be true – this has been established for a class of solenoids.

### Transitivity and Spectral Decomposition

In addition to these local structures, Axiom-A systems have a global structure theorem known as "spectral decomposition." It says that the nonwandering set of every Axiom-A map can be written as $X_1 \cup \cdots \cup X_r$ where the $X_i$ are disjoint closed invariant sets on which $f$ is topologically transitive, that is, has a dense orbit. The $X_i$ are called "basic sets." Each $X_i$ can be decomposed further into a finite union $\bigcup X_{i,j}$, where each $X_{i,j}$ is invariant and topologically mixing under some iterate of $f$. (Topological transitivity and mixing are irreducibility conditions; transitivity means that there is no proper open invariant subset, and topological mixing says that given two open sets, from some time onward the images of one will always intersect the other.) This decomposition is reminiscent of the corresponding result for finite-state Markov chains.

### Stability

One of the reasons why hyperbolic sets are important is their "robustness": they cannot be perturbed away. More precisely, let $f$ be a map with a hyperbolic set $\Lambda$ which is locally maximal, that is, it is the largest invariant set in some neighborhood $U$. Then for every map $g$ that is $C^1$-near $f$, the largest invariant set $\Lambda'$ of $g$ in $U$ is again hyperbolic; moreover, $f$ restricted to $\Lambda$ is "topologically conjugate" to $g$ restricted to $\Lambda'$. This is mathematical shorthand for saying that not only are the two sets $\Lambda$ and $\Lambda'$ topologically indistinguishable, but the orbit structure of $f$ on $\Lambda$ is indistinguishable from that of $g$ on $\Lambda'$.

The phenomenon above brings us to the idea of "structural stability." A map $f$ is said to be structurally stable if every map $g$ $C^1$-near $f$ is topologically conjugate to $f$ (on the entire phase space). It turns out that a map is structurally stable if and only if it satisfies Axiom A and an additional condition called strong transversality.

### Chains and Shadowing

We discuss next the idea of pseudo-orbits versus real orbits. Letting $d(\cdot,\cdot)$ be the metric, a sequence of points $x_0, x_1, x_2, \ldots$ in the phase space is called an "$\varepsilon$-pseudo-orbit" or a "chain" of $f$ if $d(f(x_i), x_{i+1}) < \varepsilon$ for every $i$. Computer-generated orbits, for example, are pseudo-orbits due to round-off errors. A fact of consequence to people performing numerical experiments is that in hyperbolic systems, small errors at each step get magnified exponentially fast. For example, if the expansion rate is 3 or more, then an $\varepsilon$-error made at one step is at least tripled at each subsequent step, that is, after only $O(|\log \varepsilon|)$ iterates, the error is $O(1)$, and the pseudo-orbit bears no relation to the real one. There is, however, a theorem that says that every pseudo-orbit is "shadowed" by a real one. More precisely, given a hyperbolic set, there is a constant $C$ such that if $x_0, x_1, x_2, \ldots$ is an $\varepsilon$-pseudo-orbit, then there is a phase point $z$ such that $d(x_i, f^i(z)) < C\varepsilon$ for all $i$. Thus, paradoxical as it may first seem, this result asserts that on hyperbolic sets, each pseudo-orbit approximates a real orbit, even though it may deviate considerably from the one with the same initial condition.

The shadowing orbit corresponding to a bi-infinite pseudo-orbit is, in fact, unique. From this, one deduces easily the following Closing Lemma: For any hyperbolic set, there is a constant $C$ such that the following holds: Every finite orbit segment $x, f(x), \ldots, f^{n-1}(x)$ that nearly closes up, that is, $d(x, f^{n-1}(x)) < \varepsilon$ for some small $\varepsilon$, lies within $<C\varepsilon$ of a genuine periodic orbit of period $n$. Thus, hyperbolic sets contain many periodic points.

## Examples

### Anosov Diffeomorphisms

A large class of Anosov diffeomorphisms comes from "linear toral automorphisms," that is, maps of the $n$-dimensional torus induced by $n \times n$ matrices with integer entries, det $= \pm 1$, and no eigenvalues of modulus one. The most popular example is the map obtained from

$$\begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$$

sometimes called the Arnol'd cat map because of an illustration used by Arnol'd. The unstable manifolds are lines parallel to the expanding direction shown in Figure 1 and wrapped around the torus, and the stable manifolds are obtained from the orthogonal lines.

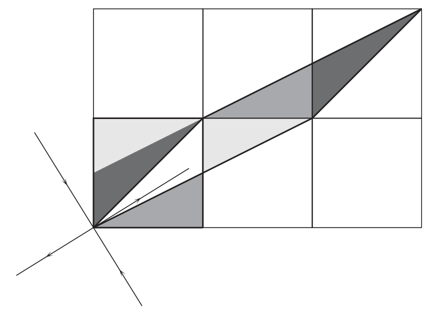

**Figure 1** A hyperbolic toral automorphism. Reproduced from Katok A and Hasselblatt B (2003) *Dynamics*: *A First Course*. Cambridge: Cambridge University Press, with permission from Cambridge University Press.

We remark that due to their structural stability, (nonlinear) perturbations of linear toral automorphisms continue to have the Anosov property. This remark applies also to all of the examples below. In fact, all known Anosov diffeomorphisms are topologically identical to a linear toral automorphism (or a slight generalization of these, infranil-manifold automorphisms).

### Geodesic Flows

Geodesic flows describe free motions of points on manifolds. Let $M$ be a manifold. Given $x \in M$ and a unit vector $v$ at $x$, there is a unique geodesic starting from $x$ in the direction $v$. The geodesic flow $\varphi^t$ is given by $\varphi^t(x, v) = (x', v')$ where $x'$ is the point $t$ units down the geodesic and $v'$ is the direction at $x'$. Geodesic flows on manifolds of strictly negative curvature are the main examples of Anosov flows. They were studied by Hadamard (ca. 1900), Hedlund and Hopf (1930s) considerably before Anosov theory was developed.

### Horseshoes

Smale's horseshoe is the prototypical example of a hyperbolic invariant set. This map, so called because it bends a rectangle $B$ into the shape of a horseshoe and puts it back on top of $B$, is shown in Figure 2. The set $\{x : f^n(x) \in B \text{ for all } n = 0, \pm 1, \pm 2, \ldots\}$ is hyperbolic. It is a two-dimensional Cantor set in $B$. The emergence of this example can be traced back directly to real-world systems.

During World War II, Cartwright and Littlewood worked on relaxation oscillations in radar circuits,

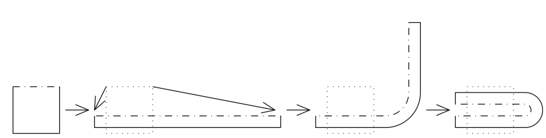

**Figure 2** The horseshoe.

consciously building on Poincaré's work. Further study of the underlying van der Pol equation by Levinson contained the first example of a structurally stable diffeomorphism with infinitely many periodic points. (Structural stability originated in 1937 but began to flourish only 20 years later.) This was brought to the attention of Smale. Inspired by Peixoto's work, who had carried out such a program in dimension 2, Smale pursued a program of studying diffeomorphisms with a view to classification (Smale 1967). Until alerted by Levinson, Smale conjectured that only Morse–Smale systems (which have only finitely many periodic points with stable and unstable sets in general position) could be structurally stable. He eventually extracted the horseshoe from Levinson's work. Smale in turn was in contact with the Russian school, where Anosov systems (then *C*- or *U*-systems) had been shown to be structurally stable, and their ergodic properties were studied by way of further development of the study of geodesic flows in negative curvature.

The appearance of horseshoes in mathematical models of real-world phenomena is quite widespread. Indeed, in a sense this is the mechanism for the production of chaotic behavior, at least in dimension 2. In disguise, one of the earliest appearances of this phenomenon occurred in the prize memoir of Poincaré, where homoclinic tangles gave a first glimpse at the serious dynamical complexity that can arise in the three-body problem in celestial mechanics. If the stable and unstable curves of a hyperbolic fixed point intersect transversely (as in Figure 3a), this engenders further such intersections and produces a complicated web of accumulations of loops or lobes of stable and unstable curves, as shown in Figure 3b. Homoclinic tangles always produce horseshoes by the Smale–Birkhoff theorem, illustrated by Figure 3c, so in trying to solve the three-body problem, Poincaré essentially discovered the possibility of nontrivial hyperbolic behavior (*see* Homoclinic Phenomena).

A related appearance of horseshoes in this context is in the work of Alekseev, who used their presence to show that capture of celestial bodies can indeed occur.

#### Solenoids

Finally we mention the solenoid, which is an example of an Axiom-A attractor (*see* Figure 4). Here the map $f$ is defined on a solid torus $M = S^1 \times D_2$, where $D_2$ is a two-dimensional disk. It is easiest to describe it in two steps: first it maps $M$ into a long thin solid torus, which is then put inside $M$

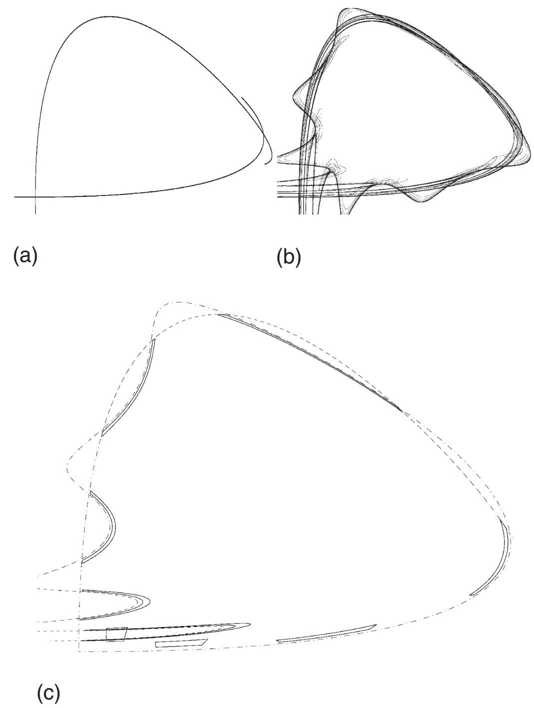

**Figure 3** Homoclinic tangles produce horseshoes. Reproduced from Katok A and Hasselblatt B (2003) *Dynamics: A First Course*. Cambridge: Cambridge University Press, with permission from Cambridge University Press.

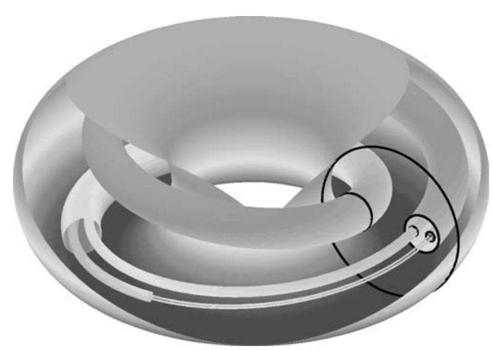

**Figure 4** The solenoid. Reproduced from Katok A and Hasselblatt B (2003) *Dynamics: A First Course*. Cambridge: Cambridge University Press, with permission from Cambridge University Press.

winding around the $S^1$ direction twice. The attractor is given by $\Lambda = \bigcap_{n \geq 0} f^n(M)$.

## Symbolic Coding of Orbits and Ergodic Theory

An important tool for studying the orbit structure of Axiom-A systems is the "Markov partition," constructed for Anosov systems by Sinai and extended to Axiom-A basic sets by Bowen. Given a partition $\{R_1, \ldots, R_k\}$ of the phase space, there is a natural way to attach to each point $x$ in the phase space a

sequence of symbols, namely $(\ldots, a_{-1}, a_0, a_1, a_2, \ldots)$, where $a_i \in \{1, 2, \ldots, k\}$ is the name of the partition element containing $f^i(x)$, that is, $f^i(x) \in R_{a_i}$ for each $i$. In general, not all sequences are realized by orbits of $f$. Markov partitions are designed so that the set of symbol sequences that correspond to real orbits has Markovian properties; it is called a shift of finite type.

The ergodic theory of Axiom-A systems has its origins in statistical mechanics. In a 1D lattice model in statistical mechanics, one has an infinite array of sites indexed by the integers; at each site, the system can be in any one of a finite number of states. Thus, the configuration space for a 1D lattice model is the set of bi-infinite sequences on a finite alphabet. Identifying this symbol space with the one coming from Markov partitions, Sinai and Ruelle were able to transport some of the basic ideas from statistical mechanics, including the notions of Gibbs states and equilibrium states, to the ergodic theory of Axiom-A systems.

The notion of equilibrium states, which is equivalent to Gibbs states for Axiom-A systems, has the following meaning in dynamical systems in general: given a potential function $\varphi$, an invariant measure is said to be an equilibrium state if it maximizes the quantity

$$h_\mu(f) - \int \varphi \mathrm{d}\mu$$

where $h_\mu(f)$ denotes the Kolmogorov–Sinai entropy of $f$ and the supremum is taken over all $f$-invariant probability measures $\mu$. In particular, when $\varphi = 0$, this measure is the measure that maximizes entropy; and when $\varphi = \log|\det(\mathrm{d}f|_{E^u})|$, it is the Sinai–Ruelle–Bowen (SRB) measure. From the physical or observational point of view, SRB measures are the most important invariant measures for dissipative dynamical systems because if $f$ is a diffeomorphism of a compact manifold $M$ and $\Lambda$ a transitive Axiom-A attractor with basin $U$, for example, $\Lambda = U = M$, then for Lebesgue-a.e. $x \in U$ and for every $\varphi \in C^0(M)$

$$\lim_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} \varphi(f^i(x)) = \int \varphi d\mu$$

that is, Lebesgue-a.e. point is $\mu$-typical. Thus, while Axiom-A attractors will have chaotic motions, they are statistically coherent in that the asymptotic distribution of any typical orbit is given by the SRB measure.

## Periodic Points and Their Growth Properties

We discuss briefly some further results related to the abundance of periodic points in Axiom-A systems.

For an Axiom-A diffeomorphism $f$, if $P(n)$ is the number of periodic points of period $\leq n$, then $P(n) \sim e^{hn}$, where $h$ is the topological entropy of $f$. That is to say, the dynamical complexity of $f$ is reflected in its periodic behavior. An analogous result holds for Axiom-A flows. This asymptotic behavior is known to remarkably fine accuracy (Margulis 2004), and these developments used the dynamical zeta function, which sums up the periodic information of a system. In the discrete-time case, $\zeta(z) := \exp\sum_{n=1}^{\infty} P(n)z^n/n$ has been shown to be a rational function analytic on $|z| < e^{-h}$. In the continuous-time case, the zeta function is given by $\zeta(z) := \prod_\gamma (1 - \exp(-zl(\gamma)))^{-1}$, where the product is taken over all (nonstationary) periodic orbits $\gamma$ and $l(\gamma)$ is the smallest positive period of $\gamma$. This function is known to be meromorphic on a certain domain, but the location of its poles, which are intimately related to correlation decay properties of the system, remains one of the yet unresolved issues in Axiom-A theory.

## Partial Hyperbolicity and Dominated Splitting

There are various ways in which the notion of hyperbolicity described above, which we will henceforth refer to as "uniform hyperbolicity," can be extended beyond the one presented so far. This can be done with a view to weakening the conditions under which some of the salient properties of hyperbolic dynamical systems appear. The study of partially hyperbolic dynamical systems and that of dynamical systems possessing a dominated splitting is of this type. Further below, we describe a different extension motivated more by a desire to bring the results and methods of hyperbolic dynamics to bear on systems that are closer to some physical situations. This led to the study of nonuniformly hyperbolic dynamical systems.

If one views hyperbolicity as requiring that the spectrum of expansion and contraction rates is separated into two components by the unit circle, then one can consider systems where this separation is provided by a circle centered at 0 whose radius may not be 1 (partial hyperbolicity in the broad sense), or by two circles centered at 0 of which one has radius less than 1 and the other has radius greater than 1, with possibly a third component of the spectrum in the annulus between these (absolute partial hyperbolicity). Further weakenings are obtained by controlling not the whole spectrum in this absolute way, but rather ratios of expansion and contraction rates along orbits (dominated splitting

and relative partial hyperbolicity, respectively). Among the motivations for these weakenings are the desire to understand which systems are topologically transitive and robustly so (stable transitivity), and to understand which ergodic volume-preserving systems remain ergodic if perturbed within the space of volume-preserving systems (stable ergodicity).

### Pseudohyperbolicity

Let $f$ be a smooth invertible map. A compact invariant set of $f$ is said to be partially hyperbolic in the broad sense if at every point in this set, the tangent space splits into a direct sum of two subspaces $E^{\mathrm{u}}$ and $E^{\mathrm{s}}$ with the property that these subspaces are invariant under the differential d$f$, that is, $\mathrm{d}f(x)E^{\mathrm{u}}(x) = E^{\mathrm{u}}(f(x)), \mathrm{d}f(x)E^{\mathrm{s}}(x) = E^{\mathrm{u}}(f(x))$, and that there are constants $0 < \lambda < \mu, c > 0$ such that if $v \in E^{\mathrm{s}}(x)$ for some $x$ then $\|\mathrm{d}f^n v\| \le c\lambda^n \|v\|$ for $n = 1, 2, \ldots$ and if $v \in E^{\mathrm{u}}(x)$ for some $x$ then $\|\mathrm{d}f^{-n} v\| \le c\mu^{-n}\|v\|$ for $n = 1, 2, \ldots$. This is sometimes also referred to as the existence of a $(\lambda, \mu)$-splitting or pseudohyperbolicity.

### Dominated Splitting

A further weakening of this condition replaces these absolute estimates by relative ones. Let $f$ be a smooth invertible map. A compact invariant set of $f$ is said to admit a dominated splitting if at every point in this set, the tangent space splits into a direct sum of two subspaces $E^{\mathrm{u}}$ and $E^{\mathrm{s}}$ with the property that these subspaces are invariant under the differential and there are constants $\lambda \in (0, 1), c > 0$ such that if $u \in E^{\mathrm{u}}(x)$ and $v \in E^{\mathrm{s}}(x)$ for some $x$ then $\|\mathrm{d}f^n v\| / \|\mathrm{d}f^n u\| \le c\lambda^n$ for $n = 1, 2, \ldots$.

The presence of a dominated splitting has been found to yield substantial information pertinent to stability of such systems, and it plays a significant role in a program of research aiming at a classification of generic diffeomorphisms up to topological conjugacy and specifically motivated by the "Palis conjecture," which aims to describe that classification. With respect to inferring topological and ergodic (i.e., statistical) properties of the orbit structure, the stricter notion of partial hyperbolicity (in the narrow sense below) is more commonly used, but in this respect the presence of a dominated splitting is also of interest because there is evidence in support of the conjecture that stable ergodicity implies the presence of a dominated splitting.

### Partial Hyperbolicity

Let $f$ be a smooth invertible map. A compact invariant set of $f$ is said to be (absolutely) partially hyperbolic if at every point in this set, the tangent space splits into a direct sum of unstable, central, and stable directions $E^{\mathrm{u}}, E^{\mathrm{c}}$, and $E^{\mathrm{s}}$ with the property that these subspaces are invariant under the differential d$f$ and that there exist numbers $C > 0$,

$$\begin{gathered} 0 < \lambda_1 \le \mu_1 < \lambda_2 \le \mu_2 < \lambda_3 \le \mu_3 \\ \text{with } \mu_1 < 1 < \lambda_3 \end{gathered} \quad [1]$$

such that if $v \in E^{\mathrm{s}}(x), w \in E^{\mathrm{c}}(x), u \in E^{\mathrm{u}}(x)$, $n = 1, 2, \ldots$, then

$$C^{-1}{\lambda_1}^n\|v\| \le \|d_x f^n(v)\| \le C{\mu_1}^n\|v\|$$
$$C^{-1}{\lambda_2}^n\|w\| \le \|d_x f^n(w)\| \le C{\mu_2}^n\|w\|$$
$$C^{-1}{\lambda_3}^n\|u\| \le \|d_x f^n(u)\| \le C{\mu_3}^n\|u\|$$

In this case, we set $E^{\mathrm{cs}} := E^{\mathrm{c}} \oplus E^{\mathrm{s}}$ and $E^{\mathrm{cu}} := E^{\mathrm{c}} \oplus E^{\mathrm{u}}$. Following Burns–Wilkinson, we say that $f$ is "center-bunched" if $\max\{\mu_1, \lambda_3^{-1}\} < \lambda_2/\mu_2$.

As in the case of (uniformly) hyperbolic dynamical systems, the sub-bundles $E^{\mathrm{s}}$ and $E^{\mathrm{u}}$ are integrable to stable and unstable foliations $W^{\mathrm{s}}$ and $W^{\mathrm{u}}$. It is not automatic that the center-stable sub-bundle $E^{\mathrm{cs}}$ and the center-unstable sub-bundle $E^{\mathrm{cu}}$ are tangent to foliations $W^{\mathrm{cs}}$ and $W^{\mathrm{cu}}$; if this happens to be the case, the partially hyperbolic system is said to be "dynamically coherent."

Partial hyperbolicity can also be defined by a cone criterion, with suitable adaptations.

### Stable Ergodicity and Transitivity

Partial hyperbolicity was introduced as a means of providing just enough hyperbolicity to render a dynamical system ergodic or topologically transitive. These are both irreducibility conditions, and to obtain these, one rules out a Cartesian product situation by assuming something like essential accessibility: almost every two points (in the sense of volume viewed as a measure) can be connected by a curve consisting of a finite concatenation of arcs, each of which lies entirely in one stable or unstable leaf. A celebrated result in this field is in its original form (with a much stronger center-bunching assumption) due to Pugh and Shub: suppose a volume-preserving diffeomorphism is partially hyperbolic on the entire manifold. If it is dynamically coherent and center bunched and has essential accessibility, then it is ergodic (Hasselblatt and Pesin 2006).

One of the motivating aims of this theory was to obtain nonhyperbolic volume-preserving systems that are stably ergodic, that is, for which all volume-preserving $C^1$-small perturbations are also ergodic. If, in addition to the above, one assumes that essential accessibility also persists under such

perturbations and that the center bundle $E^c$ is integrable to a center foliation $W^c$ that is smooth (or "plaque-expansive"), then ergodicity is indeed stable (Hasselblatt and Pesin). There are quite a few natural examples where these assumptions hold.

While essential accessibility does not always hold, it is fairly common. The stronger property of accessibility (that any two points can be connected, not only almost every two points) is conjectured to be stable under $C^1$-perturbations and has been shown to hold for an open dense set of partially hyperbolic systems with respect to the $C^1$-topology.

Ergodicity is a measure-theoretic irreducibility notion, and topological transitivity is the topological counterpart. It can also be obtained from accessibility: a partially hyperbolic volume-preserving diffeomorphism with the accessibility property is topologically transitive (in fact, almost every orbit is dense).

There are interesting converse results as well. Any stably transitive diffeomorphism exhibits a dominated splitting. Moreover, in dimension 2 it is hyperbolic and in dimension 3 it is partially hyperbolic in the broad sense.

## Nonuniform Hyperbolicity

Applications have motivated weakening assumptions of uniform hyperbolicity to require only that "many" individual orbits exhibit hyperbolic behavior, without assuming that there are any uniform estimates on the degree of hyperbolicity.

To measure the asymptotic contraction or expansion of a vector on an exponential scale, one defines the Lyapunov exponent of a (nonzero) tangent vector $v$ at $x$ for the map $f$ to be

$$\lambda(x, v) := \lim_{n\to\infty} (1/n) \log \|Df^n(v)\| \qquad [2]$$

whenever this limit exists. Note that being positive indicates asymptotic expansion of the vector, whereas negative exponents correspond to contracting vectors. This defines a measurable but, save for exceptional circumstances, discontinuous function of $x$ and $v$. It is relatively easy to see that for a given point $x$ the function $\lambda(x, \cdot)$ can only take finitely many values, so it is natural to define nonuniform hyperbolicity as the property of having all of these finitely many values nonzero for "most" points. Given that $\lambda$ is measurable, it is natural to define "most" by using a measure that is invariant under the map $f$. Therefore, the theory of nonuniformly hyperbolic dynamical systems, much of which is due to Pesin, is based on measure theory throughout.

The fundamental fact on which this theory is based is the "Oseledets multiplicative ergodic theorem," which says that for a $C^1$-diffeomorphism of a compact Riemannian manifold the set of Lyapunov-regular points has full measure with respect to any $f$-invariant Borel probability measure.

For a Lyapunov-regular point the limit [2] exists for all $v$, so this theorem tells us that no matter which invariant measure we consider, the limit [2] makes sense for all tangent vectors at points $x$ outside a null set. (One should add that this small "bad" set can be somewhat substantial; for example, its Hausdorff dimension is usually that of the whole space.)

Accordingly, one then defines a measure to be hyperbolic if at almost every point the limit [2] is nonzero for all vectors. In this case, one says that "$f$ has nonzero Lyapunov exponents." This property can also be obtained from a cone criterion, but here the family of cones may only be invariant and eventually strictly invariant, that is, there is a cone field such that cones are mapped to cones (but not necessarily into the interior of cones), and for almost every point there is an iterate that maps a cone strictly inside the cone at the image point (i.e., into the interior). Which iterate is needed is allowed to depend on the point (*see* Hyperbolic Billiards).

It is good to keep in mind that a hyperbolic measure may be concentrated on a single point, say, in which case there is not much gained by this approach. The theory is of great interest, however, if the measure is equivalent to volume or is the "physical measure" on an attractor.

Examples of this sort are fairly common, indeed any smooth compact Riemannian manifold other than the unit circle admits a volume-preserving Bernoulli diffeomorphism with nonzero Lyapunov exponents (Dolgopyat and Pesin 2002) (and every compact smooth Riemannian manifold of dimension at least 3 carries a volume-preserving Bernoulli flow for which at almost every point the only zero Lyapunov exponent is the one in the flow direction (Hu *et al.* 2004)).

Structurally, these systems exhibit many of the features seen in uniformly hyperbolic ones (e.g., stable manifolds), but instead of being continuous these are now measurable. There are, however, (noninvariant) sets of arbitrarily large measure on which these structures are continuous. This provides a handle for pushing some of the uniform theory to this context.

There are some topological results in this area, of which one of the more remarkable ones is that any surface diffeomorphism with positive entropy contains a horseshoe. Much of the current research is

directed at the ergodic theory of these systems. A central result from the initial development of the theory is that while these systems may not be ergodic, the ergodic components are (a.e. equal to) open sets, so in particular there are at most countably many of them.

One natural question is whether nonuniformly hyperbolic systems have SRB measures, and it is answered on a case-by-case basis. There are even benign examples where this fails to be the case, but for some realistic systems, such as the Lorenz and Hénon attractors, this has been established.

Because they preserve volume, this is not an issue for billiard systems, (*see* Hyperbolic Billiards), that is, the free motion of a point mass in a cavity with elastic boundary collisions. This describes not just a toy model, but also the phase space and dynamics of a gas of convex rigid bodies. Such a gas of hard spheres in a rectangular box is semidispersing and has been studied intensely. It is now known to be hyperbolic and hoped to be ergodic. (The latter would provide a solid foundation for statistical mechanics, at least for the case of spherical molecules.) A gas of nonspherical convex rigid bodies is also a point billiard, but it is not semidispersing, which puts it beyond the range of readily available techniques for establishing ergodicity.

## Further Remarks

The historical remarks made here are significantly expanded in Hasselblatt (2002), which contains some references to yet more detailed sources as well as more detail about uniformly hyperbolic dynamical systems in a concise form. A concise but reasonably comprehensive and current account of partially hyperbolic dynamics is in Hasselblatt and Pesin, and an authoritative full presentation is in Pesin (2004). A survey of nonuniformly hyperbolic dynamics is given in Barreira and Pesin (2006), and the definitive treatment is given by Barreira *et al.*. A textbook presentation of (not only) hyperbolic dynamics is in Katok and Hasselblatt (1995) as well as Hasselblatt and Katok (2003), and much current research, including on all subjects discussed here, is surveyed in Handbook.

# Image Processing: Mathematics

**G Aubert**, Université de Nice Sophia Antipolis, Nice, France
**P Kornprobst**, INRIA, Sophia Antipolis, France

Our society is often designated as being an "information society." It could also be defined as an "image society." This is not only because image is a powerful and widely used medium of communication, but also because it is an easy, compact, and widespread way to represent the physical world. If we think about it, it is indeed striking to realize just how much images are omnipresent in our lives through numerous applications such as medical and satellite imaging, videosurveillance, cinema, robotics, etc.

Many approaches have been developed to process these digital images, and it is difficult to say which one is more natural than the other. Image processing has a long history. Maybe the oldest methods come from 1D signal processing techniques. They rely on filter theory (linear or not), on spectral analysis, or on some basic concepts of probability and statistics. For an overview, we refer the interested reader to the book by Gonzalez and Woods (1992).

In this article, some recent mathematical concepts will be revisited and illustrated by the image restoration problem, which is presented below. We first discuss stochastic modeling which is widely based on Markov random field theory and deals directly with digital images. This is followed by a discussion of variational approaches where the general idea is to define some cost functions in a continuous setting. Next we show how the scale space theory is connected with partial differential equations (PDEs). Finally, we present the wavelet theory, which is inherited from signal processing and relies on decomposition techniques.

## Introduction

As in the real world, a digital image is composed of a wide variety of structures. **Figure 1** shows different kinds of "textures," progressive or sharp contours, and fine objects. This gives an idea of the complexity of finding an approach that allows to cope with the different structures at the same time. It also highlights the discrete nature of images which will be handled differently depending on the chosen mathematical tools. For instance, PDEs based approaches are written in a continuous setting, referring to analogous images, and once the existence and the uniqueness of the solution have been proved, we need to discretize them in order to find a numerical solution. On the contrary, stochastic approaches will directly consider discrete images in the modeling of the cost functions.

### The Image Restoration Problem

It is well known that during formation, transmission, and recording processes images deteriorate. Classically, this degradation is the result of two phenomena. The first one is deterministic and is related to the image acquisition modality, to possible defects of the imaging system (e.g., blur created by an incorrect lens adjustment or by motion). The second phenomenon is random and corresponds to the noise coming from any signal transmission. It can also come from image quantization. It is important to choose a degradation model as close as possible to reality. The random noise is usually modeled by a probabilistic distribution. In many cases, a Gaussian distribution is assumed. However, some applications require more specific ones, like the gamma distribution for radar images (speckle noise) or the Poisson distribution for tomography. Unfortunately, it is usually impossible to identify the kind of noise involved for a given real image.

A commonly used model is the following. Let $u : \Omega \subset \mathbb{R}^2 \to \mathbb{R}$ be an original image describing a real scene, and let $f$ be the observed image of the same scene (i.e., a degradation of $u$). We assume that

$$f = Au + \eta \qquad [1]$$

where $\eta$ stands for a white additive Gaussian noise and $A$ is a linear operator representing the blur (usually a convolution). Given $f$, the problem is

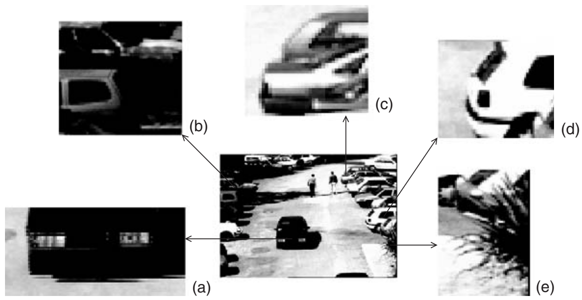

**Figure 1** Digital image example. ↷ the close-ups show examples of low resolution, low contrasts, graduated shadings, sharp transitions, and fine elements. (a) low resolution, (b) low contrasts, (c) graduated shadings, (d) sharp transitions, and (e) fine elements.

then to reconstruct $u$ knowing [1]. This problem is ill-posed, and we are able to carry out only an approximation of $u$. In this article, we will focus on the simplified model of pure denoising:

$$f = u + \eta \qquad [2]$$

## The Probabilistic Approach

### The Bayesian Framework

In this section, we show how the problem of pure denoising, that is, recovering $u$ from the equation $f = u + \eta$ knowing only some statistical information on $\eta$ can be solved by using a probabilistic approach. In this context, $f$, $u$, and $\eta$ are considered as random variables. The general idea for recovering $u$ is to maximize some prior probability. Most models involve two parts: a prior model of possible restored images $u$ and a data model expressing consistency with the observed data.

- The prior model is given by a probability space $(\Omega_u, p)$, where $\Omega_u$ is the set of all values of $u$. The model is specified by giving the probability $p(u)$ on all these values.
- The data model is a larger probability space $(\Omega_{u,f}, p)$, where $\Omega_{u,f}$ is the set of all possible values of $u$ and all possible values of the observed image $f$. This model is completed by giving the conditional probability $p(f/u)$ of any image $f$ given $u$, resulting in the joint probabilities $p(f,u) = p(f/u)p(u)$. Implicitly, we assume that the spaces $(\Omega_u)$ and $(\Omega_{u,f})$ are finite although huge.

The next step is to use a Bayesian approach introduced in image processing by Besag (1974) and Geman and Geman (1984). The probabilities $p(u)$ and $p(f/u)$ are supposed to be known and, given an observed image $f$, we seek the image $u$ which maximizes the conditional *a posteriori* probability $p(u/f)$ (MAP: Maximum A Posteriori). Thanks to the Bayes' rule, we have

$$p(u/f) = \frac{p(f/u)p(u)}{p(f)} \qquad [3]$$

Let us explain the meaning of the different terms in [3]:

- The term $p(f/u)$ expresses the probability, the likelihood, that an image $u$ is realized in $f$. It also quantifies the lack of total precision of the model and the presence of noise.
- The term $p(u)$ expresses our incomplete *a priori* information about the ideal image $u$ (it is the probability of the model, i.e., the propensity that $u$ be realized independently of the observation $f$).
- The term $p(f)$ which is the probability to observe $f$ is a constant and does not play any role when maximizing the conditional probability $p(u/f)$ with respect to $u$.

Let us remark that the problem $\max_u p(u/f)$ is equivalent to $\min_u E(u) = -\log p(f/u) - \log p(u)$. So Bayesian models lead to a minimization process.

Then the main question is how to assign these probabilities? The easiest probability to determine is $p(f/u)$. If the images $u$ and $f$ consist in a set of values $u = (u_{i,j}), i,j = 1, N$ and $f = (f_{i,j}), i,j = 1, N$, we suppose the conditional independence of $(f_{i,j}/u_{i,j})$ in any pixel:

$$p(f/u) = \prod_{i=1}^{N} p(f_{i,j}/u_{i,j})$$

and if the restoration model is of the form $f = u + \eta$ where $\eta$ is a white Gaussian noise with variance $\sigma^2$, then

$$p(f_{i,j}/u_{i,j}) = \frac{1}{\sqrt{2\pi\sigma}} \exp - \frac{(f_{i,j} - u_{i,j})^2}{2\sigma^2}$$

and

$$p(f/u) = \frac{1}{(2\pi\sigma)^{N/2}} \exp - \sum_{i,j}^{N} \frac{(f_{i,j} - u_{i,j})^2}{2\sigma^2}$$

Therefore, at this stage, the MAP reduces to minimize

$$E(u) = K_\sigma \|f - u\|^2 - \log p(u) \qquad [4]$$

where $\|.\|$ stands for the Euclidean norm on $\mathbb{R}^{N^2}$ and $K_\sigma$ is a constant. So, it remains now to assign a probability law $p(u)$. To do that, the most common way is to use the theory of Markov random fields (MRFs).

### The Theory of Markov Random Fields

In this approach, an image is described as a finite set $S$ of sites corresponding to the pixels. For each site, we associate a descriptor representing the state of the site, for example, its gray level. In order to take into account local interaction between sites, one needs to endow $S$ with a system of neighborhoods $\mathcal{V}$.

**Definition 1** For each site $s$, we define its neighborhood $\mathcal{V}(s)$ as:

$$\mathcal{V}(s) = \{t\} \text{ such that } s \notin \mathcal{V}(s) \text{ and } t \in \mathcal{V}(s) \Rightarrow s \in \mathcal{V}(t)$$

Then we associate to this neighborhood system the notion of clique: a clique is either a singleton or a set of sites which are all neighbors of each other. Depending on the neighborhood system, the family of cliques will be different and involve more and less sites. We will denote by $\mathcal{C}$ the set of all the cliques relative to a neighborhood system $\mathcal{V}$ (see Figure 2).

Before introducing the general framework of MRFs, let us define some notations. For a site $s$, $X_s$ will stand for a random variable taking its values in some set $\mathcal{E}$ (e.g., $\mathcal{E} = \{0, 1, \ldots, 255\}$) and $x_s$ will be a realization of $X_s$ and $x^s = (x_t)_{t \neq s}$ will denote an image configuration where site $s$ has been removed. Finally, we will denote by $X$ the random variable $X = (X_s, X_t, \ldots)$ with values in $\Omega = \mathcal{E}^{|S|}$.

**Definition 2** We say that $X$ is an MRF if the local conditional probability at a site $s$ is only a function of $\mathcal{V}(s)$, that is,

$$p(X_s = x_s / X^s = x^s) = p(X_s = x_s / x_t, t \in \mathcal{V}(s))$$

Therefore, the gray level at a site depends only on gray levels of neighboring pixels. Now we give the following fundamental theorem due to Hammersley–Clifford (Besag 1974) which states the equivalence between MRFs and Gibbs fields.

**Theorem 1** *Let us suppose that $S$ is finite, $\mathcal{E}$ is a discrete set and for all $x \in \Omega = \mathcal{E}^{|S|}, p(X = x) > 0$, then $X$ is an MRF relatively to a system of neighborhoods $\mathcal{V}$ if and only if there exists a family of potential functions $(V_c)_{c \in \mathcal{C}}$ such that $p(x) = (1/Z)\exp(-\sum_{c \in \mathcal{C}} V_c(x))$.*

*The function $V(x) = \sum_{c \in \mathcal{C}} V_c(x)$ is called the energy potential or the Gibbs measure and $Z$ is a normalizing constant: $Z = \exp(-\sum_{x \in \Omega} V(x))$.*

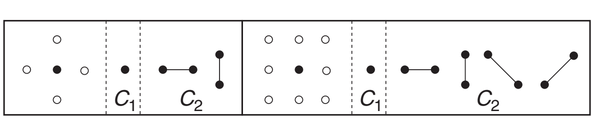

**Figure 2** Examples of neighborhood system and cliques.

If, for example, the collection of neighborhoods is the set of 4-neighbors, then the theorem says that $V(x) = \sum_{c = \{s\} \in C_1} V_c(x_s) + \sum_{c = \{(s,t)\} \in C_2} V_c(x_s, x_t)$.

### Application to the Denoising Problem

Now, given this theorem we can reformulate, thanks to [4], the restoration problem (with the change of notation $u = x$ and $u_s = x_s$): find $u$ minimizing the global energy

$$E(u) = K_\sigma \|f - u\|^2 + V(u) \qquad [5]$$

The next step is now to precise the Gibbs measure. In restoration, the potential $V(u)$ is often dedicated to impose local regularity constraints, for example, by penalizing differences between neighbors. This can be modeled using cliques of order 2 in the following manner:

$$V(u) = \beta \sum_{(s,t) \in \mathcal{C}_2} \phi(u_s - u_t)$$

where $\phi$ is a given real function. This term penalizes the difference of intensities between neighbors which may come from an edge or some noise. This discrete cost function is very similar to the gradient penalty terms in the continuous framework (see the next section). The resulting final energy is (sometimes $E(u)$ is written $E(u/f)$)

$$E(u) = K_\sigma \sum_{s \in S} (f_s - u_s)^2 + \beta \sum_{(s,t) \in \mathcal{C}_2} \phi(u_s - u_t)$$

where the constant $\beta$ is a weighting parameter which can be estimated.

The difficulty in choosing the strength of the penalty term defined by $\phi$ is to be able to penalize the noise while keeping the most salient features, that is, edges. Historically, the function $\phi$ was first chosen as $\phi(z) = z^2$ but this choice is not good since the resulting regularization is too strong introducing a blur in the image and loss of the edges. A better choice is $\phi(z) = |z|$ (Rudin *et al.* 1992) or a regularized version of this function. Of course, other choices are possible depending on the considered application and the desired degree of smoothness.

In this section, it has been shown how to model the restoration problem through MRFs and the Bayesian framework. Numerically, two main types of algorithms can be used to minimize the energy: deterministic algorithms and stochastic algorithms. The former are generally used when the global energy is strictly convex (e.g., algorithms based on

gradient descent). The latter are rather used when $E(u)$ is not convex. There are stochastic minimization algorithms mainly based on simulated annealing. Their main interest is that they always converge (almost surely) to a minimizer (this is not the case for deterministic algorithms which give only local minimizers) but they are often strongly time consuming.

We refer the reader to Li (1995) for more details about MRFs and Bayesian framework and Kirkpatrick *et al.* (1983) for more information on stochastic algorithms.

## The Variational Approach

### Minimizing a Cost Function over a Functional Space

One important issue in the previous section was the definition of $p(u)$ which gives some *a priori* on the solution. In the variational approach, this idea is also present but the way to infer it is in fact to define the more suitable functional space that describes images and their geometrical properties. The choice of a functional space sets a norm which in turn will constrain the solution to a certain smoothness.

We illustrate this idea in this section on the denoising problem [2] which can be seen as a decomposition one. This means that given the observation $f$, we look for $u$ and $\eta$ such that $f = u + \eta$, where $\eta$ incorporates all oscillations, that is, noise, and also texture. Let us define a functional to be minimized which takes into account the data $f$ and possibly some statistical informations about $\eta$:

$$\min_{(u,\eta)}\{\phi(|u|_E) \text{ such that } \psi(|\eta|_G) = \sigma \text{ with } f = u + \eta\} \qquad [6]$$

This formulation means that we look, among all decompositions $f = u + \eta$, for the one which minimizes $\phi(|u|_E)$ under the constraint $\psi(|\eta|_G) = \sigma$. Banach spaces $E$ and $G$, and functions $\phi$ and $\psi$ will be discussed in the next subsection. Since a minimization problem under constraints can be expressed with an additional term weighted by a Lagrange multiplier, the formulation [6] can be rewritten as:

$$\min_{(u,\eta)}\{\phi(|u|_E) + \lambda\psi(|\eta|_G); f = u + \eta\} \qquad [7]$$

A similar writing consists in replacing $\eta$ by $f - u$ so that [7] rewrites

$$\min_{u}\{\phi(|u|_E) + \lambda\psi(|f - u|_G)\} \qquad [8]$$

which is the classical formulation in image restoration. From a numerical point of view, the minimization is usually carried out by solving the associated Euler equations but this may be a difficult task. The main concern is the search for $E$ and $G$ and their norm (or seminorm). It is guided by the choice that an image $u$ is composed of various geometric structures (homogeneous regions, edges) while $\eta = f - u$ represents oscillations (noise and textures).

### Examples of Functional Spaces

In this section, we revisit some possible choices of functional spaces summarized in **Table 1**.

The first case (a) was inspired by the classical Tikhonov regularization. The functional space $H^1(\Omega)(\Omega \subset \mathbb{R}^2)$ is the space of functions in $L^2(\Omega)$ such that the distributional gradient $Du$ is in $L^2(\Omega)$. Unfortunately, functions in $H^1(\Omega)$ do not admit discontinuities across curves and this is a major problem with respect to image analysis since images are made of smooth patches separated by sharp variations.

Considering the problem reported in (a), Rudin *et al.* (1992) proposed to work on $\mathrm{BV}(\Omega)$, the space of bounded variations (BV) Ambrosio *et al.* (2000) defined by

$$\mathrm{BV}(\Omega) = \left\{u \in L^1(\Omega); \int_\Omega |Du| < \infty\right\}$$
$$\text{with } \int_\Omega |Du| = \sup\left\{\int_\Omega u\,\mathrm{div}\varphi\,dx;\ \varphi = (\varphi_1, \varphi_2, \ldots, \varphi_N) \in \mathcal{C}_0^1(\Omega)^N,\ |\varphi|_{L^\infty(\Omega)} \le 1\right\} \qquad [9]$$

**Table 1** Examples of functional spaces and their norm (see model [8])

| Model | $E$ and $\lvert u\rvert_E$ | $\phi(t)$ | $G$ and $\lvert u\rvert_G$ | $\psi(t)$ |
|---|---|---|---|---|
| (a) | $H^1(\Omega), \lvert u\rvert_E = \left(\int_\Omega \lvert\nabla u\rvert^2\,dx\right)^{1/2}$ | $t^2$ | $L^2(\Omega)$ with its usual norm | $t^2$ |
| (b) | $BV(\Omega), \lvert u\rvert_E = \int_\Omega \lvert Du\rvert$ | $t$ | $L^2(\Omega)$ with its usual norm | $t^2$ |
| (c) | $BV(\Omega), \lvert u\rvert_E = \int_\Omega \lvert Du\rvert$ | $t$ | $\{b \in L^2(\Omega); b = \mathrm{div}\xi, \lvert\xi\rvert_{L^\infty(\Omega)^2} \le 1, \xi\cdot N\rvert_{\partial\Omega} = 0\}$ | $t$ |

It is equivalent to define BV($\Omega$) as the space of $L^1(\Omega)$ functions whose distributional gradient $Du$ is a bounded measure and [9] is its total variation. The space BV($\Omega$) has some interesting properties:

1. lower semicontinuity of the total variation $\int_\Omega |Du|$ with respect to the $L^1(\Omega)$ topology,
2. if $u \in \mathrm{BV}(\Omega)$, we can define, for $\mathcal{H}^1$ almost everywhere $x \in S_u$, the complement of Lebesgue points (i.e., the jump set of $u$), a normal $n_u(x)$ and two approximate "right" and "left" limits $u^+(x)$ and $u^-(x)$, and
3. $Du$ can be decomposed as a sum of a regular measure, a jump measure, and a Cantor measure:

$$Du = \nabla u \, \mathrm{d}x + (u^+ - u^-) n_u \mathcal{H}^1_{/S_u} + C_u$$

where $\nabla u$ is the approximate gradient and $\mathcal{H}^1$ the one-dimensional Hausdorff measure.

This ability to describe functions with discontinuities across a hypersurface $S_u$ makes BV($\Omega$) very convenient to describe images with edges. In this context, the image restoration problem is well posed and suitable numerical tools can be proposed (Chambolle and Lions 1997).

One criticism of the model (b) in **Table 1** pointed out by Meyer (2001) is that if $f$ is a characteristic function and if $f$ is sufficiently small with respect to a suitable norm, then the model (Rudin *et al.* 1992) gives $u = 0$ and $\eta = f$ contrary to what one should expect ($u = f$ and $\eta = 0$). In fact, the main reason of this phenomenon is that the $L^2$-norm for the $\eta$ component is not the right one since very oscillating functions can have large $L^2$-norm (e.g., $f_n(x) = \cos(nx)$). To better describe such oscillating functions, Meyer (2001) introduced the space of functions which can be expressed as a divergence of $L^\infty$-fields. This work was developed in $R^N$ and this framework was adapted to bounded 2D domains by Aubert and Aujol (2005) (see (c) in **Table 1**). An example of image decomposition is shown in **Figure 3**.

In this section, we have shown how the choice of the functional spaces is closely related to the definition of a variational formulation. The functionals are written in a continuous setting and they can usually be minimized by solving the discretized Euler equations iteratively, until convergence. These PDEs and the differential operators are constrained by the energy definition but it is also possible to work directly on the equations, forgetting the formal link with the energy. Such an approach has also been much developed in the computer vision community and it is illustrated in the next section.

We refer the reader to Aubert and Kornprobst (2002) for a general review of variational approaches and PDEs as applied to image analysis.

**Figure 3** Example of image decomposition (see Aubert and Aujol (2005)).

## Scale Spaces and PDEs

Another approach to perform nonlinear filtering is to define a family of image smoothing operators $T_t$, depending on a scale parameter $t$. Given an image $f(x)$, we can define the image $u(t,x) = (T_t f)(x)$ which corresponds to the image $f$ analyzed at scale $t$. In this section, following Alvarez–Guichard–Lions–Morel (Alvarez *et al.* 1993), we show that $u(t,x)$ is the solution of a PDE provided some suitable assumptions on $T_t$.

### Basic Principles of a Scale Space

This section describes some natural assumptions to be fulfilled by scale spaces. We first assume that the output at scale $t$ can be computed from the output at a scale $t - h$ for very small $h$. This is natural, since a coarser scale view of the original picture is likely to be deduced from a finer one. $T_t$ is obtained by composition of transition filters, denoted by $T_{t+h,t}$. So the first axiom is

(A1) $T_{t+h} = T_{t+h,t} T_t \quad T_0 = \mathrm{Id}$

Another assumption is that operators act locally, that is, $(T_{t+h,t} f)(x)$ depends essentially upon the values of $f(y)$ with $y$ in a small neighborhood of $x$. Taking into account the fact that as the scale increases, no new feature should be created by the scale space, we have the local comparison principle: if an image $u$ is locally brighter than another image $v$, then this order must be conserved by the analysis. This is expressed by:

(A2) For all $u$ and $v$ such that $u(y) > v(y)$ in a neighborhood of $x$ and $y \neq x$, then for $h$ small enough, we have

$$(T_{t+h,t} u)(x) \geq (T_{t+h,t} v)(x)$$

The third assumption states that a very smooth image must evolve in a smooth way with the scale

space. Denoting the scalar product of two vectors of $\mathbb{R}^N$ by $<x, y>$, this assumption can be written as

(A3) Let $u(y) = 1/2\langle A(y-x), y-x\rangle + \langle p, y-x\rangle + c$ be a quadratic form of $\mathbb{R}^2$, $x$ fixed ($A = \nabla^2 u(x) \in S^{(2)}$ the set of $2 \times 2$ symmetric matrices, $p = \nabla u(x)$ a vector of $\mathbb{R}^2$, $c = u(x)$ a constant.). We shall say that a scale space is regular if there exists a function $F(t, x, c, p, A)$, continuous with respect to $A$, such that

$$\frac{(T_{t+h,t}u - u)(x)}{h} \to F(t, x, c, p, A) \quad \text{when } h \to 0$$

### Scale Spaces are Governed by PDEs

In the following theorem, it is stated that the former assumptions are sufficient to prove that scale spaces are in fact governed by PDEs.

**Theorem 2** *Under assumptions* A1, A2, A3, *there exists a continuous function* $F : [0, T] \times \Omega \times R \times \mathbb{R}^2 \times S^{(2)} \to \mathbb{R}$ *satisfying* $F(t,x,c,p,A) \geq F(t,x,c,p,B)$ *for all* $p \in \mathbb{R}^2$, *A and B in* $S^{(2)}$ *with* $A \geq B$ *such that*

$$\delta_t(u) = \frac{T_{t+h,t}u - u}{h} \to F(t, x, u, \nabla u, \nabla^2 u), \quad h \to 0^+ \qquad [10]$$

*uniformly for* $x \in \mathbb{R}^2$, *uniformly for* $u$.

In eqn [10], the left-hand side term can be interpreted as the partial temporal derivative with respect to $t$ so that the notion of PDEs arises. More precisely, if $f$ is continuous and uniformly bounded, then it can be established that $u(t, x) = (T_t f)(x)$ is the viscosity solution(see Definition 3) of

$$\begin{aligned} &\frac{\partial u}{\partial t} + H(t, x, u, \nabla u, \nabla^2 u) = 0 \text{ (here } H = -F) \\ &u(0, x) = f(x) \end{aligned} \qquad [11]$$

The map $H : [0, T] \times \Omega \times R \times R^2 \times S^{(2)} \to \mathbb{R}$ is called a Hamiltonian and the decreasing property of $H$ with respect to $S$ is called degenerate ellipticity.

The theory of viscosity solutions was introduced in the 1980s by Crandall and P L Lions (Crandall and Lions 1981, Crandall *et al.* 1992). When strong solutions of [11] do not exist, this theory allows to define solutions which are only continuous or even discontinuous. The definition of viscosity solutions is

**Definition 3** Let $H : \Omega \times \mathbb{R} \times \mathbb{R}^2 \times S^{(2)} \to \mathbb{R}$ be continuous and degenerate elliptic and let $u \in C^0([0, T] \times \Omega)$. Then $u$ is a viscosity solution of [11] in $[0, T] \times \Omega$ if and only if

(i) $u$ is a subsolution, that is, $\forall \phi \in C^2([0, T] \times \Omega)$, $\forall (t_0, x_0)$ a local strict maximum point of $(u - \phi)(t, x)$, we have

$$\frac{\partial \phi}{\partial t}(t_0, x_0) + H(t_0, x_0, u(t_0, x_0), \nabla \phi(t_0, x_0), \nabla^2 \phi(t_0, x_0)) \leq 0$$

(ii) $u$ is a supersolution, that is, $\forall \phi \in C^2([0, T] \times \Omega)$, $\forall (t_0, x_0)$ a local strict minimum point of $(u - \phi)(t, x)$, we have

$$\frac{\partial \phi}{\partial t}(t_0, x_0) + H(t_0, x_0, u(t_0, x_0), \nabla \phi(t_0, x_0), \nabla^2 \phi(t_0, x_0)) \geq 0$$

In this definition, it is noticeable that derivatives of $u$ are replaced by the derivatives of the test functions $\phi$. Obviously, it can be verified that this notion of weak solutions coincides with classical solution when $u$ has enough regularity.

### Diffusion Operators Coming from the Scale Space

A step further is to assume additional properties on the scale spaces and estimate the corresponding operator. Invariance properties include geometric invariance axioms, contrast invariance, or scale invariance. For example, if we assume the axioms A1–A3, gray-level shift invariance:

(I1) $T_t(0) = 0, T_t(u + c) = T_t(u) + c$ for all $u$ and all constant $c$.

and translation invariance:

(I2) $T_t(\tau_h.u) = \tau_h.(T_t u)$ for all $h$ in $\mathbb{R}^2, t \geq 0$, where $(\tau_h.u)(x) = u(x + h)$.

Then it can be established that $F$ in [10] is independent of $(x, u)$, that is, $u(t, x) = (T_t f)(x)$ is the unique viscosity solution of

$$\begin{aligned} &\frac{\partial u}{\partial t} = F(\nabla u, \nabla^2 u) \\ &u(0, x) = f(x) \end{aligned}$$

With more precise assumptions, one can even recover explicitly the operator $F$. As an example, if we look for a linear scale space which verifies some isometry assumption:

(I3) $T_t(R.u)(x) = R.(T_t u)(x)$ for all orthogonal transformation $\mathbb{R}$ on $\mathbb{R}^2$, where $(R.u)(x) = u(Rx)$.

Then it can be proved that the scale space is the unique solution of the heat equation:

$$\frac{\partial u}{\partial t} - \Delta u = 0 \qquad [12]$$
$$u(0, x) = f(x)$$

Figure 4 is an example of [12] applied to a noisy image at different scale, that is, at different time. Note that noise is quickly removed but one has to stop the evolution very early if we would like to preserve some edges. In the nonlinear cases, several operators have also been found based on curvature. For instance, under suitable axioms (Alvarez *et al.* 1993), including contrast, scale, and affine invariance, the associated scale space is

$$\frac{\partial u}{\partial t} - \operatorname{sign}(\kappa)(t\kappa)^{1/3}|\nabla u| = 0$$
$$\text{where } \kappa = \operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) \qquad [13]$$
$$u(0, x) = f(x)$$

This equation is called affine morphological scale space (AMSS) and three restored images are shown in Figure 5. Some qualitative differences are shown in Figure 6.

**Figure 4** Illustration of heat equation [12].

**Figure 5** Illustration of the AMSS model [13].

**Figure 6** Some close-ups of Figures 4 and 5 showing qualitative differences after 40 iterations.

**Remark** Scale space theory has shown the formal link between some operators and PDEs. It has to be noticed that one may propose some PDEs which do not directly come from the scale space framework. Starting from [12] which performs isotropic smoothing and smears edges, many nonlinear diffusion models have been proposed to smooth images while preserving edges (see e.g., Perona and Malik (1990)). □

To know more on scale space and PDEs, we refer the reader to Weickert (1998) and Aubert and Kornprobst (2002).

## The Wavelet Approach

Before the 1980s, the Fourier transform played a major role for analyzing oscillating signals. The interest of such a transform for real application increased after the discovery of the fast Fourier transform. However, the Fourier transform has some limit. The Fourier transform extracts from the signal details of the frequency content but loses all information on the location of particular frequency. Moreover, for computing the Fourier transform $\mathcal{F}f(\lambda)$, we need to know $f(t)$ for all the real values of $t$. These difficulties can be overcome by first windowing the signal, and then by taking its Fourier transform:

$$\mathcal{F}^{\text{win}} f(\lambda, t) = \int_{\mathbb{R}} f(s) g(s - t) \mathrm{e}^{-\mathrm{i}\lambda s} \mathrm{d}s$$

where $g$ is a window function. The parameter $\lambda$ plays the role of a frequency localized around the abscissa $t$ of the temporal signal and $\mathcal{F}^{\text{win}} f(\lambda, t)$ give an information about what is happening around $s = t$, for the frequency $\lambda$. The main drawback of this method is that the window has a fixed length which is a serious disadvantage when we want to treat signals having variations of different orders of magnitude. All these issues highlighted that a mathematical theory of time–frequency representation was necessary. This was achieved with the wavelet representation. In this section, we first recall some elements of this theory (for 1D signal) and then we show how it can be applied for restoring noisy images.

### The Wavelet Decomposition

The basic idea is to construct from a function $\psi$, called mother wavelet, an orthonormal basis $\{\psi_{j,k}\}$ of $L^2(\mathbb{R})$ deduced from $\psi$ by translation and dilatation. It is required that $\psi$ be regular, oscillating (but not too much), that $\psi$ and $\mathcal{F}\psi$ are well localized and that $\psi$ has some null moments. Once this function $\psi$ is

chosen, we set $\psi_{j,k}(x) = 2^{j/2}\psi(2^j t - k), j, k \in \mathbb{Z}$. An elegant and practical way for obtaining such a basis is to construct a multiresolution analysis of $L^2(\mathbb{R})$ (Mallat 1989).

**Definition 4** A multiresolution analysis of $L^2(\mathbb{R})$ is a sequence $V_j$, $j \in \mathbb{Z}$ of subspaces of $L^2(\mathbb{R})$, with the following properties:

(i) $\bigcap_j V_j = \{0\}$,
(ii) $V_j \subset V_{j+1}$,
(iii) $\bigcup_j V_j = L^2(\mathbb{R})$,
(iv) $f(t) \in V_j$ if and only if $f(2t) \in V_{j+1}$, and
(v) There exists a regular function $\phi$ with compact support such that the family $\phi(t-k), k \in \mathbb{Z}$, is an orthonormal basis of $V_0$ for the scalar product of $L^2(\mathbb{R})$. Such a function $\phi$ is called a scaling function.

Then it is straightforward to check that the family $\phi_{j,k}(t)$ defined by $\phi_{j,k}(t) = 2^{j/2}\phi(2^j t - k)$ is an orthonormal basis of $V_j$.

A basic example of multiresolution analysis of $L^2(\mathbb{R})$ is to choose $V_0$ as the set of piecewise constant functions on $\mathbb{R}$ and take $\phi$ as the characteristic function of the interval $[0, 1)$: $\phi(t) = \chi_{[0,1)}(t)$.

Let us now look at the link between wavelet basis and multiresolution analysis. We just give main ideas, all details can be found in the work of Mallat (1989). Assume that we have a multiresolution analysis, and let us define $W_0$ as the orthogonal complement of $V_0$ in $V_1$. We build the mother wavelet $\psi$ by imposing that the family $\psi(t-k)$, $k \in \mathbb{Z}$, is an orthonormal basis of $W_0$. For example, if $\phi(t) = \chi_{[0,1)}(t)$, it can be shown that $\psi(t) = \chi_{[0,1/2)}(t) - \chi_{[1/2,1)}(t)$ (called the Haar wavelet). By change of scale, one gets that the family $\psi_{j,k}(t) = 2^{j/2}\psi(2^j t - k), k \in \mathbb{Z}$, is an orthonormal basis of $W_j$, the orthogonal complement of $V_j$ in $V_{j+1}$, that is,

$$V_j \oplus W_j = V_{j+1} \qquad [14]$$

Since the $V_j$'s are a multiresolution analysis, we have $V_J = \oplus_{j=-\infty}^{J-1} W_j$ and $L^2 = \oplus_{j=-\infty}^{j=+\infty} W_j$. It is then clear that $\psi_{j,k}(t)$ is an orthonormal basis of $L^2(\mathbb{R})$, that is, for each function $f \in L^2(\mathbb{R})$, we get the following decomposition:

$$f(t) = \sum_{-\infty}^{+\infty} \sum_k f_{j,k} \psi_{j,k}(t) \quad \text{with } f_{j,k} = \langle f, \psi_{j,k} \rangle_{L^2}$$

Let us see now how in practice a multiresolution analysis can be interpreted. Let $f$ be a function in $L^2(\mathbb{R})$. We denote $A_{2^j} f$ (resp. $D_{2^j} f$) the operator which approximates $f$ (resp. gives the details of $f$) at resolution $2^j$. More precisely, $A_{2^j} f$ (resp. $D_{2^j} f$) is the projection of $f$ on $V_j$ (resp. on $W_j$):

$$A_{2^j} f(t) = \sum_{k=-\infty}^{k=+\infty} \langle f, \phi_{j,k} \rangle \phi_{j,k}(t)$$

$A_{2^j} f$ is characterized by the sequence of scalar products $A_{2^j}^d f = \{\langle f, \phi_{j,k} \rangle\}_{k \in \mathbb{Z}}$. We call $A_{2^j}^d f$ the discrete approximation of $f$ at resolution $2^j$.

In the same way, we have

$$D_{2^j} f(t) = \sum_{k=-\infty}^{k=+\infty} \langle f, \psi_{j,k} \rangle \psi_{j,k}(t)$$

$D_{2^j} f$ is characterized by the sequence of scalar products $D_{2^j}^d f = \{\langle f, \psi_{j,k} \rangle\}_{k \in \mathbb{Z}}$.

We call $D_{2^j}^d f$ the details of $f$ at resolution $2^j$. According to [14], approximation and detail are linked by the relation

$$A_{2^{j+1}} f = A_{2^j} f + D_{2^j} f$$

This means that $D_{2^j} f$ represents the details to be added to obtain from one level of approximation to the next level of approximation.

Finally, the decomposition of a signal $f$ on a wavelet basis is obtained as an accumulation of details at scale $2^j$ from 0 to $+\infty$:

$$f = \sum_{j=-\infty}^{j=+\infty} D_{2^j} f = \sum_{j=-\infty}^{j=+\infty} \sum_{k=-\infty}^{k=+\infty} \langle f, \psi_{j,k} \rangle \psi_{j,k} \qquad [15]$$

Instead of considering the sum over all dyadic levels $j$, one can sum over $j \geq J$ for a fixed $J$; in this case, we have

$$f = \sum_{k=-\infty}^{k=+\infty} \sum_{j \geq J} \langle f, \psi_{j,k} \rangle \psi_{j,k} + \sum_{k=-\infty}^{k=+\infty} \langle f, \phi_{J,k} \rangle \phi_{J,k}$$

We conclude this section by showing how we can construct a 2D wavelet basis from the 1D case. We can simply use a tensor product. Scaling function and mother wavelet are given, respectively, as follows:

$$\phi(x, y) = \phi(x)\phi(y), \qquad \Psi = (\psi^1, \psi^2, \psi^3)$$

with

$$\psi^1(x, y) = \phi(x)\psi(y)$$
$$\psi^2(x, y) = \phi(y)\psi(x)$$
$$\psi^3(x, y) = \psi(x)\psi(y)$$

As for the 1D case, $A_{2^j} f$ denotes the projection of $f$ on $V_j, D_{2^j}^1$ the horizontal details, $D_{2^j}^2$ the vertical

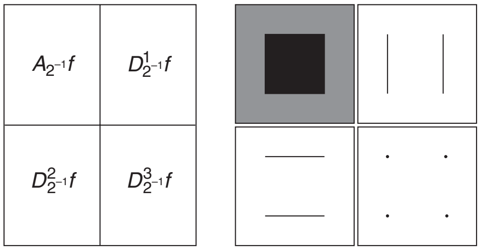

**Figure 7** Illustration on the wavelets methodology.

**Figure 8** Illustration of two regularization methods.

details, and $D^3_{2^j}$ the other details (the indice $l$ in $D^l_{2^j}$ is the same as in $\psi^l$). For a 2D image $f$, we then have the following decomposition (see Figure 7):

$$f = \sum_{\psi^l \in \Psi} \sum_{k=-\infty}^{k=+\infty} \sum_{j \geq J} \langle f, \psi_{j,k} \rangle \psi_{j,k} + \sum_{k=-\infty}^{k=+\infty} \langle f, \phi_{J,k} \rangle \phi_{J,k}$$

### Application to the Denoising Problem

We go back to the denoising problem. Our goal is to solve this problem by using a variational approach and wavelets. We recall that we have an ideal image $u$ that has been corrupted by a white Gaussian noise $\eta$ resulting in an observation $f$ with $f = u + \eta$. As it has been seen in the section "The variational approach," this question can be tackled by solving the variational problem

$$\min_u \{ \lambda \phi(|u|_E) + |f - u|_G \} \qquad [16]$$

for suitable choices of $E$, $G$, and $\phi$. Here we propose to choose $G = L^2(\Omega)$ ($\Omega$ is the domain image) and for $E$ the Besov space $B^1_1(L^1(\Omega))$ and $\phi =$ Identity. Besov spaces $B^\alpha_q(L^p(\Omega))$ are used in many domains of mathematics as harmonic analysis or approximation theory. There exist different ways for defining them. Roughly speaking, they consist of functions having $\alpha$ derivatives in $L^p(\Omega)$; the third parameter $q$ allows one to make finer distinctions in smoothness. Here we are only concerned with the Besov space $B^1_1(L^1(\Omega))$. One important property needed here is that the norm of a function in $E = B^1_1(L^1(\Omega))$ is equivalent to the $l^1$-norm of the wavelet coefficients, that is if $\{\psi_{j,k}\}$ is an orthonormal basis of $L^2(\Omega)$ and if $u_{j,k,\psi}$ are the wavelet coefficients of $u \in E$, then $|u|_E = \sum_j \sum_{k,\psi} |u_{j,k,\psi}|$.

**Remark** When one is concerned with a finite domain, then some changes must be made with respect to the construction given in [15] to obtain an orthonormal basis of $L^2(\Omega)$. To avoid further technical complications, we ignore this question. □

Let us denote, respectively, by $\{u_{j,k,\psi}\}$ and $\{f_{j,k,\psi}\}$ the wavelet coefficients of $u$ and $f$, then solving [16] amounts to finding the minimizer of the functional

$$F(u) = \lambda \sum_{j,k,\psi} |u_{j,k,\psi}| + \sum_{j,k,\psi} |u_{j,k,\psi} - f_{j,k,\psi}|^2 \qquad [17]$$

One notes immediately that minimizing problem [17] reduces to finding the minimizer $s$, given $t$, of $E(s) = |s - t|^2 + \lambda|s|$ and that the minimizer of $E(s)$ is given by $s = t - (\lambda/2)$ if $t > \lambda/2, s = 0$ if $|t| \leq \lambda/2$ and $s = t + (\lambda/2)$ if $t < -(\lambda/2)$.

Thus, we shrink the wavelet coefficients $f_{j,k,\psi}$ toward zero by an amount of $\lambda/2$ to obtain the minimizer. This is exactly the wavelet shrinkage algorithm of Donoho and Johnstone (1994). It is remarkable that the wavelet shrinkage algorithm, which has been found by using statistical tools, can also be explained via a variational approach (Chambolle *et al.* 1998). Figure 8 shows an example of the result on a noisy image.

For more details, we refer the reader to Mallat (1998).

## Conclusion

Image processing is a challenging domain of applied mathematics which has to deal with discrete and continuous representations. In this article, we have covered the core mathematical tools used in the area. The example of gray-scale image restoration allowed us to illustrate and compare the different methodologies. Naturally, as mentioned in the introduction, image processing refers to a wide variety of applications and an intensive research has been carried out on the different topics using the methodologies described here. The reader will find in the references (therein) several illustrations of challenging problems.

# Incompressible Euler Equations: Mathematical Theory

**D Chae**, Sungkyunkwan University, Suwon, South Korea

## Introduction

In this article we present comprehensive mathematical results on the incompressible Euler equations. Our presentation is focussed on the two aspects of the equations. The first one is on the theories of classical solutions and the problem of global in time continuation/finite time blow-up of the local classical solutions. The second topic is concerned on the weak solutions, mainly for the two-dimensional (2D) Euler equations for existence and uniqueness questions.

The motion of homogeneous incompressible ideal fluid in a domain $\Omega \subset \mathbb{R}^n$ is described by the following system of Euler equations:

$$\frac{\partial v}{\partial t} + (v \cdot \nabla)v = -\nabla p \qquad [1]$$

$$\operatorname{div} v = 0 \qquad [2]$$

$$v(x,0) = v_0(x) \qquad [3]$$

where $v = (v^1, v^2, \ldots, v^n), v^j = v^j(x,t), j = 1, 2, \ldots, n$, is the velocity of the fluid flows, $p = p(x,t)$ is the scalar pressure, and $v_0(x)$ is a given initial velocity field satisfying $\operatorname{div} v_0 = 0$. Here we use the standard notion of vector calculus, denoting

$$\nabla p = \left(\frac{\partial p}{\partial x_1}, \frac{\partial p}{\partial x_2}, \dots, \frac{\partial p}{\partial x_n}\right)$$

$$(v \cdot \nabla)v^j = \sum_{k=1}^{n} v^k \frac{\partial v^j}{\partial x_k}$$

$$\operatorname{div} v = \sum_{k=1}^{n} \frac{\partial v^k}{\partial x_k}$$

Equation [1] represents the balance of momentum for each portion of fluid, while eqn [2] represents the conservation of mass of fluid during its motion, combined with the homogeneity (constant density) assumption on the fluid. Equations [1] and [2] are first obtained by Euler in 1755. Although we could consider, more generally, the inhomogeneous incompressible Euler equations, in mathematical fluid mechanics considerations the incompressible Euler equations usually mean the above system [1]–[2]. For a bounded domain with fixed boundary $\partial\Omega$, the natural boundary condition is

$$v(x,t) \cdot \nu(x) = 0 \quad \forall (x,t) \in \partial\Omega \times [0,\infty) \qquad [4]$$

where $\nu(x)$ is the unit normal vector at the boundary point $x \in \partial\Omega$. Several studies are concerned with the Cauchy problem of the system [1]–[3], where we consider the case

$$\Omega = \begin{cases} \mathbb{R}^n (\text{whole domain of } \mathbb{R}^n), \text{or} \\ \mathbb{R}^n/\mathbb{Z}^n (\text{periodic domain}) \end{cases} \qquad [5]$$

In this article for simplicity we suppose $\Omega = \mathbb{R}^n, n = 2, 3$ unless otherwise stated. We note that the Euler equation is obtained formally by setting the viscosity $= 0$, or, equivalently, Reynolds number $= \infty$ in the Navier–Stokes equations. Thus, we may view the Euler equations as the one describing approximately the extremely high Reynolds number turbulent flows. For detailed mathematical studies on the finite Reynolds number Navier–Stokes equations, see Temam (1984) and Lions (1996). For much shorter and more comprehensive review see Constantin (1995). In the study of the Euler equations the notion of vorticity, $\omega = \operatorname{curl} v$, plays a very important role. In particular, we can reformulate the system in terms of vorticity fields only as follows. We first suppose we are working in three-dimensional (3D) space, and rewrite [1] as

$$\frac{\partial v}{\partial t} - v \times \operatorname{curl} v = -\nabla\left(p + \frac{1}{2}|v|^2\right) \qquad [6]$$

Taking curl of [6], and using elementary vector identities we obtain the following vorticity formulation:

$$\frac{\partial \omega}{\partial t} + (v \cdot \nabla)\omega = \omega \cdot \nabla v \qquad [7]$$

$$\operatorname{div} v = 0, \qquad \operatorname{curl} v = \omega \qquad [8]$$

$$\omega(x,0) = \omega_0(x) \qquad [9]$$

The linear elliptic system [8] for $v$ can be solved explicitly in terms of $\omega$ to give the Biot–Savart law

$$v(x,t) = \frac{1}{4\pi}\int_{\mathbb{R}^3} \frac{(x-y) \times \omega(y,t)}{|x-y|^3}\,dy \qquad [10]$$

Substituting this $v$ into [7] formally, we obtain a integrodifferential system for $\omega$. The term in the right-hand side of [7] is called the "vortex stretching term," and is regarded as the main source of difficulties in the mathematical theory of the 3D Euler equations. In the 2D case we take the vorticity as the scalar, $\omega = \partial v^2/\partial x_1 - \partial v^1/\partial x_2$, and the evolution equation of $\omega$ becomes

$$\frac{\partial \omega}{\partial t} + (v \cdot \nabla)\omega = 0 \qquad [11]$$

combined with the 2D Biot–Savart law,

$$v(x,t) = \frac{1}{2\pi}\int_{\mathbb{R}^2} \frac{(-y_2 + x_2, y_1 - x_1)}{|x-y|^2}\,\omega(y,t)\,dy \qquad [12]$$

In many studies of the Euler equations it is convenient to introduce the notion of "particle trajectory mapping," $\Phi(\cdot,t)$ defined by

$$\frac{\partial \Phi(\alpha,t)}{\partial t} = v(\Phi(\alpha,t),t)$$
$$\Phi(\alpha,0) = \alpha, \qquad \alpha \in \Omega \qquad [13]$$

The mapping $\Phi(\cdot,t)$ transforms from the location of the initial fluid particles to the location at time $t$, and the parameter $\alpha$ is called the Lagrangian particle marker. If we denote the Jacobian of the transformation, $\det(\nabla_\alpha \Phi(\alpha,t)) = J(\alpha,t)$, then we can show easily that

$$\frac{\partial J}{\partial t} = (\operatorname{div} v)J$$

which implies the fact that the velocity field $v$ satisfies the incompressibility, $\operatorname{div} v = 0$ if and only if the mapping $\Phi(\cdot,t)$ is volume preserving. At this moment, we note that, although the Euler equations are originally derived by applying the mass conservation and the momentum balance principles, we could also derive them by applying the principle of least action to the action defined by

$$\mathcal{A}(\Phi) = \frac{1}{2}\int_{t_1}^{t_2}\int_{\Omega}\left|\frac{\partial \Phi(x,t)}{\partial t}\right|^2 dx\,dt$$

Here, $\Phi(\cdot,t): \Omega \to \Omega$ is a parametrized family of volume-preserving diffeomorphism. This variational approach to the Euler equations implies that we can

view solutions of the Euler equations as a geodesic curve in the $L^2$-metric on the infinite-dimensional manifold of volume-preserving diffeomorphisms (see for more details, e.g., Arnol'd and Khesin (1998)).

The 3D Euler equations have many conserved quantities. We list some important ones below.

1. *Energy*

$$E(t) = \frac{1}{2}\int_\Omega |v(x,t)|^2 \, dx \qquad [14]$$

2. *Helicity*

$$H(t) = \int_\Omega v(x,t) \cdot \omega(x,t) \, dx \qquad [15]$$

3. *Circulation*

$$\Gamma_{C(t)} = \oint_{C(t)} v \cdot dl \qquad [16]$$

where $C(t) = \{\Phi(\alpha,t) | \alpha \in C\}$ is the curve moving along with the fluid.

4. *Impulse*

$$I(t) = \frac{1}{2}\int_\Omega x \times \omega \, dx \qquad [17]$$

5. *Moment of impulse*

$$M(t) = \frac{1}{3}\int_\Omega x \times (x \times \omega) \, dx \qquad [18]$$

The proof of conservations of the above quantities can be carried out without difficulty by using elementary vector calculus (for details see, e.g., Chorin and Marsden (1993), Majda and Bertozzi (2002), Marchioro and Pulvirenti (1994)). The helicity above, in particular, represents the degree of knotedness of the vortex lines in the fluid, where the vortex lines are the integral curves of the vorticity fields. Arnol'd and Khesin (1998) discuss in detail aspects of helicity and other geometric aspects of the Euler equations. For the 2D Euler equations there is no analog of helicity, while the circulation conservation is replaced by the vorticity flux integral,

$$\int_{A(t)} \omega(x,t) \, dx \qquad [19]$$

where $A(t) = \{\Phi(\alpha,t) | \alpha \in A\}$ is a planar region moving along the fluid. The impulse and the moment of impulse integrals are replace by

$$\frac{1}{2}\int_\Omega (x_2, -x_1)\omega \, dx \qquad [20a]$$

and

$$-\frac{1}{3}\int_\Omega |x|^2 \omega \, dx \qquad [20b]$$

respectively.

In the 2D ideal incompressible fluids we have extra conserved quantities; namely for any $p \in [1,\infty]$ the integral

$$\int_\Omega |\omega(x,t)|^p dx \qquad [21]$$

is conserved (as a matter of fact we can extend this statement by replacing the integral by $\int_\Omega f(\omega(x,t))dx$ for any continuous function $f$). There are many known explicit solutions to the Euler equations (See e.g., Lamb (1932) and Majda and Bertozzi (2002)).

## Local Existence and the Blow-Up Problem

### The Classical Results

We first introduce some notations of function spaces. The Lebesgue space $L^p(\Omega), p \in [1,\infty]$, is the Banach space defined by the norm

$$\|f\|_{L^p} := \begin{cases} \left(\int_\Omega |f(x)|^p dx\right)^{1/p}, & p \in [1,\infty) \\ \text{ess.}\sup_{x\in\Omega} |f(x)|, & p = \infty \end{cases}$$

Let us set $\alpha := (\alpha_1, \alpha_2, \ldots, \alpha_n) \in (\mathbb{Z}_+ \cup \{0\})^n$ with $|\alpha| = \alpha_1 + \alpha_2 + \cdots + \alpha_n$. Then, $D^\alpha := D_1^{\alpha_1} D_2^{\alpha_2} \cdots D_n^{\alpha_n}$, where $D_j = \partial/\partial x_j, j = 1, 2, \ldots, n$. For given $k \in \mathbb{Z}$ and $p \in [1,\infty)$ the Sobolev space, $W^{k,p}(\Omega)$ is the Banach space of functions consisting of functions $f \in L^p(\Omega)$ such that

$$\|f\|_{W^{k,p}} := \left(\int_\Omega |D^\alpha f(x)|^p \, dx\right)^{1/p} < \infty$$

where the derivatives are in the sense of distributions. For $p = \infty$ we replace the $L^p$-norm by the $L^\infty$ norm. In order to cooperate with the fractional derivatives of order $s \in \mathbb{R}$, we use the space $L^s_p(\Omega)$ defined by the Banach spaces norm,

$$\|f\|_{L^{s,p}} := \|(1-\Delta)^{s/2} f\|_{L^p}$$

where $(1-\Delta)^{s/2} f = \mathcal{F}^{-1}[(1+|\xi|^2)^{s/2}\mathcal{F}(f)(\xi)]$ with $\mathcal{F}(\cdot)$ and $\mathcal{F}^{-1}(\cdot)$ denoting the Fourier transform and its inverse. Below we outline the key ideas of proving the local existence theorems for the Euler equations. For more details we refer the reader to Majda and Bertozzi (2002). For simplicity, we use the function space $H^m(\mathbb{R}^n) = W^{m,2}(\mathbb{R}^n), n = 2, 3$. Taking derivatives $D^\alpha$ on [1], and then taking its

$L^2$ inner product with $D^\alpha v$, and summing over the multi-indices $\alpha$ with $|\alpha| \le m$, we obtain

$$\begin{aligned}\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|v\|_{H^m}^2 &= -\sum_{|\alpha|\le m}(D^\alpha(v\cdot\nabla)v-(v\cdot\nabla)D^\alpha v, D^\alpha v)_{L^2}\\ &\quad-\sum_{|\alpha|\le m}((v\cdot\nabla)D^\alpha v, D^\alpha v)_{L^2}\\ &\quad-\sum_{|\alpha|\le m}(D^\alpha\nabla p, D^\alpha v)_{L^2}\\ &\equiv \mathrm{I}+\mathrm{II}+\mathrm{III}\end{aligned}$$

By integration by parts, we obtain

$$\mathrm{III} = -\sum_{|\alpha|\le m}(D^\alpha p, D^\alpha \operatorname{div} v)_{L^2} = 0$$

Integrating by parts again, and using the fact that div $v = 0$, we have

$$\begin{aligned}\mathrm{II} &= -\frac{1}{2}\sum_{|\alpha|\le m}\int_{\mathbb{R}^3}(v\cdot\nabla)|D^\alpha v|^2\,\mathrm{d}x\\ &= \frac{1}{2}\sum_{|\alpha|\le m}\int_{\mathbb{R}^3}\operatorname{div} v|D^\alpha v|^2\,\mathrm{d}x = 0\end{aligned}$$

We now use the so-called commutator type of estimate,

$$\begin{aligned}&\sum_{|\alpha|\le m}\|D^\alpha(fg)-fD^\alpha g\|_{L^2}\\ &\quad\le C(\|\nabla f\|_{L^\infty}\|g\|_{H^{m-1}}+\|f\|_{H^m}\|g\|_{L^\infty})\end{aligned}$$

and obtain

$$\begin{aligned}I &\le \sum_{|\alpha|\le m}\|D^\alpha(v\cdot\nabla)v-(v\cdot\nabla)D^\alpha v\|_{L^2}\|v\|_{H^m}\\ &\le C\|\nabla v\|_{L^\infty}\|v\|_{H^m}^2\end{aligned}$$

Summarizing the above estimates, I–III, we have

$$\frac{\mathrm{d}}{\mathrm{d}t}\|v\|_{H^m}^2 \le C\|\nabla v\|_{L^\infty}\|v\|_{H^m}^2 \qquad [22]$$

Further estimate, using the Sobolev inequality, $\|\nabla v\|_{L^\infty} \le C\|v\|_{H^m}$ for $m > 5/2$, gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\|v\|_{H^m}^2 \le C\|v\|_{H^m}^3$$

Thanks to Gronwall's lemma, we have the local-in-time uniform estimate

$$\|v(t)\|_{H^m} \le \frac{\|v_0\|_{H^m}}{1-Ct\|v_0\|_{H^m}} \le 2\|v_0\|_{H^m}$$

for all $t \in [0, 1/(2C\|v_0\|_{H^m})]$. This is the key *a priori* estimate for the construction of the local solutions. The local-in-time solution of the Euler equations in the Sobolev space $H^m(\mathbb{R}^n)$ for $m > n/2+1, m \in \mathbb{Z}$, was obtained by Kato (1972). For the above-constructed local-in-time solutions, one of the most outstanding open problems in mathematical fluid mechanics is whether the solution can be continued to any future time up to infinity, or the solution will lose regularity and blow up in finite time. Even in terms of numerical experiments, the answer is not yet settled down. In the direction of solving this problem there is a celebrated results, called the Beale–Kato–Majda criterion (1984), which states

$$\limsup_{t\nearrow T_*}\|v(t)\|_{H^s} = \infty \quad \text{if and only if} \quad \int_0^{T_*}\|\omega(s)\|_{L^\infty}ds = \infty \qquad [23]$$

We outline the proof of this result below (for more details see Majda and Bertozzi (2002)). We first recall the Beale–Kato–Majda's version of the logarithmic Sobolev inequality,

$$\|\nabla v\|_{L^\infty} \le C\|\omega\|_{L^\infty}(1+\log(1+\|v\|_{H^m}))+C\|\omega\|_{L^2} \qquad [24]$$

for $m > 5/2$. Now suppose $\int_0^{T_*}\|\omega(t)\|_{L^\infty}\,\mathrm{d}t < \infty$. Taking $L^2$ inner product of [7] with $\omega$, then after integration by part we obtain

$$\begin{aligned}\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\omega\|_{L^2}^2 &= ((\omega\cdot\nabla)v,\omega)_{L^2}\\ &\le \|\omega\|_{L^\infty}\|\nabla v\|_{L^2}\|\omega\|_{L^2}\\ &= \|\omega\|_{L^\infty}\|\omega\|_{L^2}^2\end{aligned}$$

where we used the identity $\|\nabla v\|_{L^2} = \|\omega\|_{L^2}$. Applying the Gronwall lemma, we obtain

$$\begin{aligned}\|\omega(t)\|_{L^2} &\le \|\omega_0\|_{L^2}\exp\left(\int_0^{T_*}\|\omega(s)\|_{L^\infty}\,\mathrm{d}s\right)\\ &\le C(\omega_0, T_*)\end{aligned} \qquad [25]$$

for all $t \in [0, T_*]$. Substituting [24] into [22], and combining this with [25], we have

$$\begin{aligned}&\frac{\mathrm{d}}{\mathrm{d}t}\|v\|_{H^m}^2\\ &\quad\le C[1+\|\omega\|_{L^\infty}[1+\log(1+\|v\|_{H^m})]\|v\|_{H^m}^2\end{aligned}$$

Applying the Gronwall's lemma, we obtain

$$\begin{aligned}\|v(t)\|_{H^m} &\le \|v_0\|_{H^m}\\ &\qquad\times\exp\left[C_1\exp\left(C_2\int_0^{T_*}\|\omega(\tau)\|_{L^\infty}\,\mathrm{d}\tau\right)\right]\\ &\le C(v_0, T_*)\end{aligned}$$

for all $t \in [0, T_*]$ and for some constants $C_1, C_2$. Thus, we proved the "necessity part" of [23], The

"sufficiency part" is an easy consequence of the Sobolev inequality,

$$\int_0^{T_*} \|\omega(s)\|_{L^\infty}\, ds \le T_* \sup_{0\le t\le T_*} \|\nabla v(t)\|_{L^\infty} \le CT_* \sup_{0\le t\le T_*} \|v(t)\|_{H^m}$$

for $m > 5/2$.

### Other Related Results

The previous local existence result in $H^m(\mathbb{R}^n), m > n/2+1$, is basically due to T Kato in 1972. He and G Ponce extended this existence result using the fractional Sobolev space, $L^s_p(\mathbb{R}^n), s > n/2+1, s \in \mathbb{R}$ in 1986. These results were further extended, using the Besov and the Triebel–Lizorkin spaces, by the present author in 2001.

For bounded domain $\Omega \subset \mathbb{R}^n$, R Temam obtained the local-existence result using the space $W^{k,p}(\Omega)$ in 1975. On the other hand, in the setting of the Hölder space, $C^{1,\alpha}(\mathbb{R}^n)$ L Lichtenstein (1925) and W Wolibner (1933) obtained local existence of solutions of the Euler equations. More recently, J-Y Chemin considered the Zygmund $C^s(\mathbb{R}^n)$, which is identical to the Hölder space $C^{[s],s-[s]}(\mathbb{R}^n)$ for noninteger $s$, where $[s]$ means the largest integer not greater than $s$, but is different from $C^{[s],0}(\mathbb{R}^n)$ for integer $s$. He proved, in 1992, local existence of solutions to the 3D Euler equations in this space in 1992. See Chemin (1998) for details of this proof.

The Beale–Kato–Majda criterion for the finite-time blow-up of the classical solutions of the 3D Euler equations has been refined recently by many authors; replacing the $L^\infty$-norm of vorticity $\omega(x,t)$ by the weaker BMO (the space of functions with bounded mean oscillations) norm (H Kozono and Y Taniuchi, 2000), and by the even weaker Besov space or Triebel–Lizorkin space norms by the present author in 2001 (see Triebel (1983) for more details on those spaces). Here we just note that these spaces are refinements of the usual Sobolev spaces. For a bounded domain case, there is a result by A Ferrari in 1993. The blow-up problem is still open even in the case of axisymmetric 3D Euler equations if there is a nonzero swirl (angular velocity). In this case, the blow-up is controlled only by the angular component of the vorticity as shown by the present author (1996). In the region off the axis, in particular, the axisymmetric 3D Euler equation has the same form as the 2D Boussinesq equations.

Some researchers also tried to approach to regularity/singularity problem of the 3D Euler equations by investigating the geometric structure of the vortex stretching term, and obtained a geometric type of blow-up criterion (P Constantin, C Fefferman, and A Majda, 1996). For more detailed review of studies in this direction see Constantin (1995).

Since the blow-up problem of the 3D Euler equation itself looks too difficult to solve, it has also been studied on the simplified model problems. In 1985, P Constantin, PD Lax, and A Majda considered the following 1D model problem of the 3D Euler equations:

$$\theta_t + (H(\theta)\theta)_x = 0, \quad \theta(x,0) = \theta_0(x)$$

where $H(\cdot)$ is the Hilbert transform defined by

$$H(\omega) = \frac{1}{\pi} PV \int_{-\infty}^{\infty} \frac{\omega(y)}{x-y}\, dy$$

They proved finite-time blow-up of this model problem by explicitly obtaining the solution. There is another, 2D model problem of the 3D Euler equations, the quasigeostrophic equations,

$$\begin{gathered} \theta_t + (u\cdot\nabla)\theta = 0 \\ u = \nabla^\perp\psi, \qquad \theta = -(-\Delta)^{1/2}\psi \\ \theta(x,0) = \theta_0(x) \end{gathered} \qquad [26]$$

where $\nabla^\perp = (-\partial_2, \partial_1)$. Contrary to the above 1D model equation, this 2D model has real physical relevance in the atmospheric science, and $\theta(x,t)$ represents the temperature of the air. The resemblance of this equation to the 3D Euler equation was first observed by P Constantin, A Majda, and E Tabak in 1994, and they derived the finite blow-up criterion of the equations. In spite of many interesting partial results, including the work by D Cordoba (1998), the blow-up problem of [26] is still open.

## The 2D Euler Equations and the Weak Solutions

### The Case of $W^{1,p}$ Weak Solutions

In 2D Euler equations, the problem of global well-posedness of the classical solutions is settled down. This is an immediate consequence of the conservation of $\|\omega(t)\|_{L^\infty}$ as stated in [21] combined with the Beale–Kato–Majda criterion [23]. On the other hand, the notion of weak solutions is not well understood. A weak solution of the Euler equations is a singular (nondifferentiable) solution of the equations. More precisely, by a weak solution of

[1]–[2] in $\Omega \times (0,T)$ we mean a vector field $v \in C([0,T); L^2_{\mathrm{loc}}(\Omega))$ satisfying the integral identity:

$$-\int_0^T \int_{\mathbb{R}^3} v(x,t) \cdot \frac{\partial \phi(x,t)}{\partial t} \, \mathrm{d}x \, \mathrm{d}t - \int_{\mathbb{R}^3} v(x,0) \cdot \phi(x,0) \, \mathrm{d}x - \int_0^T \int_{\mathbb{R}^3} v(x,t) \otimes v(x,t) : \nabla \phi(x,t) \, \mathrm{d}x \, \mathrm{d}t = 0 \quad [27a]$$

$$\int_0^T \int_{\mathbb{R}^3} v(x,t) \cdot \nabla \psi(x,t) \, \mathrm{d}x \, \mathrm{d}t = 0 \quad [27b]$$

for every vector test function $\phi = (\phi_1, \phi_2, \ldots, \phi_n) \in C_0^\infty(\Omega \times [0,T))$ satisfying div $\phi = 0$, and for every scalar test function $\psi \in C_0^\infty(\Omega \times [0,T))$. Here we used the notation $(u \otimes v)_{ij} = u_i v_j$, and $A : B = \sum_{i,j=1}^n A_{ij} B_{ij}$ for $n \times n$ matrices $A$ and $B$. We observe that [27a] and [27b] are obtained by multiplying $\phi$ and $\psi$ to [1] and [2], respectively, and integrating by parts. Thus, even the locally square-integrable vector fields, which are not differentiable in the classical sense, could be solutions of the Euler equations. For the general 3D Euler equations, we do not yet have the global existence theorems for the weak solutions. Actually, it is even suggested that we need more weaker notion of solution (the so-called "measure-valued solutions") to describe generic global solutions for the 3D Euler equations. For the 2D Euler equations, however, we have global existence theorems for $\omega_0 \in L^1(\mathbb{R}^2) \cap L^p(\mathbb{R}^2)$ for $p \in [1, \infty]$. This better situation of 2D Euler equations compared to the 3D case for the weak solutions is mainly due to the conservation law of $L^p$-norm described in [21]. Here we present briefly the existence proof of the weak solutions for 2D Euler equations in the simplest situation. We will prove the global existence of weak solutions for $\omega_0 \in L^p(\mathbb{R}^2), 1 < p < \infty$. Let $\rho_\varepsilon(x) = (1/\varepsilon^2)\rho(x/\varepsilon)$, where $\rho \in C_0^\infty(\mathbb{R}^2)$ is a standard mollifier, satisfying $\rho \geq 0$, supp $\rho \subset \{x \in \mathbb{R}^2 | |x| < 1\}$, and $\int_{\mathbb{R}^2} \rho \, \mathrm{d}x = 1$. Let $v_0$ be the velocity associated with the initial vorticity $\omega_0$, given by the Biot–Savart law [12]. Define the sequence of initial data $v_0^\varepsilon(x) = \rho_\varepsilon * v_0(x) = \int_{\mathbb{R}^2} \rho_\varepsilon(x-y) v_0(y) \, \mathrm{d}y$. For each $v_0^\varepsilon$ we have global-in-time smooth solutions $v^\varepsilon(x,t)$. Moreover, thanks to [21], we have the following estimate of the vorticity that is uniform in $\varepsilon$:

$$\|\omega(t)^\varepsilon\|_{L^p} = \|\omega_0^\varepsilon\|_{L^p} \leq \|\omega_0\|_{L^p} \quad [28]$$

where we used the property of the mollifier in the second inequality. If we take the (distributional) derivative of the Biot–Savart law [12], we find $\nabla v = K * \omega + C\omega$, where $K(x)$ is a kernel function defining a singular integral operator of the convolution type, and $C$ is a constant vector. The well-known Calderon–Zygmund inequality implies that

$$\|\nabla v\|_{L^p} \leq C_p \|\omega\|_{L^p} \quad [29]$$

Combining [28] and [29] we have

$$\sup_{0 \leq t \leq T} \|\nabla v^\varepsilon(t)\|_{L^p} \leq C(v_0), \quad \forall T > 0 \quad [30]$$

namely the sequence $\{v^\varepsilon\}$ is uniformly bounded in $L^\infty(0,T; W^{1,p}(\mathbb{R}^2))$. Next, we claim that $\{v^\varepsilon\}$ satisfies the inequality

$$\|v^\varepsilon(t_1) - v^\varepsilon(t_2)\|_{H^{-3}(\mathbb{R}^2)} \leq C\|v_0\|_2^2 |t_1 - t_2| \quad [31]$$

for all $t_1, t_2$ with $0 < t_1 \leq t_2 < T$, where $C$ is an absolute constant. Here the negative-order Sobolev space $H^{-m}(\Omega), m > 0$, is defined as the dual of $H_0^m(\Omega)$, and can be identified with the space of functions $C_0^\infty(\Omega)$ completed with metric in $H^m(\Omega)$. Indeed, let $\phi \in C_0^\infty(\mathbb{R}^2)$. Taking $L^2(\mathbb{R}^2)$ inner product of [1] with $\phi$ we have the estimates

$$\begin{aligned}
\left| \int_{\mathbb{R}^2} \frac{\partial v^\varepsilon(x,t)}{\partial t} \cdot \phi(x) \, \mathrm{d}x \right| 
&\leq \left| \int_{\mathbb{R}^2} (\phi \cdot \nabla) p^\varepsilon \, \mathrm{d}x \right| + \left| \int_{\mathbb{R}^2} \phi \cdot (v^\varepsilon \cdot \nabla) v^\varepsilon \, \mathrm{d}x \right| \\
&= \left| \int_{\mathbb{R}^2} p^\varepsilon \nabla \phi \, \mathrm{d}x \right| + \left| \int_{\mathbb{R}^2} (v^\varepsilon \cdot \nabla) \phi v^\varepsilon \, \mathrm{d}x \right| \\
&\leq \|p^\varepsilon(t)\|_{H^{-2}} \|\nabla \phi\|_{H^2} + \|v^\varepsilon(t)\|_{L^2}^2 \|\nabla \phi\|_\infty \\
&\leq C(\|p^\varepsilon(t)\|_{H^{-2}} + \|v_0^\varepsilon\|_{L^2}^2) \|\phi\|_{H^3}
\end{aligned} \quad [32]$$

where we used the Sobolev inequality $\|\nabla \phi\|_{L^\infty} \leq C\|\phi\|_{H^3}$ and the energy equality in the last step. Since [32] holds for all $\phi \in C_0^\infty(\mathbb{R}^2)$, by taking the closure of $C_0^\infty(\mathbb{R}^2)$ in $H^3(\mathbb{R}^2)$ we obtain

$$\left\| \frac{\mathrm{d}v^\varepsilon(t)}{\mathrm{d}t} \right\|_{H^{-2}} \leq C\|p^\varepsilon(t)\|_{H^{-2}} + \|v_0\|_{L^2}^2 \quad [33]$$

We now estimate $\|p^\varepsilon(t)\|_{H^{-2}}$. Taking the divergence operation on [1], we have the Poisson equation

$$\Delta p^\varepsilon = -\mathrm{div}(v^\varepsilon \cdot \nabla v^\varepsilon)$$

Let $\eta \in C_0^\infty(\mathbb{R}^2)$, then

$$\begin{aligned}
\left| \int_{\mathbb{R}^2} \Delta p^\varepsilon(x,t) \eta(x) \, \mathrm{d}x \right| &= \left| \int_{\mathbb{R}^2} \mathrm{div}(v^\varepsilon \cdot \nabla v^\varepsilon) \eta \, \mathrm{d}x \right| \\
&= \left| \int_{\mathbb{R}^2} (v^\varepsilon \cdot \nabla) v^\varepsilon \cdot \nabla \eta \, \mathrm{d}x \right| \\
&= \left| \int_{\mathbb{R}^2} (v^\varepsilon \cdot \nabla) \nabla \eta \cdot v^\varepsilon \, \mathrm{d}x \right| \\
&\leq \|v^\varepsilon(t)\|_{L^2}^2 \|\Delta^2 \eta\|_{L^\infty} \\
&\leq C\|v_0\|_{L^2}^2 \|\eta\|_{H^4}
\end{aligned} \quad [34]$$

where we used the energy equality [14] and the Sobolev inequality in the last step. Since [34] holds for all $\eta \in C_0^\infty(\mathbb{R}^2)$, taking the closure of $C_0^\infty(\mathbb{R}^2)$ in $H^4(\mathbb{R}^2)$, we obtain

$$\left| \int_{\mathbb{R}^2} \Delta p^\varepsilon(x,t)\eta(x)\,dx \right| \le C\|v_0\|_{L^2}^2 \|\eta\|_{H^4} \quad \forall \eta \in H^4(\mathbb{R}^2) \qquad [35]$$

Thus,

$$\|\Delta p^\varepsilon(t)\|_{H^{-4}} \le C\|v_0\|_{L^2}^2 \quad \forall t \in [0,T)$$

This provides us with

$$\|p^\varepsilon(t)\|_{H^{-2}} \le \|D^2 p^\varepsilon(t)\|_{H^{-4}} \le C\|\Delta p^\varepsilon(t)\|_{H^{-4}} \le C\|v_0\|_{L^2}^2$$

Combining [33] with [36], we obtain

$$\sup_{0\le t\le T} \left\| \frac{dv^\varepsilon(t)}{dt} \right\|_{H^{-2}} \le C\|v_0\|_{L^2}^2$$

Thus, from

$$v^\varepsilon(t_1) - v^\varepsilon(t_2) = \int_{t_2}^{t_1} \frac{dv^\varepsilon(t)}{dt}\,dt$$

we have

$$\|v^\varepsilon(t_1) - v^\varepsilon(t_2)\|_{H^{-2}} \le \sup_{0\le t\le T} \left\| \frac{dv^\varepsilon(t)}{dt} \right\|_{H^{-2}} |t_1 - t_2| \le C\|v_0\|_{L^2}^2 |t_1 - t_2|$$

Thus, [31] is proved as claimed. Thanks to the Aubin–Nitsche compactness lemma together with [30] and [31] we have a subsequence, denoted by the same notation, $\{v^\varepsilon\}$ and $v$ in $L^\infty(0,T;W^{1,p}(\mathbb{R}^2))$ such that

$$v^\varepsilon \to v \text{ weakly} - * \text{ in } L^\infty(0,T;W^{1,p}(\mathbb{R}^2)) \qquad [36]$$

and

$$v^\varepsilon \to v \quad \text{in } L^2_{\text{loc}}(\mathbb{R}^2 \times (0,T)) \qquad [37]$$

as $\varepsilon \to 0$. We know that as a classical solution each $v^\varepsilon$ and $v_0^\varepsilon$ satisfies

$$\int_{\mathbb{R}^2} \phi(x,0) v_0^\varepsilon(x)\,dx + \int_0^T \int_{\mathbb{R}^2} (\phi_t \cdot v^\varepsilon + \nabla\phi : v^\varepsilon \otimes v^\varepsilon)\,dx\,dt = 0 \qquad [38]$$

for all $\phi \in C_0^\infty(\mathbb{R}^2 \times [0,T))$ with $\operatorname{div}\phi = 0$ and

$$\int_0^T \int_{\mathbb{R}^2} \nabla\psi \cdot v^\varepsilon\,dx\,dt = 0 \qquad [39]$$

for all $\psi \in C_0^\infty(\mathbb{R}^2 \times [0,T))$. We can check easily that the convergence [36] and [37] is enough to pass to the limit $\varepsilon \to 0$ in [38] and [39] to obtain the corresponding equations with $v^\varepsilon$ and $v_0^\varepsilon$ replaced by $v$ and $v_0$. Thus, $v$ is a weak solution of the Euler equations with initial data $v_0$. This completes the outline of the proof of weak solutions to the 2D Euler equations.

### Notes on Further Results

The study of weak solutions of the 2D Euler equations was initiated by V Yudovich in 1963, where he proved the existence of weak solutions for initial data $\omega_0 \in L^1(\mathbb{R}^2) \cap L^\infty(\mathbb{R}^2)$. Subsequenthy, theory of weak solutions has been developed by studies of the vortex sheet problem due to DiPerna and Majda in 1987. For the existence of weak solutions to the vortex sheet initial data, namely the existence problem for initial vorticity $\omega_0 \in H^{-1}(\mathbb{R}^2) \cap \mathcal{M}(\mathbb{R}^2)$, where $\mathcal{M}(\mathbb{R}^2)$ is the space of Radon measures on $\mathbb{R}^2$, is still an outstanding open problem. The main physical motivation of this problem is to understand the dynamics of vortex sheets in the 3D turbulence. For this problem JM Delort proved existence assuming single-signedness of the initial vortex sheet in 1991. The proof is simplified by A Majda in 1993, using the conservation of moment of impulse. The result is also reproved by LC Evans and S Müller in 1994, using the weak compactness of the Hardy space. Later in 2001, MC Lopes Filho, HJ Nussenzveig Lopes and Z Xin allowed the change of sign for initial vortex sheet, but assumed special reflection symmetry to prove existence of global weak solutions. Related to this problem is the one of characterizing the precise borderline function space to which initial data belongs, and above which there is no concentration phenomenon for weakly approximating sequence of solutions; a recent analysis of this problem was done by E Tadmor in 2001.

For the uniqueness problem of the weak solutions of the 2D Euler equations, there are remarkable works by V Scheffer (1993) and A Shnirelman (1997), where they constructed explicitly an $L^2_{\text{loc}}(\mathbb{R}^2 \times \mathbb{R})$ weak solution starting from zero initial data. Also M Vishik (1999) extended the uniqueness class of the weak solutions of the 2D Euler equations, improving previous work by V Yudovich (1995). The class found by M Vishik, in particular, includes the BMO. There is another problem closely related to the weak solutions of the 2D Euler equations, called the vortex patch problem. The main question was if there is any singularity of the boundary of a patch $\Omega(t) = \{X(\alpha,t) \mid \alpha \in \Omega_0\}$, where $X(\alpha,t)$ is the particle trajectory mapping generated by a weak solution $v(x,t)$, which is evolving from the initial data $\omega_0(x) = \chi_{\Omega_0}(x)$, the characteristic function of set $\Omega_0$

with smooth boundary. The problem itself is well defined, due to the work of V Yudovich (1963), and there exists unique particle trajectories associated with such weak solutions. The problem was settled by J-Y Chemin in 1991. He proved the global-in-time preservation of the $C^{1,\alpha}$ regularity of the boundary $\partial\Omega(t)$, contrary to the previous numerical experiments. The proof of this result was later simplified by A Bertozzi and P Constantin in 1993.

Another interesting problem related to the weak solutions of the Euler equations (2D or 3D) is whether or not the energy is preserved for the weak solutions, namely if there is any "intrinsic dissipation" to the singular solutions of the ideal fluids. In 1949, L Onsager conjectured that if the weak solution of 3D Euler equations belongs to certain Hölder space, then the energy is conserved. This conjecture, in the setting of Besov space, was proved by P Constantin, W E and E S Titi in 1994. This question of possibility of dissipation of energy for weak solutions is further studied by J Duchon and R Robert in 2000. Later, in 2003 the present author considered the problem of helicity conservation for the weak solutions of the 3D Euler flows, which is related to the question of crossing/reconnections of the vortex tubes for weak solutions, and showed that for large class of weak solutions in certain Besov spaces the helicity is preserved.

## Introduction

If, in a problem of quantization, state spaces with indefinite inner product are used instead of Hilbert spaces, one speaks of quantization with indefinite metric. The main domain of application is the quantization of gauge fields, like the electromagnetic vector potential $A_\mu(x)$ or Yang–Mills fields in quantum chromodynamics (QCD) and the standard model.

The conceptual problem with the indefinite metric is the occurrence of senseless negative probabilities in the formalism. Such negative probabilities, however, only arise in expectation values of fields that are not gauge invariant and hence do not correspond to observable quantities. Equivalently, the inner product of vectors generated by application of such fields to the vacuum vector with itself can be negative or null. In order to extract the observable content of an indefinite-metric quantum theory, a subsidiary condition is needed to single out the physical subspace. Restricted to this subspace, the inner product is positive semidefinite. This subsidiary condition can be seen as the implementation of a gauge, as, for example, the Lorentz gauge $\partial_\mu A^\mu(x) = 0$ in quantum electrodynamics (QED). This procedure is also known under the name Gupta–Bleuler formalism.

The use of indefinite metric in the quantization of gauge theories like QED can be avoided entirely.

This is called quantization in a physical gauge. The problem with such gauges is that they are not Lorentz invariant and that the vector potential $A^{\mu}(x)$ is not a local field. An example is the Coulomb gauge defined by $A_0(x) = 0$ and $\partial^i A_i(x) = 0$ in QED. Furthermore, Dirac spinor fields $\psi(x)$ in such gauges do not anticommute when localized in spacelike separated regions. The Dirac fields therefore are also nonlocal quantities. Although not in contrast with special relativity, as Dirac spinors and the vector potential are not gauge invariant and hence are unobservable, this leads to severe technical problems in the formulation of interacting theories. In particular, the theory of renormalization heavily uses both locality and invariance. Therefore, the Gupta–Bleuler formalism generally is the preferred quantization procedure for a gauge theory.

That a local and invariant quantization is not possible using a (positive-metric) Hilbert space has been proved by F Strocchi in a series of articles published between 1967 and 1970. If one wants to preserve locality and/or invariance of the quantized field theory, it is thus strictly necessary to give up the positivity of the state space.

A short digression into the early history of the idea might be of interest. It dates back to 1941, where the use of indefinite metric in the quantization of relativistic equations was proposed by Paul Dirac in a lecture at the London Royal Society. The negative probabilities for the bosonic vector potential were thought to be connected with the problem of negative-energy solutions of relativistic equations as a type of surrogate of the "Dirac sea" in the quantization of fermions. Furthermore, Dirac proposed that negative-energy solutions and negative probabilities would jointly lead to the cancellation of divergences in QED. The latter idea was taken up by W Heisenberg in his lectures on the theory of elementary particles held in Munich in 1961, but the generally accepted solution to the problem of ultraviolet divergences was achieved without recourse to Dirac's original motivation. In 1950 the consistent quantization of vector potential in the Lorentz gauge was formulated by S N Gupta and K Bleuler eliminating the use of negative-energy solutions. Since then the indefinite metric has become a building block of the standard theory of quantized gauge fields.

## No-Go Theorems

The strict necessity of the Gupta–Bleuler procedure for the local or covariant quantization of gauge fields has been demonstrated by F Strocchi in the form of no-go theorems for positive metric. Here we review their content for the case of the electromagnetic field. Related statements can be obtained for nonabelian gauge theories. The main problem lies in the fact that standard assumptions on the quantization of relativistic fields are in conflict with Maxwell equations that should hold as operator identities in a positive-metric theory containing no unobservable states. Let

$$F_{\nu\mu}(x) = \partial_\mu A_\nu(x) - \partial_\nu A_\mu(x) \qquad [1]$$

be the quantized electromagnetic field strength tensor. Classically, the existence of $A_\mu(x)$ is guaranteed from the first set of Maxwell equations $\epsilon^{\alpha\beta\nu\mu}\partial_\beta F_{\nu\mu}(x) = 0$. Here (and henceforth) indices are raised and lowered with respect to the Minkowski metric $g_{\alpha\beta}$ and $\epsilon^{\alpha\beta\mu\nu}$ is the completely antisymmetric tensor on $\mathbb{R}^d$. Furthermore, we apply Einstein's convention on summation over repeated upper and lower indices. Standard assumptions from axiomatic quantum field theory are:

1. The field strength tensor $F_{\nu\mu}(x)$ is an operator-valued distribution acting on a (dense core of a) Hilbert space $\mathcal{H}$ with scalar product $\langle .,. \rangle$ – in the indefinite-metric case, $\langle .,. \rangle$ only needs to be an inner product.
2. $F_{\mu\nu}(x)$ transforms covariantly, that is, there is a strongly continuous unitary (with respect to $\langle .,. \rangle$) representation $U$ of the orthochronous, proper Poincaré group on $\mathcal{H}$ such that for translation $a \in \mathbb{R}^d$ combined with a restricted Lorentz transformation $\Lambda$, one has
$$\begin{aligned} &U(a,\Lambda)F_{\mu\nu}(x)U(a,\Lambda)^{-1} \\ &\quad = (\Lambda^{-1})^{\rho}{}_{\mu}(\Lambda^{-1})^{\kappa}{}_{\nu}F_{\rho\kappa}(\Lambda x + a) \end{aligned} \qquad [2]$$
3. There exists a unique (up to multiplication with $\mathbb{C}$-numbers) translation invariant vector $\Omega \in \mathcal{H}$ (the "vacuum"), that is, $U(a,1)\Omega = \Omega \forall a \in \mathbb{R}^d$.
4. The representation of the translations fulfills the spectral condition
$$\int_{\mathbb{R}^4} \langle \Phi, U(a,1)\Psi \rangle e^{ip\cdot a}\,da = 0 \qquad [3]$$
$\forall \Psi, \Phi \in \mathcal{H}$ if $p$ is not in the closed forward light cone $\bar{V}^+ = \{p \in \mathbb{R}^4 : p\cdot p \geq 0, p^0 \geq 0\}$. Here the dot is the Minkowski inner product.
So far the assumptions concerned only observable quantities. In the following, we also demand.
5. The vector potential $A_\mu(x)$ is realized as an operator-valued distribution on $\mathcal{H}$ and transforms covariantly under translations
$$U(a,1)A_\mu(x)U(a,1)^{-1} = A_\mu(x+a) \qquad [4]$$

The assumptions on the nature of the vector potential so far are rather weak. Strocchi's no-go theorems show that one cannot add further desirable properties as Lorentz covariance and/or locality without getting into conflict with the Maxwell equations:

**Theorem 1** *Suppose that the above assumptions* (1)–(3) *and* (5) *hold. If Maxwell's equations in the absence of charges,*

$$\epsilon^{\alpha\beta\nu\mu}\partial_\beta F_{\nu\mu}(x) = 0, \quad \partial^\mu F_{\mu\nu}(x) = 0 \qquad [5]$$

*are valid as δ operator identities on $\mathcal{H}$ and the gauge potential transforms covariantly*

$$U(a,\Lambda)A_\mu(x)U(a,\Lambda)^{-1} = (\Lambda^{-1})^\nu{}_\mu A_\nu(\Lambda x + a) \qquad [6]$$

*the two-point function of the electromagnetic field tensor vanishes identically*:

$$\langle \Omega, F_{\nu\mu}(x)F_{\kappa\rho}(y)\Omega\rangle = 0 \quad \forall\, x, y \in \mathbb{R}^4 \qquad [7]$$

To gain a better understanding, where the difficulties in the quantization of the Maxwell equations arise from, here is a rough sketch of the proof: Maxwell equations and covariance imply that $f_{\mu\nu\rho}(x-y) = \langle \Omega, A_\mu(x)F_{\nu\rho}(y)\Omega\rangle$ fulfills $\partial^\alpha\partial_\alpha f_{\mu\nu\rho}(x) = 0$ and hence its Fourier transform has support in the union of the forward and backward light cone. The Fourier transform thus can be split into a positive- and a negative-frequency part, and $f_{\mu\nu\rho} = f^+_{\mu\nu\rho} + f^-_{\nu\mu\rho}$ accordingly. By the general analysis of axiomatic field theory (*see* Axiomatic Quantum Field Theory), the functions $f^\pm_{\nu\mu\rho}$ are boundary values of complex analytic functions on certain tubar domains $\mathcal{T}^\pm$ transforming covariantly under a certain representation of the complex Lorentz group. By a theorem of Araki and Hepp giving a general representation of such functions and using the antisymmetry of the field tensor, the following formula can be derived:

$$f^\pm_{\mu\nu\rho}(z) = (g_{\mu\rho}\partial_\nu - g_{\mu\nu}\partial_\rho)f^\pm(z) + \epsilon_{\mu\nu\rho\alpha}\partial^\alpha h^\pm(z)$$
$$z \in \mathcal{T}^\pm \qquad [8]$$

with $f^\pm, h^\pm$ invariant under complex Lorentz transformations. Taking boundary values in $\mathcal{T}^\pm$, one obtains $f_{\mu\nu\rho} = (g_{\mu\rho}\partial_\nu - g_{\mu\nu}\partial_\rho)f + \epsilon_{\mu\nu\rho\alpha}\partial^\alpha h$, with $f = \bar{f}^+ + \bar{f}^-$ and $h = \bar{h}^+ + \bar{h}^-$, where the bar stands for the distributional boundary value. Maxwell's equations imply $\partial^\nu f_{\mu\nu\rho} = (\partial^\nu\partial_\nu g_{\mu\rho} - \partial_\mu\partial_\rho)f = 0$ and $\epsilon_\alpha{}^{\beta\nu\rho}\partial_\beta f_{\mu\nu\rho} = (\partial^\nu\partial_\nu g_{\alpha\mu} - \partial_\alpha\partial_\mu)h = 0$. The only Lorentz-invariant solutions to these equations are constant, which implies the statement of Theorem 1.

The second no-go theorem eliminates the assumption that the vector potential $A_\mu(x)$ is covariant; however, a local gauge is assumed. The result is the same as in Theorem 1:

**Theorem 2** *Suppose that the above assumptions* (1)–(5) *and Maxwell's equations hold as operator identities on $\mathcal{H}$. If, furthermore, the gauge is local, that is,*

$$[A_\mu(x), A_\nu(y)] = 0 \quad \textit{if } x - y \textit{ is spacelike} \qquad [9]$$

*the two-point function of the field strength tensor vanishes again as in Theorem 1.*

Analyzing the interplay of the covariance properties of $F_{\mu\nu}(x)$ with the locality of $A_\mu(x)$, Strocchi was able to show that the function $f_{\mu\nu\rho}(x-y)$ must have the same covariance properties as in Theorem 1, which implies the assertion of Theorem 2.

The first two no-go theorems deal with the free electromagnetic field that is not coupled to charge-carrying fields. This is, of course, already a real obstruction also for an interacting theory, since, by the LSZ formalism, one expects the asymptotic incoming and outgoing fields $A^{\mathrm{in/out}}_\mu(x), F^{\mathrm{in/out}}_{\mu\nu}(x)$ to be free. In fact, it has been proved by D Buchholz that, in the positive-metric case, such asymptotic fields can always be constructed. If one assumes a local and covariant gauge and positivity, the vanishing of the two-point function would also imply that the field $F_{\mu\nu}(x) = 0$ identically by the Reeh–Schlieder theorem.

The next no-go theorem shows that the problems connected to the quantization of the Maxwell equations are not connected only to the free electromagnetic fields. Let us assume that the second set of Maxwell equations is given by

$$\partial^\mu F_{\mu\nu}(x) = j_\nu(x) \qquad [10]$$

where $j_\nu$ is the leptonic current, that is, $j_\nu(x) = e : \psi^\dagger(x)\gamma_\nu\psi(x)$: in the case of QED, where $\psi$ is the quantized Dirac field associated with electrons and positrons. Here $:\cdot:$ stands for Wick ordering and $\gamma_\nu$ are the Dirac matrices, $\psi^\dagger = \psi^*\gamma^0$. The conservation of the current $\partial^\nu j_\nu(x) = 0$ implies that the current charge

$$Q_{\mathrm{C}} = \lim_{R\to\infty} \int_{\mathbb{R}^3}\int_{\mathbb{R}} \alpha(x^0)\chi(\boldsymbol{x}/R)j_0(x^0, \boldsymbol{x})\,\mathrm{d}x^0\,\mathrm{d}\boldsymbol{x} \qquad [11]$$

is a constant of motion, where $\alpha$ and $\chi$ are compactly supported infinitely differentiable functions with $\int_{\mathbb{R}} \alpha(x^0) = 1$ and $\chi(\boldsymbol{x}) = 1$ for $|\boldsymbol{x}| < 1$. Now, an alternative definition of charge, called gauge charge (it generates the global U(1)-gauge transformation), is given by

$$Q_{\mathrm{G}}\Omega = 0, \quad [Q_{\mathrm{C}}, A_\mu(x)] = 0 \quad \text{and}$$
$$[Q_{\mathrm{G}}, \psi(x)] = -e\psi(x) \qquad [12]$$

A third formulation of charge, the Maxwell charge $Q_{\mathrm{M}}$, can also be given by replacing $j^0(x)$ in [11] by $\partial_\nu F^{\nu 0}(x)$. Obviously, if Maxwell equations hold as operator identities, $Q_{\mathrm{C}} = Q_{\mathrm{M}}$. On observable states, all charges $Q_{\mathrm{M}}$, $Q_{\mathrm{C}}$, and $Q_{\mathrm{G}}$ ought to coincide. Strocchi's third theorem shows that this cannot be achieved within a local gauge:

**Theorem 3** *If the Maxwell equations [9] hold and the Dirac field $\psi(x)$ is local with respect to the electromagnetic field tensor $F_{\mu\nu}(x)$, that is,*

$$[F_{\mu\nu}(x), \psi(y)] = 0 \quad \text{if } x - y \text{ is spacelike} \qquad [13]$$

*then $[Q_{\mathrm{M}}, \psi(x)] = 0$, hence $Q_{\mathrm{C}} = Q_{\mathrm{M}} \neq Q_{\mathrm{C}}$.*

The proof is a simple consequence of the observation that $j_0(x) = \partial^\nu F_{\nu 0}(x) = \partial^i F_{i0}(x)$ is a three-divergence as $F_{00}(x) = 0$ by antisymmetry of $F_{\mu\nu}(x)$. Hence,

$$\begin{aligned}[Q_{\mathrm{C}}, \psi(y)] &= \lim_{R\to\infty} \int_{\mathbb{R}^4} [j_0(x), \psi(y)] \alpha(x^0) \chi(\mathbf{x}/R)\, \mathrm{d}x^0\, \mathrm{d}\mathbf{x} \\ &= -\lim_{R\to\infty} \int_{\mathbb{R}^4} [F_{i0}(x), \psi(y)] \alpha(x^0) \partial^i \chi(\mathbf{x}/R) \\ &\quad \times \mathrm{d}x^0\, \mathrm{d}\mathbf{x} = 0 \end{aligned} \qquad [14]$$

since, for $R$ sufficiently large, the support of $\alpha(x^0)\partial_i \chi(\mathbf{x}/R)$ becomes spacelike separated from $y$.

It should be noted that the proof of none of the above theorems relies on the definiteness of the inner product. The main clue of the indefinite-metric formalism, therefore, is rather to give up Maxwell equations as operator identities. In the usual positive-metric formalism, where all states in $\mathcal{H}$ are physical states, this would not be legitimate. But in indefinite metrics, many states are unobservable – in particular, those with negative "norm" $\langle \Psi, \Psi \rangle < 0$. On such states we can neglect the Maxwell equations.

## Axiomatic Framework

The formalism of axiomatic quantum field theory (*see* Axiomatic Quantum Field Theory) requires a revision in order to cover the case of gauge fields. The necessary adaptations have been elaborated by G Morchio and F Strocchi, but also earlier work of E Scheibe and J Yngvasson played a significant role in this development.

Let $\phi(x)$ be a $V'$-valued quantum field, where $V$ is a finite-dimensional $\mathbb{C}$-vector space with involution $*$. The prime stands for the (topological) dual. For the case of QED, $V$ is eight dimensional, containing four dimensions for the vector potential $A_\mu(x)$ and another four for the Dirac spinors $\psi(x), \psi^\dagger(x)$.

Such a quantum field can be reconstructed from its vacuum expectation values (Wightman functions) as follows: let $S_1 = S(\mathbb{R}^4, V)$ be the space of rapidly decreasing functions $f : \mathbb{R}^4 \to V$ endowed with the Schwarz topology. Then the Borcher's algebra $\underline{S}$ be the free, unital, involutive tensor algebra over $\mathcal{S}_1$, that is, $\underline{S} = \mathbb{C}\mathbf{1} \oplus_{n\geq 0} \mathcal{S}_1^{\otimes n}$ with the multiplication induced by the tensor product and involution $(f_1 \otimes \cdots \otimes f_n)^* = f_n^* \otimes \cdots \otimes f_1^*$. $\underline{S}$ is endowed with the direct-sum topology. One can show that any linear, normalized, continuous functional $\underline{W} : \underline{S} \to \mathbb{C}, W(\mathbf{1}) = 1$, is determined by its restrictions $W_n$ to $\mathcal{S}_1^{\otimes n}$. By the Schwarz kernel theorem, $W_n \in \mathcal{S}'(\mathbb{R}^{4n}, V^{\otimes n})$. Conversely, any such sequence of Wightman distributions $W_n$ determines a $\underline{W}$.

Given a Hermitian Wightman functional $\underline{W}$ such that $W(f^*) = \overline{W(f)}, \forall \underline{f} \in \underline{S}, \mathcal{L}_{\underline{W}} = \{\underline{f} \in \underline{S}: \underline{W}(\underline{h}^* \otimes \underline{f}) = 0\, \forall \underline{h} \in \underline{S}\}$ forms a left ideal and the inner product $\underline{W}(\underline{f}^* \otimes \underline{h})$ induces a nondegenerate inner product $\langle .,. \rangle$ on $\mathcal{H}_0 = \underline{S}/\mathcal{L}_{\underline{W}}$. Furthermore, Borchers' algebra $\underline{S}$ acts from the left on $\mathcal{H}_0$. The quantum field $\phi(x)$ defined as the restriction of this canonical representation to the space $\mathcal{S}_1 \subset \underline{S}$ according to $\phi(f) =$ "$\int_{\mathbb{R}^4} \phi^a(x) f_a(x) \mathrm{d}x$" where the index $a$ runs over a basis of $V$.

If the Wightman functional $\underline{W}$ has further properties from axiomatic QFT (*see* Axiomatic Quantum Field Theory) like invariance with respect to a given representation of the Lorentz group on $V$, translation invariance, locality, and the spectral property, the quantum field $\phi(x)$ fulfills the related requirements in analogy with the items (1)–(5) listed in the previous section for the case of the vector potential $A_\mu(x)$. The Wightman distributions $W_n$ as in the positive-metric case are related to the vacuum expectation values of the theory by

$$W_n^{a_1,\ldots,a_n}(x_1, \ldots, x_n) = \langle \Omega, \phi^{a_1}(x_1) \cdots \phi^{a_n}(x_n) \Omega \rangle \qquad [15]$$

where $\Omega$ is the equivalence class of $\mathbf{1}$ in $\mathcal{H}_0$.

The state-space $\mathcal{H}_0$ produced by the Gelfand–Naimark–Segal (GNS) construction for inner-product spaces might be too small to contain all states of physical interest. For example, in the QED case, it does not contain charged states (cf. Theorem 3). Depending on the physical problem, one might also be interested in constructing coherent or scattering states and translation-invariant states apart from the vacuum. Such states appear in problems related to symmetry breaking and confinement (the so-called $\Theta$-vacua) or in some problems of conformal QFT (*see* Boundary Conformal Field

Theory) in two dimensions. It, therefore, has become the standard point of view that one needs to make a suitable closure of $\mathcal{H}_0$ such that this closure includes the states of interest (for an alternative point of view, see the last paragraph of the following section).

Typically, larger closures are favorable, as they contain more states. One therefore focuses on maximal Hilbert closures of $\mathcal{H}_0$. A Hilbert topology $\tau$ is induced by an auxiliary scalar product $(.,.)$ on $\mathcal{H}_0$. It is admissible, if it dominates the indefinite inner product $|\langle\Phi,\Psi\rangle|^2 \leq C(\Psi,\Psi)(\Phi,\Phi)\,\forall\Psi,\Phi\in\mathcal{H}_0$ for some $C>0$. This guarantees that the inner product extends to the Hilbert space closure $\mathcal{H}$ of $\mathcal{H}_0$ with respect to $\tau$. Furthermore, there exists a self-adjoint contraction $\eta$ on $\mathcal{H}$ such that $\langle\Psi,\eta\Phi\rangle = (\Psi,\eta\Phi)\,\forall\Phi,\Psi\in\mathcal{H}$. A Hilbert topology $\tau$ is maximal if there is no admissible Hilbert topology $\tau'$ that is strictly weaker than $\mathcal{H}_0$. The classification of maximal admissible Hilbert topologies in terms of the metric operator $\eta$ is given by the following theorem:

**Theorem 4** *A Hilbert topology $\tau$ on $\mathcal{H}_0$ generated by a scalar product $(.,.)$ is maximal if and only if the metric operator $\eta$ has a continuous inverse $\eta^{-1}$ on the Hilbert space closure $\mathcal{H}$ of $\mathcal{H}_0$. In that case, one can replace $(.,)$ by the scalar product $(\Psi,\Phi)_1 = (\Psi,|\eta|\Phi)$ without changing the topology $\tau$. The new metric operator $\eta_1$ then fulfills $\eta_1^2 = 1_{\mathcal{H}}$.*

For a proof of the first statement, see the original work of Morchio and Strocchi (1980). One can easily check that $\eta_1 = \eta|\eta^{-1}|$ which implies the second assertion of the theorem. A Hilbert space $(\mathcal{H},(.,.))$ with an indefinite inner product induced by a metric operator $\eta$ with $\eta^2 = 1_{\mathcal{H}}$ is called a Krein space. For an extensive study of Krein spaces, see the monograph by Azizov and Iokhvidov (1989).

Furthermore, one can show that given a nonmaximal admissible Hilbert space topology $\tau$ induced by some $(.,.)$, one obtains a maximal admissible Hilbert topology as follows: given the metric operator $\eta$, we define a scalar product $(\Psi,\Phi)_1 = (\Psi,(1-P_0)\Phi)$ on $\mathcal{H}$ with $P_0$ the null space projector of $\eta$. Obviously, this scalar product is still admissible and it leads to a new metric operator $\eta_1$ and a new closure $\mathcal{H}_1$ of $\mathcal{H}_0$. Furthermore, it is easy to show that the scalar product $(\Psi,\Phi)_2 = (\Psi,|\eta_1|\Phi)_1$ still induces an admissible Hilbert topology which is also maximal, as $\eta_2 = \eta_1|\eta_1^{-1}|$ clearly fulfills the Krein relation $\eta_2^2 = 1_{\mathcal{H}_2}$.

The question of the existence of a Krein space closure of $\mathcal{H}_0$, therefore, reduces to the question of the existence of an admissible Hilbert topology on $\mathcal{H}_0$. The following condition on the Wightman functions $W_n$ replaces the positivity axiom in the case of indefinite-metric quantum fields:

**Theorem 5** *Given a Wightman functional $\underline{W}$, there exists an admissible Hilbert space topology $\tau$ on $\mathcal{H}_0 = \underline{\mathcal{S}}/\mathcal{L}_{\underline{W}}$ if and only if there exists a family of Hilbert seminorms $p_n$ on $\mathcal{S}_n$ such that $|W_{n+n}(f\otimes h)| \leq p_n(f)p_m(h), \forall n, m\in\mathbb{N}_0, f\in\mathcal{S}_n, h\in\mathcal{S}_m$.*

In some cases, covering also examples with nontrivial scattering in arbitrary dimension, the condition of Theorem 5 can be checked explicitly (*see* Non-trivial Models of Quantum Fields with Indefinite Metric).

It should be mentioned that different choices of the Hilbert seminorms $p_n$ lead to potentially different maximal Hilbert space closures (Hoffmann 1998, Constantinescu and Gheondea 2001). In fact, often the topology is not even Poincaré invariant and hence the states that can be approximated with local states depend on a chosen inertial frame. This fact, for the case of QED, has been interpreted in terms of physical gauges.

Many results from axiomatic field theory (*see* Axiomatic Quantum Field Theory) with positive metric also hold in the case of QFT with indefinite metric, like the PCT and the Reeh–Schlieder theorem, the irreducibility of the field algebra (for massive theories) and the Bisoniano–Wichmann theorem (*see* Algebraic Approach to Quantum Field Theory). Other classical results, like the Haag–Ruelle scattering theory and the spin and statistics theorem definitively do not hold, as has been proved by counterexamples. This is, however, far from being a disadvantage, as, for example, it permits the introduction of various gauges in the scattering theory of the vector potential $A_\mu(x)$ and fermionic scalar "ghost" fields in the BRST quantization (*see* BRST Quantization) formalism.

## Gupta–Bleuler Gauge Procedure

Here the Gupta–Bleuler gauge procedure is presented in a slightly generalized form following Steinmann's monograph. Classically, the equations of motion for the vector potential $A_\mu(x)$,

$$\partial^\nu\partial_\nu A_\mu(x) + \lambda\partial_\mu\partial^\nu A_\nu(x) = j_\mu(x) \qquad [16]$$

together with Lorentz gauge condition $B(x) = \partial_\mu A^\mu(x) = 0$ imply the Maxwell equations [10]. Here, $\lambda\in\mathbb{R}$ plays the role of a gauge parameter. As seen above, both equations, the so-called pseudo-Maxwell equations [16] and the Lorentz gauge condition $B(x) = 0$, cannot both hold as operator identities. The idea for the quantization

of the theory therefore is to give up the Lorentz gauge condition as an operator identity on the entire state space $\mathcal{H}$.

Suppose one has constructed such a theory with an indefinite inner state space $\mathcal{H}$. Already for the noninteracting theory, any invariant, spectral, local, and covariant solution requires indefinite metric, cf. the explicit formula [18] below. To complete the Gupta–Bleuler program, one needs to find a subspace of (equivalence classes of) physical states $\mathcal{H}'$ of the inner-product space $\mathcal{H}'$ such that the following conditions hold:

1. the vacuum is a physical state, that is, $\Omega \in \mathcal{H}'$;
2. observable fields like $j_\mu(x)$ and $F_{\nu\mu}(x)$ map $\mathcal{H}'$ to itself;
3. the inner product $\langle .,. \rangle$ restricted to $\mathcal{H}'$ is positive semidefinite;
4. observable fields map $\mathcal{H}''$, the set of null vectors in $\mathcal{H}'$, to itself; and
5. the Maxwell equations hold on $\mathcal{H}'$ in the sense

$$\langle \Psi, \partial^\nu F_{\nu\mu}(x)\Phi \rangle = \langle \Psi, j_\mu(x)\Phi \rangle, \quad \forall \Psi, \Phi \in \mathcal{H}' \qquad [17]$$

Then one obtains $\mathcal{H}^{\mathrm{ph}}$ as the completion of the quotient space $\mathcal{H}'/\mathcal{H}''$. The physical Hilbert space $\mathcal{H}^{\mathrm{ph}}$ contains the vacuum $\Omega$ (1), observable fields act on $\mathcal{H}^{\mathrm{ph}}$ (2) and (4), it is a Hilbert space (3) and the Maxwell equations hold on it (5).

To see that such a construction is possible, consider the noninteracting case $j_\nu(x) = 0$, that is, the limit case of vanishing electrical charge $e \to 0$, first. By taking the divergence of [16], one obtains $(1-\lambda)\partial^\nu \partial_\nu \partial^\mu A_\mu(x) = 0$. Excluding the Landau gauge ($\lambda = 1$), this implies $(\partial^\nu \partial_\nu)^2 A_\mu(x) = 0$. The most general solution for the two-point vacuum expectation values that is in agreement with [16] and the requirements of locality, translation invariance, the spectral condition, uniqueness of the vacuum, and the Lorentz covariance of $A^\mu(x)$ is then

$$\begin{aligned}\langle \Omega, A_\nu(x) A_\mu(y) \Omega \rangle &\\ = (-g_{\mu\nu} + \rho \partial_\mu \partial_\nu) D^+(x-y) &\\ + \frac{\lambda}{1-\lambda} \partial_\mu \partial_\nu E^+(x-y) & \qquad [18]\end{aligned}$$

where $D^+$ and $E^+$ are the inverse Fourier transforms of $\theta(p^0)\delta(p^2)$ and $\theta(p^0)\delta'(p^2)$ respectively, $p^2 = p \cdot p$, $\theta$ being the Heavyside function, $\delta$ the Dirac measure on $\mathbb{R}$ of mass one in zero and $\delta'$ its derivative. $\rho$ and $\lambda$ are gauge parameters, for example, the Feynman gauge corresponds to $\lambda = \rho = 0$. We have also omitted an overall factor corresponding to a field strength normalization (choice of numerical value of $\hbar$ – here $\hbar = 1$).

Using Wick's theorem and the GNS construction for inner-product spaces (cf. the preceding section), it is possible to realize a representation of the vector potential $A_\nu(x)$ as operator-valued distribution on some indefinite-metric state space $\mathcal{H}$ with Fock structure, for example, a Krein closure of the GNS space with $\Omega$ the GNS vacuum and $\mathcal{D} \subseteq \mathcal{H}$ the canonical domain of definition. In the case of Feynman gauge, the metric operator $\eta$ can be obtained by a second quantization of the operator $f_\mu \to \sum_{\nu=1}^4 g_{\mu\nu} f_\nu$ on the one-particle space $\mathcal{S}_1$.

In particular, the field $B(x)$ acts as an operator-valued distribution on $\mathcal{H}$ and, by taking the divergence of [16], it follows that $\partial^\nu \partial_\nu B(x) = 0$. Thus, $B(x) = B^+(x) + B^-(x)$ can be decomposed into a positive ("annihilation") and a negative ("creation") frequency part $B^\pm(x)$. One obtains:

**Theorem 6** *The space* $\mathcal{H}' = \{\Psi \in \mathcal{D}: B^+(x)\Psi = 0\}$ *fulfills all requirements* (1)–(5) *of the Gupta–Bleuler gauge procedure.*

Condition (1) is obvious and (2) follows from the fact that the fields $F_{\nu\mu}(x)$ and $B(x)$ commute, which can be checked on the level of two-point functions [18]. In the same spirit, one can also use [18] to check (3) and (4) by explicit calculations on the one-particle space and showing that $\mathcal{H}'$ is the Fock space over the one-particle states annihilated by $B^+(x)$. Finally, by Hermiticity of $A^\mu(x)$, $B^+(x)^* = B^-(x)$ and thus $\langle \Psi, B(x)\Phi \rangle = \langle \Psi, B^+(x)\Phi \rangle + \langle B^+(x)\Psi, \Phi \rangle = 0$. As the field $B(x)$ stands for the obstruction to Maxwell equations, this implies condition (5).

It should be noted that the physical state space $\mathcal{H}^{\mathrm{ph}}$ does not depend on the gauge parameters $\lambda, \rho$ and that it is spanned by repeated application of the field tensor $F_{\mu\nu}(x)$ to the vacuum.

By current conservation, the divergence of [16] still yields $\partial^\nu \partial_\nu B(x) = 0$ also in the interacting case where $e \neq 0$. One can then choose the same gauge condition as in Theorem 6 to define $\mathcal{H}'$. One can then try to prove that this space fulfills all the requirements of the Gupta–Bleuler procedure, for example, in the sense of perturbation theory. Using more advanced formulations as, for example, BRST quantization and Bogoliubov's local $S$-matrix formalism, this program has been completed up to a solution of the infrared problem (*see* Perturbative Renormalization Theory and BRST).

A different procedure, motivated by the necessity of coincidence of all charges $Q_{\mathrm{C}}, Q_{\mathrm{G}}$, and $Q_{\mathrm{M}}$ on the physical state space, has been elaborated by Steinmann. It deviates from the standard procedure in the sense that the physical space $\mathcal{H}'$ is not included in $\mathcal{H}$, but $\mathcal{H}^{\mathrm{ph}}$ is directly obtained from the GNS procedure after taking certain limits of Wightman functions restricted to

certain gauge-invariant algebras constructed from the Borchers algebra and a limiting procedure in a gauge parameter. The Wightman functional on this gauge-invariant algebras are positive (in the sense of perturbation theory), the limiting procedure, however, implies that the so-obtained physical states are singular (i.e., have diverging inner product) to states in $\mathcal{H}$, hence the so-defined state spaces corresponding to going to a physical gauge after solving the problem of a perturbative construction of an indefinite-metric solution, are not subspaces of $\mathcal{H}$.

## Introduction

Let $g$ be a Riemannian metric on a smooth compact manifold $M$ of dimension $m$. We assume for the moment that the boundary of $M$ is empty and postpone until later a discussion of the more general setting. If $x=(x_1,\ldots,x_m)$ is a local system of coordinates on $M$, let

$$g_{ij} := g\left(\partial_i^x, \partial_j^x\right)$$

give the components of the metric tensor. Let $D$ be an operator of Laplace type on a smooth vector bundle $V$ over $M$. Adopt the Einstein convention and sum over repeated indices. Relative to a local coordinate frame for $V, D$ has the form

$$D = -\left\{g^{ij}\mathrm{Id}\partial_i^x\partial_j^x + A^k\partial_k^x + B\right\}$$

where $A^k$ and $B$ are endomorphisms (i.e., matrices) of $V$.

We assume that $V$ is equipped with a positive-definite inner product and that $D$ is self-adjoint. There is then a complete orthonormal basis $\{\phi_i\}$ for $L^2(V)$, where $\phi_i \in C^\infty(V)$ and $D\phi_i = \lambda_i\phi_i$. The collection $\{\phi_i, \lambda_i\}$ is called a discrete spectral resolution of $D$. For example, if $D = -\partial_\theta^2$ on the circle, then the discrete spectral resolution is

$$\left\{\mathrm{e}^{\sqrt{-1}n\theta}, n^2\right\}_{n\in\mathbb{Z}}$$

If we order the eigenvalues $\lambda_1 \leq \lambda_2 \leq \cdots$ and repeat each eigenvalue according to multiplicity, then there is the following estimate due to Weyl:

$$\lambda_n \sim n^{2/m} \quad \text{as} \quad n \to \infty$$

We now suppose given a pair of vector bundles $V_1$ and $V_2$ over $M$ and a $k$th-order partial differential elliptic operator

$$A : C^\infty(V_1) \to C^\infty(V_2)$$

Locally, we decompose

$$A = \sum_{|I|\le k} a_I \partial_x^I$$

where $I = (i_1, \ldots, i_m)$ is a multi-index and where

$$\partial_x^I = (\partial_1^x)^{i_1} \ldots (\partial_m^x)^{i_m}$$

The $a_I$ are linear maps from $V_1$ to $V_2$. The leading symbol of A is then defined by setting

$$\sigma_L(A)(x, \xi) := (\sqrt{-1})^k \sum_{|I|=k} a_I(x)\xi^I$$

where $\xi^I = (\xi_1)^{i_1} \ldots (\xi_m)^{i_m}$, and

$$\xi = (\xi_1, \ldots, \xi_m)$$

are local fiber coordinates on the cotangent bundle. The leading symbol is an invariantly defined map

$$\sigma_L : T^*M \to \mathrm{End}(V_1,\ V_2)$$

For example, if $V_1 = V_2$ and if $D$ is an operator of Laplace type, then the leading symbol is given by the metric tensor, that is,

$$\sigma_{\mathrm{L}}(D) = g^{ij}\xi_i\xi_j \mathrm{Id} = |\xi|^2 \mathrm{Id}$$

If $d$ is exterior differentiation, then the leading symbol is given by exterior multiplication, that is,

$$\sigma_{\mathrm{L}}(d)(\xi)\omega = \sqrt{-1}\xi \wedge \omega$$

The operator $A$ is said to be elliptic if $\sigma_{\mathrm{L}}(A)$ is an isomorphism from $V_1$ to $V_2$ for any $\xi \neq 0$. If $A$ is an elliptic partial differential operator, then

$$\begin{aligned}\mathrm{index}(A) &:= \dim \ker(A) - \dim \mathrm{coker}(A) \\ &= \dim \ker(A^*A) - \dim \ker(AA^*)\end{aligned}$$

is well defined. As the index vanishes if $m$ is odd, we assume for the most part that $m$ is even.

If $A_\varepsilon$ is a smooth one-parameter family of such operators, then index $(A_\varepsilon)$ is independent of $\varepsilon$. The index depends only on the homotopy class of the leading symbol of $A$ within the class of invertible symbols; it does not depend on the underlying metric of the manifold and it does not depend on the fiber metrics chosen for $V_1$ and $V_2$.

The Atiyah–Singer index theorem expresses the index as the integral of suitably chosen polynomials in the curvature tensor for the classical elliptic complexes and, more generally, in terms of cohomological information for general elliptic complexes. Further details appear later in the article.

The primary focus here is on the complexes which are of Dirac type, that is, complexes where $A$ is a first-order partial differential operator and where the associated second operators $D_1 := A^*A$ and $D_2 := AA^*$ are of Laplace type.

Here is a brief outline of this article. The classical elliptic complexes (de Rham, signature, spin, Dolbeault, Yang–Mills) are discussed first. Next the characteristic classes are introduced, followed by the relevant formula for the index of the classical elliptic complexes, manifolds with boundary, and the equivariant index. Index theory is an enormous topic and here only classical features are emphasized as a complete treatment is beyond the scope of a short expository note such as this one. As some guide to various applications in mathematical physics, the reader is referred to the Further Reading section.

## The Classical Elliptic Complexes

### The de Rham Complex

Let $\Lambda^p M$ be the bundle of smooth $p$ forms over $M$ and let

$$d : C^\infty(\Lambda^p M) \to C^\infty(\Lambda^{p+1} M)$$

and

$$\delta : C^\infty(\Lambda^p M) \to C^\infty(\Lambda^{p-1} M)$$

be the exterior derivative and dually the interior derivative, respectively. We set

$$\Delta := (d + \delta)^2 \quad \text{on} \quad C^\infty(\Lambda M)$$

and the decompose $\Delta = \oplus_p \Delta^p$, where $\Delta^p$ is an operator of Laplace type on $C^\infty(\Lambda^p M)$.

We have $d^2 = 0$. The de Rham cohomology groups are given by taking the quotient of the closed forms by the exact forms:

$$H^p(M; \mathbb{R}) := \frac{\ker(d : C^\infty(\Lambda^p M) \to C^\infty(\Lambda^{p+1} M))}{\mathrm{im}(d : C^\infty(\Lambda^{p-1} M) \to C^\infty(\Lambda^p M))}$$

The Hodge–de Rham theorem identifies $H^p(M; \mathbb{R})$ with the kernel of the Laplacian

$$\ker(\Delta^p) = H^p(M; \mathbb{R})$$

and with the topological cohomology groups.

If $\xi$ is a cotangent vector, let $\mathrm{e}(\xi) : \omega \to \xi \wedge \omega$ be exterior multiplication. Let $\mathrm{i}(\xi)$ be the dual operator, interior multiplication. If $\{e_i\}$ is a local

ortho-normal frame for $TM$, let $e^I = e^{i_1} \wedge \cdots \wedge e^{i_p}$, where $I = \{1 \le i_1 < \cdots < i_p \le m\}$. Then we have

$$\mathfrak{e}(e^1)e^I = \begin{cases} 0 & \text{if } i_1 = 1 \\ e^1 \wedge e^I & \text{if } i_1 > 1 \end{cases}$$
$$\mathfrak{i}(e^1)e^I = \begin{cases} e^{i_2} \wedge \cdots \wedge e^{i_p} & \text{if } i_1 = 1 \\ 0 & \text{if } i_1 > 1 \end{cases}$$

Define a Clifford module structure on $\Lambda M$ by

$$\gamma(\xi) := \mathfrak{e}(\xi) - \mathfrak{i}(\xi)$$

If $\{e_i\}$ is a local orthonormal basis for $TM$, then

$$\gamma(e^i)\gamma(e^j) + \gamma(e^j)\gamma(e^i) = -2\delta_{ij}\mathrm{Id}$$

so the usual Clifford commutation rules are satisfied. Let $\nabla$ be the Levi-Civita connection on $M$. We may then expand

$$d = \mathfrak{e}(e^i)\nabla_{e_i}, \qquad \delta = -\mathfrak{i}(e^i)\nabla_{e_i}$$
$$d + \delta = \gamma(e^i)\nabla_{e_i}$$

The de Rham complex is then defined by taking

$$\Lambda^{\mathrm{even}}M := \oplus_k \Lambda^{2k}M, \qquad \Lambda^{\mathrm{odd}}M := \oplus_k \Lambda^{2k+1}M$$
$$d + \delta : C^\infty(\Lambda^{\mathrm{even}}M) \to C^\infty(\Lambda^{\mathrm{odd}}M)$$

### The Signature Complex

The signature complex arises from a different decomposition of the exterior algebra. Let Clif $M$ be the Clifford algebra of $T^*M$; this is the universal unital algebra generated by $T^*M$ subject to the Clifford commutation relations given above:

$$\xi_1 * \xi_2 + \xi_2 * \xi_1 = -2g(\xi_1, \xi_2) \cdot \mathrm{Id}$$

We suppose $M$ is orientable and let

$$\mathrm{orn} = e_1 * \cdots * e_m \in \mathrm{Clif}\, M$$

be the orientation class. The map $\xi \to \gamma(\xi)$ extends to a unital algebra homomorphism

$$\gamma : \mathrm{Clif}\, M \to \mathrm{End}(\Lambda M)$$

$\gamma(\mathrm{orn})$ defines an endomorphism of $\Lambda M$ which is, modulo suitable sign conventions, the Hodge $\star$ operator. If $m = 2k$ is even, then

$$(d + \delta)\gamma(\mathrm{orn}) = -\gamma(\mathrm{orn})(d + \delta)$$

Set

$$\Theta := (\sqrt{-1})^k \gamma(\mathrm{orn})$$

As $\Theta^2 = \mathrm{Id}$, we can decompose

$$\Lambda M \otimes \mathbb{C} = \Lambda^+ M \oplus \Lambda^- M$$

where $\Lambda^\pm M$ are the $\pm 1$ eigenspaces of $\Theta$. The signature complex is then given by

$$(d + \delta) : C^\infty(\Lambda^+ M) \to C^\infty(\Lambda^- M)$$

### Twisted Signature Complex

Let $V$ be an auxiliary complex vector bundle over $M$ which is equipped with a unitary connection $\nabla^V$. We use the connection $\nabla^V$ on $V$ and the Levi-Civita connection on $TM$ to covariantly differentiate tensors of all types. The twisted signature complex is defined by setting

$$(d+\delta)_V := (\gamma(e^i) \otimes \mathrm{Id})\nabla_{e_i} : C^\infty(\Lambda^+ M \otimes V) \to C^\infty(\Lambda^- M \otimes V)$$

### Yang–Mills complex

This complex in dimension 4 arises from yet another decomposition of the exterior algebra. We use the discussion in the previous section to decompose

$$\Lambda^2 M = \Lambda^{2,+}M \oplus \Lambda^{2,-}M$$

into the $\pm 1$ eigenspaces of $\Theta$. Let

$$\pi : \Lambda^2 M \to \Lambda^{2,-}M$$

be orthogonal projection. The Yang–Mills complex is the 3-term sequence

$$d : C^\infty(\Lambda^0 M) \to C^\infty(\Lambda^1 M)$$

and

$$\pi d : C^\infty(\Lambda^1 M) \to C^\infty(\Lambda^{2,-}M)$$

We can wrap up this sequence to obtain an equivalent elliptic complex

$$(d + \delta) : C^\infty(\Lambda^{\mathrm{even},-}M) \to C^\infty(\Lambda^{\mathrm{odd},+}M)$$

As with the signature complex, this complex can be twisted by taking coefficients in an auxiliary vector bundle $V$. It is crucial to the study of four-dimensional geometry using Yang–Mills theory.

### Dolbeault Complex

Let $z = (z_1, \ldots, z_k)$ be a local system of holomorphic coordinates on a complex manifold $M$, where $z_i = x_i + \sqrt{-1}y_i$. We define

$$\mathrm{d}z^i := \mathrm{d}x^i + \sqrt{-1}\mathrm{d}y^i, \quad \mathrm{d}\bar{z}^i := \mathrm{d}x^i - \sqrt{-1}\mathrm{d}y^i$$
$$\partial_i^z = \tfrac{1}{2}\left(\partial_i^x - \sqrt{-1}\partial_i^y\right), \ \bar{\partial}_i^z = \tfrac{1}{2}\left(\partial_i^x + \sqrt{-1}\partial_i^y\right)$$

and decompose $d = \partial + \bar{\partial}$, where

$$\partial := \mathfrak{e}(\mathrm{d}z^i)\partial_i^z \quad \text{and} \quad \bar{\partial} := \mathfrak{e}(\mathrm{d}\bar{z}^i)\partial_i^{\bar{z}}$$

on the complexified exterior algebra. Let $\delta'$ be the adjoint of $\partial$ and $\delta''$ be the adjoint of $\bar{\partial}$. Let

$$\mathrm{d}\bar{z}^I := \mathrm{d}\bar{z}^{i_1} \wedge \cdots \wedge \mathrm{d}\bar{z}^{i_p}$$

$$\Lambda^{(0,\text{even})} := \text{Span}\{\mathrm{d}\bar{z}^I\}_{|I| \text{ is even}}$$

$$\Lambda^{(0,\text{odd})} := \text{Span}\{\mathrm{d}\bar{z}^I\}_{|I| \text{ is odd}}$$

The Dolbeault complex is then defined by

$$(\bar{\partial} + \delta'') : C^\infty(\Lambda^{(0,\text{even})}M) \to C^\infty(\Lambda^{(0,\text{odd})}M)$$

This complex can be twisted by taking coefficients in a holomorphic bundle $V$ over $M$.

### The Spin Complex

Let $M$ be orientable. Let $P_{\text{SO}}$ be the principal SO bundle of orthonormal frames for the tangent bundle. A spin structure $s$ on $M$ is a principal Spin bundle $P_{\text{Sp}}$ together with a double cover $\rho : P_{\text{Sp}} \to P_{\text{SO}}$ which respects the usual double cover $\rho : \text{Spin} \to \text{SO}$ of the structure groups. Equivalently, a spin structure is a lifting of the transition functions from SO to Spin which preserves the cocycle condition. One says that $M$ is spin if it admits a spin structure.

A manifold is orientable if and only if the first Stiefel–Whitney class of $M$ vanishes; an orientable manifold is spin if and only if the second Stiefel–Whitney class of $M$ vanishes as well; these are $\mathbb{Z}_2$-valued cohomology classes. Inequivalent spin structures are parametrized by the cohomology group $H^1(M; \mathbb{Z}_2)$ or, equivalently, by real-line bundles on $M$.

The spin representation $\mathcal{S}$ of Spin defines an associated spin bundle $\mathcal{S}M = \mathcal{S}(M, s)$. There is a natural Clifford action $c$ of $TM$ on $\mathcal{S}M$. The Levi-Civita connection lifts to define the spin connection on $\mathcal{S}$ and the Dirac operator is defined by

$$A(s) := c(\mathrm{d}x^i)\nabla_{\partial_i^x} \quad \text{on} \quad C^\infty(\mathcal{S}M)$$

Let $m = 2k$ and let $\Theta := (\sqrt{-1})^k c(\text{orn})$. Since $c(\Theta)^2 = \text{Id}$, one can decompose

$$\mathcal{S}M = \mathcal{S}^+M \oplus \mathcal{S}^-M$$

as the direct sum of the half-spin bundles to obtain the spin complex:

$$A(s) : C^\infty(\mathcal{S}^+M) \to C^\infty(\mathcal{S}^-M)$$

As with the signature complex, the spin complex can be twisted by taking coefficients in an auxiliary vector bundle $V$.

### Relating the Classic Elliptic Complexes

One has natural isomorphisms of virtual representations of the spinor group:

$$\Lambda^+ - \Lambda^- = (\mathcal{S}^+ - \mathcal{S}^-) \otimes (\mathcal{S}^+ + \mathcal{S}^-)$$

$$\Lambda^{\text{even}} - \Lambda^{\text{odd}} = (-1)^{m/2}(\mathcal{S}^+ - \mathcal{S}^-) \otimes (\mathcal{S}^+ - \mathcal{S}^-)$$

which show that the signature complex and de Rham complexes are the spin complexes with coefficients in the virtual bundles

$$\mathcal{S}^+M + \mathcal{S}^-M \quad \text{and} \quad (-1)^{m/2}(\mathcal{S}^+M - \mathcal{S}^-M)$$

respectively. If $M$ is complex and spin, then the Dolbeault complex is the spin complex with coefficients in the square root of the canonical bundle.

One can consider complex spinors to define the group $\text{Spin}^c(m)$. Any spin manifold admits a $\text{Spin}^c$ structure with trivial associated complex line bundle. Any complex manifold admits a $\text{Spin}^c$ structure with associated complex line bundle given by the canonical bundle. Thus, a complex manifold admits a $\text{Spin}^c$ structure if and only if it is possible to take a square root of the canonical line bundle; inequivalent Spin structures are parametrized by inequivalent square roots. If $M$ is orientable, then $M$ admits a $\text{Spin}^c$ structure if and only if the second Stiefel–Whitney class of $M$ lifts from $H^2(M; \mathbb{Z}_2)$ to $H^2(M; \mathbb{Z})$; in the complex setting, this lifting is performed by the first Chern class. Inequivalent $\text{Spin}^c$ structures are parametrized by $H^2(M; \mathbb{Z})$ or, equivalently, by complex line bundles over $M$.

## Characteristic Classes

### The Euler Form

Let $\nabla$ be the Levi-Civita connection on $M$. Let

$$R(x, y) := \nabla_x\nabla_y - \nabla_y\nabla_x - \nabla_{[x,y]}$$

be the curvature operator. Let $\{e_1, \ldots, e_m\}$ be a local orthonormal frame for $TM$ and let

$$R_{ijkl} := g(R(e_i, e_j)e_k, e_l)$$

give the components of the curvature relative to a local orthonormal frame. Let

$$\varepsilon^{I,J} := g(e^{i_1} \wedge \cdots \wedge e^{i_m}, e^{j_1} \wedge \cdots \wedge e^{j_m})$$

be the totally antisymmetric tensor; this is the sign of the permutation which sends $i_\nu \to j_\nu$. Let $m = 2\bar{m}$. The Euler form is given by setting

$$\mathcal{E}_m := \frac{1}{8^{\bar{m}}\pi^{\bar{m}}\bar{m}!}\varepsilon^{I,J}R_{i_1i_2j_1j_2}\ldots R_{i_{m-1}i_mj_{m-1}j_m}$$

Let $\rho_{ij} := R_{ikkj}$ and $\tau := \rho_{ii}$ be the Ricci tensor and the scalar curvature, respectively. Then,

$$\mathcal{E}_2 = \frac{1}{4\pi}\tau \quad \text{and} \quad \mathcal{E}_4 = \frac{1}{32\pi^2}\{\tau^2 - 4|\rho|^2 + |R|^2\}$$

### The Pontrjagin Forms

Since $R(x,y) = -R(y,x)$, we can regard $R$ as a 2-form-valued endomorphism of the tangent bundle. We define the Pontrjagin forms $p_i \in C^\infty(\Lambda^{4i}M)$ by expanding

$$\det\left(I + \frac{1}{2\pi}R\right) = 1 + p_1 + p_2 + \cdots$$

These differential forms are closed and the corresponding cohomology classes

$$P_i = [p_i] \in H^{4i}(M;\mathbb{R})$$

in the de Rham cohomology are independent of the particular Riemannian metric on $M$ which was chosen.

The $\hat{A}$ genus and the Hirzebruch $L$ polynomial are expressed in terms of these classes using the splitting principle. Let $A$ be a skew-symmetric matrix. One sets

$$p(A) := \det(I + A) = 1 + p_1(A) + p_2(A) + \cdots$$

As $A$ is skew symmetric, it decomposes as the direct sum of $2 \times 2$ blocks of the form

$$\begin{pmatrix} 0 & \lambda_i \\ -\lambda_i & 0 \end{pmatrix}$$

We then have

$$p(A) = \prod_\nu \{1 + \lambda_\nu^2\}$$

so

$$p_i(A) = s_i(\lambda_1^2, \lambda_2^2, \ldots)$$

where $s_i$ is the $i$th symmetric function;

$$p_1 = \sum_i \lambda_i^2, \qquad p_2 = \sum_{i<j} \lambda_i^2 \lambda_j^2$$

and so forth. Let

$$\begin{aligned} L(\vec{\lambda}) &:= \prod_\nu \frac{\lambda_\nu}{\tanh(\lambda_\nu)} \\ &= 1 + L_1(\vec{\lambda}) + L_2(\vec{\lambda}) + \cdots \\ \hat{A}(\vec{\lambda}) &:= \prod_\nu \frac{\lambda_\nu}{2\sinh\left(\frac{1}{2}\lambda_\nu\right)} \\ &= 1 + \hat{A}_1(\vec{\lambda}) + \hat{A}_2(\vec{\lambda}) + \cdots \end{aligned}$$

As $L_i$ and $\hat{A}_i$ are even symmetric functions of $\vec{\lambda}$, one can write $L_i = L_i(p_1(A), \ldots, p_k(A))$. For example,

$$\begin{aligned} L &= 1 + \tfrac{1}{3}p_1 + \tfrac{1}{45}\left(7p_2 - p_1^2\right) + \cdots \\ \hat{A} &= 1 - \tfrac{1}{24}p_1 + \tfrac{1}{5760}(7p_1^2 - 4p_2) + \cdots \end{aligned}$$

Substituting $(1/2\pi)R$ for $A$ then permits one to define the Hirzebruch polynomial $L(R)$ and the $\hat{A}$ genus $\hat{A}(R)$.

### The Chern Forms

Let $V$ be a $k$-dimensional complex vector bundle over $M$. Let $\nabla$ be a Hermitian connection on $V$ and let $\Omega$ be the associated curvature endomorphism. The Chern forms $c_i \in C^\infty(\Lambda^{2i}M)$ are defined by expanding

$$\det\left(I + \frac{\sqrt{-1}}{2\pi}\Omega\right) = 1 + c_1 + c_2 + \cdots$$

As with the Hirzebruch polynomial and the $\hat{A}$ genus, the Chern character and Todd genus are expressed in terms of the generating functions:

$$\mathrm{Td}(\vec{\lambda}) = \prod_\nu \frac{\lambda_\nu}{1 - \mathrm{e}^{-\lambda_\nu}}$$

and

$$\mathrm{ch}(\vec{\lambda}) = \sum_\nu \frac{\lambda_\nu}{\nu!}$$

One has

$$\begin{aligned} \mathrm{Td} &= 1 + \mathrm{Td}_1 + \mathrm{Td}_2 + \cdots \\ &= 1 + \tfrac{1}{2}c_1 + \tfrac{1}{12}\left(c_1^2 + c_2\right) + \cdots \\ \mathrm{Ch} &= \mathrm{ch}_0 + \mathrm{ch}_1 + \mathrm{ch}_2 + \cdots \\ &= k + c_1 + \tfrac{1}{2}\left(c_1^2 - 2c_2\right) + \cdots \end{aligned}$$

## The Index Theorem

### The Gauss–Bonnet Theorem

We return to the de Rham complex. Let

$$\chi(M) = \sum_p (-1)^p \dim H^p(M;\mathbb{R})$$

be the Euler–Poincaré characteristic; $\chi(M) = 0$ if $m$ is odd. Let $M$ have a simplicial structure with $n(k)$ cells of degree $k$; $n(0)$ is the number of vertices, $n(1)$ is the number of edges, $n(2)$ is the number of triangles, etc. Then

$$\chi(M) = \sum_k (-1)^k n(k)$$

so the Euler–Poincaré characteristic is a combinatorial invariant. By the Hodge–de Rham theorem,

$$\begin{aligned}\text{index}(d+\delta) &= \dim\ker(\Delta^{\text{even}}) - \dim\ker(\Delta^{\text{odd}})\\ &= \chi(M)\end{aligned}$$

The Chern–Gauss–Bonnet theorem expresses this invariant in terms of curvature

$$\chi(M) = \int_M \mathcal{E}_m \, \mathrm{d}x$$

where $\mathcal{E}_m$ is the Euler form given above. If one twists the de Rham complex to take coefficients in an auxiliary vector bundle $V$, then no new information results, since

$$\text{index}\{d+\delta\}_V = \chi(M)\cdot\dim(V)$$

### The Hirzebruch Signature Theorem

Let sign $(M)$ be the index of the signature complex on a manifold of dimension $4k$; the index vanishes in dimensions $m \equiv 2 \bmod 4$. Let $\star$ be the Hodge duality operator. As $\star\Delta^p\star^{-1} = \Delta^{m-p}, \star$ preserves the eigenspaces of the Laplacian. In particular, $\star$ induces an isomorphism

$$\begin{aligned}\star : H^p(M;\mathbb{R}) &= \ker(\Delta^p)\\ \to\ H^{m-p}(M;\mathbb{R}) &= \ker(\Delta^{m-p})\end{aligned}$$

which implements Poincaré duality. In dimension $2k$, $\star^2 = \text{Id}$. Decompose

$$H^{2k}(M;\mathbb{R}) = H^{2k,+}(M;\mathbb{R}) \oplus H^{2k,-}(M;\mathbb{R})$$

into the $\pm 1$ eigenspaces of $\star$; these may be identified with $\ker(\Delta^{2k,\pm})$ acting on $C^\infty(\Lambda^{2k,\pm}M)$. As the contributions to the signature away from the middle dimension cancel,

$$\text{sign}(M) = \dim H^{2k,+}(M;\mathbb{R}) - \dim H^{2k,-}(M;\mathbb{R})$$

As with the de Rham complex, there is a topological description of this invariant. If $\alpha$ and $\beta$ are closed $2k$ forms, one sets

$$\langle\alpha,\,\beta\rangle := \int_M \alpha\wedge\beta$$

One can use Stoke's theorem to see that this induces a symmetric bilinear form on the de Rham cohomology groups $H^{2k}(M;\mathbb{R})$. Poincaré duality then shows that this symmetric bilinear form is nondegenerate, so this is a form of type $(p,q)$; sign$(M)$ is the signature of this quadratic form:

$$\text{sign}(M) = q - p$$

The Hirzebruch signature formula expresses sign $(M)$ in terms of curvature; if $L$ is the Hirzebruch polynomial described above and if $m = 4k$, then

$$\text{sign}(M) = \int_M L_k$$

Let $V$ be an auxiliary coefficient bundle. Taking coefficients in $V$ then yields the formula

$$\text{sign}_V(M) = \sum_{4i+2j=m} 2^j \int_M L_i \wedge \text{ch}_j(V)$$

### The Index of the Yang–Mills Complex

Let $\text{YM}_V$ be the Yang–Mills complex with coefficients in an auxiliary vector bundle $V$, then the index can be evaluated using the formulas given above as

$$\begin{aligned}\text{index}\{\text{YM}_V\} &= \tfrac{1}{2}\{\dim(V)\chi(M) - \text{sign}(M,\,V)\}\\ &= \tfrac{1}{2}\textstyle\int_M\{\dim V\mathcal{E}_4 - \dim V L_1 - 4\,\text{ch}_2(V)\}\end{aligned}$$

### The Index of the Dolbeault Complex

If $V$ is a holomorphic bundle over a complex manifold $M$, then

$$\text{index}\{(\bar\partial + \delta'')_V\} = \sum_{2i+2j=m}\int_M \text{Td}_i(M)\wedge\text{ch}_j(V)$$

The index of the untwisted Dolbeault complex is called the arithmetic genus and denoted by ag$(M)$.

### The Index of the Spin Complex

If $M$ is a spin manifold and if $A_V$ is the Dirac operator with coefficients in an auxiliary coefficient bundle, then

$$\text{index}\{A_V\} = \sum_{4i+2j=m}\int_M \hat{A}_i(M)\wedge\text{ch}_j(M)$$

The index of the spin complex is called the $\hat{A}$ genus and is denoted by $\hat{A}(M)$. If $M$ is a Spin$^c$ manifold, the appropriate formula becomes

$$\text{index}\{A_V^c\} = \sum_{4i+2j+2k=m}\int_M \hat{A}_i(M)\wedge\text{ch}_j(M)\wedge\theta^k$$

where $\theta = \frac{1}{2}c_1(L)$, $L$ being the complex line bundle associated with the Spin$^c$ structure.

#### Properties

The classic elliptic complexes defined above are multiplicative with respect to Cartesian product. Suppose that $M_1$ and $M_2$ are Riemannian manifolds with the appropriate structures. For the signature complex, suppose $M_1$ and $M_2$ are oriented; for the Dolbeault complex, suppose $M_1$ and $M_2$ are holomorphic; for the spin complex, suppose $M_1$ and $M_2$ are spin. By taking the twisting coefficient bundle to be trivial in the interests of simplicity, one has

$$\begin{aligned}\chi(M_1\times M_2) &= \chi(M_1)\chi(M_2)\\ \mathrm{sign}(M_1\times M_2) &= \mathrm{sign}(M_1)\mathrm{sign}(M_2)\\ \mathrm{ag}(M_1\times M_2) &= \mathrm{ag}(M_1)\mathrm{ag}(M_2)\\ \hat{A}(M_1\times M_2) &= \hat{A}(M_1)\hat{A}(M_2)\end{aligned}$$

These complexes behave well under finite coverings. Let $F\to M_2\to M_1$ be a finite covering projection with $|F|$ sheets. Then

$$\begin{aligned}\chi(M_2) &= |F|\chi(M_1)\\ \mathrm{sign}(M_2) &= |F|\mathrm{sign}(M_1)\\ \mathrm{ag}(M_2) &= |F|\mathrm{ag}(M_1)\\ \hat{A}(M_2) &= |F|\hat{A}(M_1)\end{aligned}$$

The connected sum $M_1\#M_2$ is defined by punching out small disks about points $P_i$ in $M_i$ and then joining along the spherical boundaries that remain. It is necessary, of course, to smooth out the resulting corners. Note that if $M_1$ and $M_2$ are complex manifolds, then $M_1\#M_2$ is no longer a complex manifold in general. Since

$$\chi(S^m)=2,\quad \mathrm{sign}(S^m)=0,\ \text{and}\ \hat{A}(S^m)=0$$

the following additivity results follow from the integral formulas given above:

$$\begin{aligned}\chi(M_1\#M_2) &= \chi(M_1)+\chi(M_2)-2\\ \mathrm{sign}(M_1\#M_2) &= \mathrm{sign}(M_1)+\mathrm{sign}(M_2)\\ \hat{A}(M_1\#M_2) &= \hat{A}(M_1)+\hat{A}(M_2)\end{aligned}$$

#### Examples and Applications

Let $S^m$ be the standard sphere and let $\mathbb{CP}^j$ be the complex projective plane. One then has

$$\begin{aligned}&\chi(S^4)=2, &&\mathrm{sign}(S^4)=0\\ &\chi(S^2\times S^2)=4, &&\mathrm{sign}(S^2\times S^2)=0\\ &\chi(\mathbb{CP}^2)=3, &&\mathrm{sign}(\mathbb{CP}^2)=1\end{aligned}$$

In dimension 4, the Riemann–Roch formula yields

$$\mathrm{ag}(M^4)=\tfrac{1}{4}\{\chi(M)+\mathrm{sign}(M)\}$$

This would yield $\mathrm{ag}(S^4)=\frac{1}{2}$; since $\frac{1}{2}$ is not an integer, this shows that $S^4$ does not admit a complex structure; a similar argument shows that $S^n$ does not admit a complex structure for $n\neq 2,6$, and it is not known whether $S^6$ admits a holomorphic structure; it does admit an almost-complex structure.

If we set $M=\mathbb{CP}^2\#\mathbb{CP}^2$, then

$$\mathrm{ag}(M)=\tfrac{1}{4}(3+3-2+1+1)=\tfrac{3}{2}$$

and thus $\mathbb{CP}^2\#\mathbb{CP}^2$ does not admit a complex structure. These examples are typical of the use of the index theorem to prove the nonexistence of certain structures.

#### The General Index Theorem

Let $S(T^*M)$ be the sphere bundle of unit cotangent vectors and let $D(T^*M)$ be the disk bundle of cotangent vectors of length at most 1. Let

$$P : C^\infty(V_1)\to C^\infty(V_2)$$

be an elliptic pseudodifferential operator. The leading symbol $p:=\sigma_L(P)$ induces a smooth map

$$p : S(T^*M)\to \mathrm{End}(V_1,\ V_2).$$

We form $\Sigma(M)$ by gluing two copies of $D(M)$ together along their common boundary $S(M)$ and we define a bundle $\Sigma(p,V_1,V_2)$ over $\Sigma(M)$ by gluing $V_1$ to $V_2$ over $S(M)$ using the clutching function $p$. The Atiyah–Singer index theorem expresses the index of $P$ in terms of cohomological data involving the Chern class of the symbol bundle and the characteristic classes of the tangent bundle of $M$. If $\Sigma(M)$ is given a suitable orientation, then

$$\mathrm{index}(P)=\sum_{2i+4j=2m}\int_{\Sigma(M)}\mathrm{ch}_i(\Sigma(p,\ V_1,\ V_2))\wedge \mathrm{Td}_j(M)$$

It specializes to the results given above for the classical elliptic complexes. Conversely, by using $K$-theoretic methods, the index theorem in full generality can be derived from the special case of the twisted signature complex.

## Manifolds with Boundary

If the boundary of $M$ is nonempty, we must impose suitable boundary conditions.

#### Local Boundary Conditions

Choose local coordinates $x=(x^1,\ldots,x^m)$ near the boundary of $M$ so that $x^m$ is the geodesic distance to the boundary. On the boundary, we can decompose a differential form $\omega\in C^\infty(\Lambda M)$ in the form $\omega=\omega_1+\mathrm{d}x^m\wedge\omega_2$, where $\omega_1$ and $\omega_2$ are tangential

differential forms. Absolute and relative boundary conditions are defined by setting

$$\mathcal{B}_a\omega := \omega_2|_{\partial M} \quad \text{and} \quad \mathcal{B}_r\omega := \omega_1|_{\partial M}$$

Let $(d+\delta)_a$ and $(d+\delta)_r$ be the associated realizations. These operators preserve the grading of the exterior algebra $\Lambda M = \Lambda^{\text{even}}M \oplus \Lambda^{\text{odd}}M$ and define elliptic complexes

$$(d+\delta)_a : C^\infty(\Lambda^{\text{even}}M) \to C^\infty(\Lambda^{\text{odd}}M)$$
$$(d+\delta)_r : C^\infty(\Lambda^{\text{even}}M) \to C^\infty(\Lambda^{\text{odd}}M)$$

We consider a collection

$$J = \{1 \le j_1 < \cdots < j_p < m\}$$

of tangential indices and let

$$dx^J = dx^{j_1} \wedge \cdots \wedge dx^{j_p}$$

The associated absolute boundary conditions for the Laplacian are defined by

$$\begin{aligned}&\tilde{\mathcal{B}_a}(\phi_J dx^J + \psi_J dx^m \wedge dx^J)\\ &\quad = (\psi_J|_{\partial M} dx^J) \oplus (\partial_m^x \phi_J|_{\partial M}) dx^J\end{aligned}$$

If $\star$ is the Hodge operator, then one sets dually:

$$\tilde{\mathcal{B}_r}(\omega) = \tilde{\mathcal{B}_a}(\star\omega)$$

Let $\Delta_a^p$ and $\Delta_r^p$ be the associated realizations of the Laplacian with these boundary conditions. The Hodge–de Rham theorem extends to this setting to yield isomorphisms

$$\ker(\Delta_a^p) = H^p(M; \mathbb{R})$$

and

$$\ker(\Delta_r^p) = H^p(M, \partial M; \mathbb{R})$$

The Hodge $\star$ operator intertwines $\Delta_a^p$ and $\Delta_r^{m-p}$ and implements the Poincaré duality isomorphism $H^p(M;\mathbb{R}) = H^{m-p}(M, \partial M; \mathbb{R})$. This also shows that

$$\text{index}(d+\delta)_a = \sum_p (-1)^p \dim H^p(M;\mathbb{R}) = \chi(M)$$

and

$$\begin{aligned}\text{index}(d+\delta)_r &= \sum_p (-1)^p \dim H^p(M, \partial M; \mathbb{R})\\ &= \chi(M, \partial M) = \chi(M) - \chi(\partial M)\end{aligned}$$

Let $\mathcal{E}_m$ be the Euler form if $m$ is even. We set $\mathcal{E}_m = 0$ if $m$ is odd. Let $L$ be the second fundamental form. Let $A = (a_1, \ldots, a_{m-1})$ and $B = (b_1, \ldots, b_{m-1})$ be collections of distinct indices ranging from 1 to $m-1$. Set

$$\begin{aligned}\mathcal{L}_{m-1} := \sum_k &\frac{1}{\pi^k 8^k k!(m-1-2k)!\text{vol}(S^{m-1-2k})}\\ &\times \varepsilon^{A,B} R_{a_1a_2b_2b_1} \ldots R_{a_{2k-1}a_{2k}b_{2k}b_{2k-1}}\\ &\times L_{a_{2k+1}b_{2k+1}} \ldots L_{a_{m-1}b_{m-1}}\end{aligned}$$

The Chern–Gauss–Bonnet theorem generalizes to this setting to yield

$$\begin{aligned}\chi(M) &= \text{index}(d+\delta)_a\\ &= \int_M \mathcal{E}_m \text{dx} + \int_{\partial M} \mathcal{L}_{m-1} \text{dy}\end{aligned}$$

For example,

$$\begin{aligned}\chi(M^2) &= \frac{1}{4\pi}\left\{\int_{M^2} \tau \text{dx} + 2\int_{\partial M^2} L_{aa}\text{dy}\right\}\\ \chi(M^3) &= \frac{1}{8\pi}\int_{\partial M^3}\{R_{abba} + L_{aa}L_{bb} - L_{ab}L_{ab}\}\text{dy}\\ \chi(M^4) &= \frac{1}{32\pi^2}\int_{M^4}\{\tau^2 - 4|\rho|^2 + |R|^2\}\text{dx}\\ &\quad + \frac{1}{24\pi^2}\int_{\partial M^4}\{3\tau L_{aa} + 6R_{amam}L_{bb}\\ &\quad + 6R_{acbc}L_{ab} + 2L_{aa}L_{bb}L_{cc}\\ &\quad - 6L_{ab}L_{ab}L_{cc} + 4L_{ab}L_{bc}L_{ac}\}\text{dy}\end{aligned}$$

The interior integral vanishes if $m$ is odd. The boundary integral can be nonzero in any dimensions. Thus, in particular, the index of this elliptic complex can be nonzero even if $m$ is odd; $\chi(D^m) = 1$ for any $m$. The index of $(d+\delta)_r$ is computed similarly.

### Spectral Boundary Conditions

In contrast to the de Rham complex, there do not exist local boundary conditions for the signature, spin, and Dolbeault complexes. To simplify the discussion, we assume that the metric is the product near the boundary; there are appropriate compensating terms involving the second fundamental form in the more general setting. Let $A : C^\infty(V_1) \to C^\infty(V_2)$ denote either the twisted signature or the twisted spin complexes; there are some additional difficulties for the Dolbeault complex. Near the boundary, we can express

$$A = \sigma(\partial_m^x + A_{\text{T}})$$

where $A_{\text{T}}$ is a self-adjoint tangential operator of Dirac type on $V_1|_{\partial M}$ and $\sigma$ is a unitary bundle

isomorphism from $V_1|_{\partial M}$ to $V_2|_{\partial M}$. Let $\{\phi_i, \lambda_i\}$ be the discrete spectral resolution of $A_{\mathrm{T}}$. One defines

$$\eta(A_{\mathrm{T}}, s) = \sum_{\lambda_k \neq 0} \mathrm{sgn}(\lambda_k)|\lambda_k|^{-s}$$

as a measure of the spectral asymmetry of $A_{\mathrm{T}}$. This is well defined for $\mathrm{Re}(s) \gg 1$ and has a meromorphic extension to the complex plane $\mathbb{C}$. It turns out that 0 is a regular value and one defines

$$\eta(A_T) := \tfrac{1}{2}\{\eta(A_{\mathrm{T}},\, s) + \dim\, \ker(A_{\mathrm{T}})\}|_{s=0}$$

The spectral boundary conditions can now be imposed. Let $\Pi_{\geq}$ be orthogonal projection in $L^2(V_1|_{\partial M})$ on the span of the eigensections of $A_{\mathrm{T}}$ corresponding to non-negative eigenvalues and let $A_{\geq}$ be the associated realization defined by this boundary condition.

One can use the Atiyah–Patodi–Singer index theorem to generalize the relations given above to this setting. Let $f_A$ be the local integral given above that involves the Hirzebruch $L$ polynomial for the signature complex or the $\hat{A}$ genus for the spin complex. One then has

$$\mathrm{index}(A_{\geq}) = \eta(A_{\mathrm{T}}) + \int_M f_A$$

There are suitable correction formulas involving integrals of polynomials in the second fundamental form and in the curvature tensor if the structures are not product near the boundary.

## Equivariant Problems

### The Classical Lefschetz Formula

Let $M$ be a compact Riemannian manifold without boundary. Let $T$ be a smooth map from $M$ to $M$. Then pullback $T^*$ induces an action on $C^\infty(\Lambda^p M)$ which commutes with the exterior derivative $d$ and hence an action on the de Rham cohomology groups $H^p(M;\mathbb{R})$. The Lefschetz number of $T$ is then given by

$$\mathcal{L}(T) = \sum_p (-1)^p \mathrm{tr}\{T^* \text{ on } H^p(M;\mathbb{R})\}$$

To illustrate the Lefschetz number, let $M = \mathbb{T}^2$ be the two-dimensional torus. Let $e^1 := \mathrm{d}x^1$, let $e^2 := \mathrm{d}x^2$, and let $e^{12} := \mathrm{d}x^1 \wedge \mathrm{d}x^2$. Then,

$$\begin{aligned} H^0(\mathbb{T}^2;\mathbb{R}) &= 1 \cdot \mathbb{R} \\ H^1(\mathbb{T}^2;\mathbb{R}) &= e^1 \cdot \mathbb{R} + e^2 \cdot \mathbb{R} \\ H^2(\mathbb{T}^2;\mathbb{R}) &= e^{12} \cdot \mathbb{R} \end{aligned}$$

Let $T(x_1, x_2) = (n_{11}x_1 + n_{12}x_2,\ n_{21}x_1 + n_{22}x_2)$. Then,

$$\begin{aligned} T^*(1) &= 1 \\ T^*(e^1) &= n_{11}e^1 + n_{12}e^2 \\ T^*(e^2) &= n_{21}e^1 + n_{22}e^2 \\ T^*(e^{12}) &= (n_{11}n_{22} - n_{12}n_{21})e^{12} \end{aligned}$$

and, consequently, the Lefschetz number becomes

$$\begin{aligned} \mathcal{L}(T) &= \det(I - T^*) \\ &= 1 - (n_{11} + n_{22}) + (n_{11}n_{22} - n_{12}n_{21}) \end{aligned}$$

The classical Lefschetz fixed-point formula expresses $\mathcal{L}$ in terms of data for the fixed-point set $\mathcal{F}(T)$ and is an example of the equivariant index theorem. One assumes that the fixed-point set of $T$ consists of smooth submanifolds $N_1, \ldots, N_k$ and that the induced map $\mathrm{d}T_\nu$ on the normal bundles of these manifolds is nondegenerate. This means that $\det(I - \mathrm{d}T_\nu) \neq 0$, that is, that there are no infinitesimal normal directions which are left fixed. One then has

$$\mathcal{L}(T) = \sum_i \mathrm{sign}(\det(I - \mathrm{d}T_\nu))\chi(N_i)$$

### The Lefschetz Formula for the Other Classical Elliptic Complexes

Let $T$ be an orientation-preserving isometry of $M$. When dealing with the spin complex, suppose that $T$ preserves the spin structure; when dealing with the Dolbeault complex, suppose that $T$ preserves the holomorphic structure. If

$$A\,:\,C^\infty(V_1) \to C^\infty(V_2)$$

is one of the classical elliptic complexes, then by assumption $T^*$ commutes with $A$ and hence preserves the eigenspaces of the associated Laplacians. The Lefschetz number is defined by setting

$$\begin{aligned} \mathcal{L}_A(T) := &\,\mathrm{tr}(T^* \text{ on } \ker(A^*A)) \\ &- \mathrm{tr}(T^* \text{ on } \ker(AA^*)) \end{aligned}$$

Setting $T = \mathrm{Id}$, one recovers the standard index.

To simplify the discussion, we assume henceforth that $T$ is an orientation-preserving isometry of $M$ with only isolated fixed points. Let $\{\theta_1, \ldots, \theta_{m/2}\}$ be the rotation angles of $\mathrm{d}T$ at a fixed point $x$ of $T$. Set

$$\lambda_j := \cos(\theta_j) + \sqrt{-1}\sin(\theta_j)$$

We take the sum over the isolated fixed points $x$ and then the product over the rotation angles $1 \leq j \leq m/2$ to express

$$\mathcal{L}_{\text{sign}}(T) = \sum_x \prod_j \left\{ -\sqrt{-1}\cot\left(\frac{\theta_j}{2}\right) \right\}$$
$$\mathcal{L}_{\text{spin}}(T) = \sum_x \prod_j \left\{ -\frac{1}{2}\sqrt{-1}\csc\left(\frac{\theta_j}{2}\right) \right\}$$
$$\mathcal{L}_{\text{Dolb}}(T) = \sum_x \prod_j (1-\bar{\lambda}_j)^{-1}$$

In considering the spin complex, we assume $T$ preserves the spin structure. This permits us to lift $\mathrm{d}T$ from $\mathrm{SO}(m)$ to $\mathrm{Spin}(m)$ and defines liftings of the rotation angles $\theta_i$ from $[0, 2\pi]$ to $[0, 4\pi]$ in such a way that the formula given above for the spin complex is well defined. In considering the Dolbeault complex, we assume that $T$ preserves a complex structure, so the formula given above for the Dolbeault complex involving the complex eigenvalues $\lambda_j$ is well defined.

# Inequalities in Sobolev Spaces

**M Vaugon**, Université P.-M. Curie, Paris VI, Paris, France

## Introduction

Given $1 \leq p < n$, it was shown by Sobolev that there exists a constant $K > 0$ such that, for any $u \in C_0^\infty(\mathbb{R}^n)$, the space of smooth functions with compact support in $\mathbb{R}^n$,

$$\left(\int_{\mathbb{R}^n} |u|^{p^\star}\,\mathrm{d}x\right)^{1/p^\star} \leq K\left(\int_{\mathbb{R}^n} |\nabla u|^p\,\mathrm{d}x\right)^{1/p} \qquad [1]$$

where $\nabla u$ is the gradient of $u$ and $p^\star = np/(n-p)$. It is easily seen that $p^\star$ in [1] is critical in the following sense. Let $\|\cdot\|_p$ stand for the $L^p$-norm. For $u \in C_0^\infty(\mathbb{R}^n)$, and $\lambda > 0$, let also $u_\lambda$ be the function given by $u_\lambda(x) = u(\lambda x)$. For $p$ and $q$ two real numbers,

$$\|\nabla u_\lambda\|_p = \lambda^{1-(n/p)}\|\nabla u\|_p$$
$$\|u_\lambda\|_q = \lambda^{-n/q}\|u\|_q$$

Letting $\lambda \to 0$ and $\lambda \to +\infty$, it follows that an inequality like $\|u\|_q \leq K\|\nabla u\|_p$ holds true for all $u$ (in particular for the $u_\lambda$'s) only when $q = p^\star$. To

prove [1], the approach of Sobolev was based on the straightforward representation formula

$$u(x) = -\frac{\Gamma(n/2)}{2\pi^{n/2}}\int_{\mathbb{R}^n}\sum_{k=1}^{n}\frac{x^k - y^k}{|x-y|^n}\partial_k u(y)\mathrm{d}y$$

where $\Gamma$ is the Gamma function, and on an $n$-dimensional version of a theorem of Hardy–Littlewood concerning fractional integrals that we apply to the right-hand side of the above representation formula. More direct arguments were later discovered in independent works by Gagliardo and Nirenberg. In particular, the explicit inequality

$$\left(\int_{\mathbb{R}^n}|u|^{n/(n-1)}\mathrm{d}x\right)^{(n-1)/n} \le \frac{1}{2}\prod_{k=1}^{n}\left(\int_{\mathbb{R}^n}|D_k u|\mathrm{d}x\right)^{1/n} \le \frac{1}{2}\int_{\mathbb{R}^n}|\nabla u|\mathrm{d}x \quad [2]$$

was proved to hold, where $D_k$ is the partial derivative $D_k = \partial/\partial x_k$. Inequality [2] is of the form [1] when $p = 1$, since $1^\star = n/(n-1)$. By geometric measure theory, and the coarea formula, it can be expressed as an isoperimetric type inequality.

There have been several symbols and several definitions for Sobolev spaces. Before they became generally associated with the name of Sobolev, they were sometimes referred to by other names, for instance, as "Beppo Levi spaces." We often find two definitions and two notations in the literature. For $\Omega$ a domain in $\mathbb{R}^n, p \ge 1$ real, and $u$ of class $C^m$ in $\Omega$, we let

$$\|u\|_{m,p} = \left(\sum_{0\le|\alpha|\le m}\|D^\alpha u\|_p^p\right)^{1/p} \quad [3]$$

when the right-hand side makes sense, where $\|\cdot\|_p$ is the $L^p$-norm, $\alpha = (\alpha_1, \ldots, \alpha_n)$ is a multi-index, $|\alpha| = \sum_i \alpha_i$, and $D^\alpha = D_1^{\alpha_1}\cdots D_n^{\alpha_n}$. We define

$$H^{m,p}(\Omega) = \text{the completion of } \{u \in C^m(\Omega) \text{ s.t. } \|u\|_{m,p} < +\infty\} \text{ with respect to the norm } \|\cdot\|_{m,p}$$

$$W^{m,p}(\Omega) = \{u \in L^p(\Omega) \text{ s.t. } D^\alpha u \in L^p(\Omega) \text{ for all } 0 \le |\alpha| \le m\}$$

where $D^\alpha$ is the weak (or distributional) partial derivative of $u$ with respect to the multi-index $\alpha$. Both $H^{m,p}(\Omega)$ and $W^{m,p}(\Omega)$ are Banach spaces (and even Hilbert when $p = 2$). It is easily seen that $H^{m,p}(\Omega) \subset W^{m,p}(\Omega)$, but we had to wait for the work of Meyers and Serrin to realize that $H^{m,p}(\Omega) = W^{m,p}(\Omega)$. The spaces $H^{m,p}(\Omega)$, also denoted $W^{m,p}(\Omega)$, are referred to as Sobolev spaces. The spaces $H_0^{m,p}(\Omega)$, also denoted $W_0^{m,p}(\Omega)$, are defined as the closure of $C_0^\infty(\Omega)$ in $H^{m,p}(\Omega)$, where $C_0^\infty(\Omega)$ is the space of smooth functions with compact support in $\Omega$.

Inequality [1] states that the Sobolev space $H_0^{1,p}(\mathbb{R}^n)$ is naturally embedded in the Lebesgue space $L^{p^\star}(\mathbb{R}^n)$, a particular case of what we now refer to as Sobolev embeddings.

## Sobolev Inequalities and the Sobolev Embedding Theorem in Its First Part

Let $m$ be an integer and let $p \ge 1$ be real. The Sobolev space $H^{m,p}(\mathbb{R}^n)$, also denoted by $W^{m,p}(\mathbb{R}^n)$, is defined by in one of the two equivalent ways:

$$H^{m,p}(\mathbb{R}^n) = \text{the completion of } \{u \in C^m(\mathbb{R}^n) \text{ s.t. } \|u\|_{m,p} < +\infty\} \text{ with respect to the norm } \|\cdot\|_{m,p}$$

or

$$H^{m,p}(\mathbb{R}^n) = \{u \in L^p(\mathbb{R}^n) \text{ s.t. } D^\alpha u \in L^p(\mathbb{R}^n) \text{ for all } 0 \le |\alpha| \le m\}$$

where $D^\alpha$ is the weak (or distributional) partial derivative of $u$ with respect to the multi-index $\alpha$, and $\|\cdot\|_{m,p}$ is as in [3]. The Sobolev space $(H^{m,p}(\mathbb{R}^n), \|\cdot\|_{m,p})$ is a Banach space, and even a Hilbert space when $p = 2$. The space is reflexive when $p > 1$, and we also have that $H^{m,p}(\mathbb{R}^n) = H_0^{m,p}(\mathbb{R}^n)$, where $H_0^{m,p}(\mathbb{R}^n)$ is defined as the closure of $C_0^\infty(\mathbb{R}^n)$ in $H^{m,p}(\mathbb{R}^n)$. What we usually refer to as the first part of Sobolev inequalities can be expressed as follows.

**Sobolev embeddings** (*Part I*). For $p$, $q$ two real numbers with $1 \le q < p$, and $k$, $m$ two integers with $0 \le m < k$, if $1/p = 1/q - (k-m)/n$, then $H^{k,q} \subset H^{m,p}$, and there exists $K > 0$ such that $\|u\|_{m,p} \le K\|u\|_{k,q}$ for all $u \in H^{k,q}$.

The Sobolev theorem in its first part states that the above Sobolev embeddings (resp. inequalities) hold true for the Euclidean space. A particular case of interest is when $k = 1$. In this case, we get, as in the introduction, that for any $1 \le p < n, H^{1,p}(\mathbb{R}^n) \subset L^{p^\star}(\mathbb{R}^n)$ where $p^\star = np/(n-p)$. The embedding for the Euclidean space reduces to the Sobolev inequality [1]. An important remark is that there is a hierarchy for Sobolev embeddings. In particular, that if $H^{1,1} \subset L^{n/(n-1)}, 1^\star = n/(n-1)$, then all the other embeddings $H^{k,q} \subset H^{m,p}$ hold true. Thanks to this remark, the Sobolev embedding theorem for Euclidean space easily follows from an inequality like [2]. The hierarchy for Sobolev embeddings is an easy consequence of Hölder's inequalities when $k = 1$, and of Hölder's inequalities together with Kato's inequality when $k > 1$.

There are several extensions of Sobolev inequalities in the literature. Famous extensions were discovered by Gagliardo and Nirenberg. The Nash inequality, which reads as

$$\left(\int_{\mathbb{R}^n} u^2\,\mathrm{d}x\right)^{(n+2)/n} \le K\left(\int_{\mathbb{R}^n} |u|\,\mathrm{d}x\right)^{4/n} \times \int_{\mathbb{R}^n} |\nabla u|^2\,\mathrm{d}x \qquad [4]$$

for all $u \in H^{1,2}(\mathbb{R}^n)$, is one of the Gagliardo–Nirenberg's inequalities. The Nash inequality easily follows from [1] when $p=2$ and Hölder's inequality. There are also extensions of Sobolev spaces, for instance, spaces of BV-functions or Orlicz–Sobolev spaces.

## The Sobolev Embedding Theorem in Its Second Part

For $m$ integer, let $C_B^m(\mathbb{R}^n)$ be the space of functions of class $C^m$ in $\mathbb{R}^n$ for which the norm

$$\|u\|_{C^m} = \sum_{0\le|\alpha|\le m} \sup_{x\in\mathbb{R}^n} |D^\alpha u(x)|$$

is finite. What we usually refer to as the second part of Sobolev inequalities can be expressed as follows.

**Sobolev embeddings** (*Part II*). For $q \ge 1$ a real number, and $k$, $m$ two integers with $0 \le m < k$, if $1/q - (k-m)/n < 0$, then $H^{k,q} \subset C_B^m$, and there exists $K > 0$ such that $\|u\|_{C^m} \le K\|u\|_{k,q}$ for all $u \in H^{k,q}$.

The Sobolev theorem in its second part states that the above Sobolev embeddings (resp. inequalities) hold true for the Euclidean space. Refinements were then obtained by Morrey with embeddings in Hölder spaces. Let, for instance, $C^{0,\alpha}(\mathbb{R}^n)$ be the Hölder space of continuous functions in $\mathbb{R}^n$ for which the norm

$$\|u\|_{C^{0,\alpha}} = \sup_{x\in\mathbb{R}^n} |u(x)| + \sup_{x\ne y} \frac{|u(y)-u(x)|}{|y-x|^\alpha}$$

is finite. For $k=1, m=0$, and $q \ge 1$ such that $1/q - 1/n < 0$, the embedding $H^{1,q}(\mathbb{R}^n) \subset C_B^0(\mathbb{R}^n)$ can be refined into an embedding like $H^{1,q}(\mathbb{R}^n) \subset C^{0,\alpha}(\mathbb{R}^n)$, where $\alpha \in (0,1)$ is such that $1/q - (1-\alpha)/n < 0$.

## The Case of Domains and the Kondrakov Theorem

The Sobolev embeddings in their first and second parts extend to regular domains $\Omega$. A typical condition is that $\Omega$ satisfies a cone property. When $\Omega$ is bounded, and thus of finite volume, an embedding like $H^{1,p}(\Omega) \subset L^{p^\star}(\Omega)$ implies that we also have that $H^{1,p}(\Omega) \subset L^q(\Omega)$ for all $1 \le q \le p^\star$. The Kondrakov theorem states that such embeddings are all compact, unless $q = p^\star$, in the sense that bounded sequences of functions in $H^{1,p}$ possess converging subsequences in $L^q$.

For $p \ge 1$ real, the Sobolev embedding theorem in its first part provides embeddings of $H^{1,p}$ into Lebesgue spaces when $p < n$, while the Sobolev embedding theorem in its second part provides embeddings of $H^{1,p}$ into Hölder spaces when $p > n$. For $p = n$, it is false that $H^{1,n}$ can be embedded into $L^\infty$. However, when $\Omega$ is bounded, we can prove that $\exp(u) \in L^1(\Omega)$ when $u \in H_0^{1,n}(\Omega)$, and that

$$\int_\Omega \exp(u)\,\mathrm{d}x \le K\exp(\mu\|u\|_{1,n}^n)$$

where $\mu, K > 0$ are independent of $u$. We also have that

$$\int_\Omega \exp(\mu|u|^{n/(n-1)})\,\mathrm{d}x \le K$$

for all $u \in H_0^{1,n}(\Omega)$ such that $\|\nabla u\|_n \le 1$, where $\mu$, $K > 0$ are independent of $u$. Such inequalities are often referred to as Moser–Trüdinger type inequalities.

## The Case of Riemannian Manifolds

Riemannian manifolds are natural extensions of Euclidean space. For $(M, g)$ a Riemannian manifold, $m$ integer, and $p \ge 1$ real, we define the Sobolev space $H^{m,p}(M)$ by

$$H^{m,p}(M) = \text{the completion of } \{u \in C^m(M) \text{ s.t. } \|u\|_{m,p} < +\infty\} \text{ with respect to the norm } \|\cdot\|_{m,p}$$

where $\|u\|_{m,p} = \sum_{i=0}^m \|\nabla^i u\|_p$, $\nabla^i u$ is the $i$th covariant derivative of $u$, and $\|\cdot\|_p$ is the $L^p$-norm in $(M, g)$. A notation like $\|\nabla^i u\|_p$ stands for the $L^p$-norm of the pointwise norm $|\nabla^i u|$ of $\nabla^i u$. Sobolev spaces on manifolds are Banach spaces, even Hilbert when $p=2$, and they are reflexive when $p > 1$. They do not depend on the metric when $M$ is compact.

For compact Riemannian manifolds, everything works as for bounded domains. The Sobolev embeddings in their first and second parts remain valid. The Kondrakov theorem also remains valid. However, since constant functions are in Sobolev spaces when the manifold is compact, the $L^p$-norm of $u$ in the $H^{1,p}$-norm of $u$ should be added to the right-hand side in inequalities like [1]. More precisely, if $(M,g)$ is a compact Riemannian

manifold of dimension $n$, and $1 \leq p < n$, then the inequality for the embedding $H^{1,p}(M) \subset L^{p^\star}(M)$ reads as: there exists $K > 0$ such that for any $u \in H^{1,p}(M)$,

$$\left(\int_M |u|^{p^\star} dv_g\right)^{p/p^\star} \leq K\left(\int_M |\nabla u|^p dv_g + \int_M |u|^p dv_g\right) \quad [5]$$

where $dv_g$ is the Riemannian volume element with respect to $g$. When $(M, g)$ is no longer compact, the Sobolev embedding theorem might become false. A nontrivial key observation is that a Sobolev inequality like [5] on a complete manifold $(M, g)$ implies the existence of a uniform (with respect to the center) lower bound for the volume of balls of radius 1. It follows that for any $n \geq 2$, there exist complete Riemannian $n$-manifolds $(M, g)$ for which, for any $p \in [1, n), H^{1,p}(M) \not\subset L^{p^\star}(M)$. Possible examples are warped products of the real line $\mathbb{R}$ and the $(n-1)$-sphere $S^{n-1}$. When the Ricci curvature is bounded from below, the condition that there is a uniform (with respect to the center) lower bound for the volume of balls of radius 1 is necessary and sufficient in order to get that the Sobolev embeddings are valid.

## Isoperimetric and Euclidean Type Inequalities

Let $(M, g)$ be a complete Riemannian $n$-manifold. Euclidean type inequalities are said to hold on $(M, g)$ if there exists $K > 0$ such that for any $1 \leq p < n$, and any $u \in H^{1,p}(M)$,

$$\left(\int_M |u|^{p^\star} dv_g\right)^{1/p^\star} \leq K\left(\int_M |\nabla u|^p dv_g\right)^{1/p} \quad [6]$$

where $p^\star = np/n - p$. As for the Euclidean space, if the above inequality holds for some $p_0$, then it holds, with distinct $K$, for all $p_0 \leq p < n$. In particular, if the inequality holds for $p = 1$, it holds for all $p$'s. The inequality when $p = 1$ was shown to be true by Hoffman and Spruck when the manifold is simply connected of nonpositive sectional curvature. Such manifolds are referred to as Cartan–Hadamard manifolds. The inequality when $p = 2$ is related to the nonparabolicity of the manifold, namely the existence of a minimal Green's function, and to the behavior of the minimal Green's function.

By geometric measure theory and the coarea formula, [6] when $p = 1$ is equivalent to the isoperimetric inequality

$$\mathrm{Area}_g(\partial\Omega) \geq \frac{1}{C}\mathrm{Vol}_g(\Omega)^{(n-1)/n} \quad [7]$$

where $C > 0, \Omega$ is a smooth bounded domain in $M$, $\mathrm{Area}_g(\partial\Omega)$ is the volume of $\partial\Omega$ for the metric induced by $g$, and $\mathrm{Vol}_g(\Omega)$ is the volume of $\Omega$ with respect to $g$. Moreover, the constants $C$ and $K$ (for $p = 1$) are the same in the sense that if [6] for $p = 1$ holds with $K$, then [7] holds with $C = K$, and if [7] holds with $C$, then [6] for $p = 1$ holds with $K = C$.

The sharp constant for the isoperimetric inequality [7] in Euclidean space is known. When $n = 2$ its value is $C(2) = 1/(4\pi)$ and the sharp isoperimetric inequality is the well-known inequality $L^2 \geq 4\pi A$, where $A$ is the volume of a smooth bounded domain in $\mathbb{R}^2$, and $L$ is the length of its boundary. For arbitrary $n$, the sharp constant $C(n)$ for the isoperimetric inequality is given by

$$C(n) = \frac{1}{n}\left(\frac{n}{\omega_{n-1}}\right)^{1/n} \quad [8]$$

where $\omega_{n-1}$ is the volume of the unit $(n-1)$-sphere. Moreover, still for the Euclidean space, equality holds in the sharp isoperimetric inequality if and only if $\Omega$ is a ball. A famous conjecture concerning sharp isoperimetric inequalities, often referred to as the Cartan–Hadamard conjecture, is that the sharp isoperimetric inequality holds on Cartan–Hadamard manifolds. Thanks to works by Croke, Kleiner, and Weil, the conjecture is known to be true in dimensions 2, 3, and 4. From the Bishop–Gromov comparison theorem, we also get that the only complete manifold of non-negative Ricci curvature for which the sharp isoperimetric inequality holds is the Euclidean space itself.

The sharp constants $K = K(n, p)$ for [6] when $p > 1$ have been computed in Euclidean space by Aubin, Rodemich, and Talenti. The extremal functions were also computed, where, by definition, an extremal function is a function which realizes the case of equality in the inequality. We get that

$$K(n, p) = \frac{1}{n}\left(\frac{n(p-1)}{n-p}\right)^{(p-1)/p} \times \left(\frac{\Gamma(n+1)}{\Gamma(n/p)\Gamma(n+1-n/p)\omega_{n-1}}\right)^{1/n} \quad [9]$$

where, as above, $\Gamma$ is the gamma function. Moreover, $u$ is an extremal function for the sharp inequality in Euclidean space if and only if, up to a scale factor,

$$u(x) = \left(\frac{\mu}{\mu^2 + \frac{|x-a|^{p/(p-1)}}{n(n-2)}}\right)^{(n-p)/p} \quad [10]$$

for some $\mu > 0$, and $a \in \mathbb{R}^n$. When $p = 2$, the functions $u$ in [10] are both the only extremal functions for the sharp Sobolev inequality in Euclidean space, and the only positive solutions of the equation $\Delta u = u^{2^\star - 1}$ in $\mathbb{R}^n$, where $\Delta = -\sum_i D_i^2$ is the Laplace–Beltrami operator (the usual Laplacian with a minus sign in front of it). Sharp constants are also known for several of the Gagliardo–Nirenberg inequalities in Euclidean space. The sharp constant for the Nash inequality in Euclidean space was computed by Carlen and Loss. If the sharp isoperimetric inequality holds on a complete Riemannian $n$-manifold, then the sharp inequalities [6] hold for all $1 \le p < n$.

## Sharp Inequalities on Compact Riemannian Manifolds

The study of sharp Sobolev inequalities on compact manifolds if often referred to as the $AB$ program for Sobolev inequalities. For $(M, g)$ a compact Riemannian $n$-manifold, and $1 \le p < n$, [5] can be rewritten in two different forms:

$$\left(\int_M |u|^{p^\star} \mathrm{d}v_g\right)^{1/p^\star} \le A\left(\int_M |\nabla u|^p \mathrm{d}v_g\right)^{1/p} + B\left(\int_M |u|^p \mathrm{d}v_g\right)^{1/p} \qquad [11]$$

and

$$\left(\int_M |u|^{p^\star} \mathrm{d}v_g\right)^{p/p^\star} \le A' \int_M |\nabla u|^p \mathrm{d}v_g + B' \int_M |u|^p \mathrm{d}v_g \qquad [12]$$

where $A, B, A', B'$ are positive constants independent of $u$. An easy remark is that if [12] holds with constants $A'$ and $B'$, then [11] holds with $A = (A')^{1/p}$ and $B = (B')^{1/p}$. The sharp first (resp. second) constants in [11] and [12] are defined as the lowest possible values for $A$ and $A'$ (resp. for $B$ and $B'$) in [11] and [12]. The sharp first constants are independent of the manifold and are given by $A' = A^p = K(n, p)^p$, where $K(n, p)$ is as in [9]. The sharp second constants depend on the manifold and are given by $B' = B^p = V_g^{-p/n}$, where $V_g$ is the volume of $(M, g)$. A typical question in the $AB$ program is to know whether or not we can take $A$ or $B$ to be the sharp constants in [11] and, similarly, whether or not we can take $A'$ or $B'$ to be the sharp constants in [12]. Another typical question in the $AB$ program is whether or not there are nonzero extremal functions for the saturated form of the sharp inequalities when they are valid. Concerning the $B$-part of the program, the sharp inequality [11] with $B = V_g^{-1/n}$ is true on any manifold, and constant functions are extremal functions. On the other hand, it can be proved that the stronger [12] with $B' = V_g^{-p/n}$ is always false when $p > 2$, whatever the manifold. Concerning the $A$-part of the $AB$-program, Hebey and Vaugon proved that the sharp inequality [12] with $A' = K(n, 2)^2$ is true on any manifold. In other words, for any compact Riemannian manifold $(M, g)$ of dimension $n \ge 3$, there exists $B' > 0$ such that, for any $u \in H^{1,2}(M)$,

$$\left(\int_M |u|^{2^\star} \mathrm{d}v_g\right)^{2/2^\star} \le K(n, 2)^2 \int_M |\nabla u|^2 \mathrm{d}v_g + B' \int_M |u|^2 \mathrm{d}v_g \qquad [13]$$

We then get the saturated form of [13] by taking $B' = B'(g)$ to be the lowest possible $B'$ in [13]. In general, when $p \ne 2$, we can prove that the sharp inequality [11] with $A = K(n, p)$ is true on any manifold, and that there are nonzero extremal functions for the saturated form of the sharp inequality. On the other hand, the stronger [12] with $A' = K(n, p)^p$ when $p > 2$ is false when the curvature is positive, but true when the curvature is negative. The $p = 2$ case in the $A$-part of the $AB$ program is of importance for its connection with the Yamabe problem. The $p = 1$ case in the $A$-part of the $AB$ program is of importance for its connection with the isoperimetric inequality. The $AB$ program has also been considered for Gagliardo–Nirenberg inequalities, including the Nash inequality, and Sobolev–Poincaré inequalities on compact manifolds.

# Infinite-Dimensional Hamiltonian Systems

**R Schmid**, Emory University, Atlanta, GA, USA

## Introduction

Infinite-dimensional Hamiltonian systems arise in many areas in pure and applied mathematics and in mathematical physics. These are partial differential equations (PDEs) which can be written as evolution equations (dynamical systems) in the form

$$\dot{F} = \{F, H\}$$

where $H$ is the Hamiltonian ("energy") and $\{.,.\}$ is a Poisson bracket on an infinite-dimensional phase space, called Poisson manifold. Unlike finite-dimensional Hamiltonian systems, which are ordinary differential evolution equations on finite-dimensional phase spaces, for which general existence and uniqueness theorems for solutions exist, this is not the case for PDEs. There are no general existence and uniqueness theorems for solutions of infinite-dimensional Hamiltonian systems. These have to be established case by case. This article gives only a broad mathematical framework of infinite-dimensional Hamiltonian systems. Precise definitions are presented and the concept is illustrated through physical examples.

## Hamilton's Equations on Poisson Manifolds

A Poisson manifold is a manifold $P$ (in general infinite dimensional) equipped with a bilinear operation $\{.,.\}$, called Poisson bracket, on the space $C^\infty(P)$ of smooth functions on $P$ such that:

1. $(C^\infty(P), \{.,.\})$ is a Lie algebra, that is, $\{.,.\}: C^\infty(P) \times C^\infty(P) \to C^\infty(P)$ is bilinear, skew-symmetric and satisfies the Jacobi identity $\{\{F,G\},H\} + \{\{H,F\},G\} + \{\{G,H\},F\} = 0$ for all $F, G, H \in C^\infty(P)$ and
2. $\{.,.\}$ satisfies the Leibniz rule, that is, $\{.,.\}$ is a derivation in each factor: $\{F \cdot G, H\} = F \cdot \{G, H\} + G \cdot \{F, H\}$, for all $F, G, H \in C^\infty(P)$.

The notion of Poisson manifolds was rediscovered many times under different names, starting with Lie, Dirac, Pauli, and others. The name Poisson manifold was coined by Lichnerowicz.

For any $H \in C^\infty(P)$, the Hamiltonian vector field $X_H$ is defined by

$$X_H(F) = \{F, H\}, \quad F \in C^\infty(P)$$

It follows from (2) that, indeed, $X_H$ defines a derivation on $C^\infty(P)$, hence a vector field on $P$. Hamilton's equations of motion for a function $F \in C^\infty(P)$ with Hamiltonian $H$ (energy function) are then defined by the flow (integral curves) of the vector field $X_H$, that is,

$$\dot{F} = X_H(F) = \{F, H\} \qquad [1]$$

where the overdot implies differentiation with respect to time. $F$ is then called a Hamiltonian system on $P$ with energy (Hamiltonian function) $H$.

## Examples of Poisson Manifolds and Hamilton's Equations

### Finite-Dimensional Classical Mechanics

For finite-dimensional classical mechanics, we take $P = \mathbb{R}^{2n}$ and coordinates $(q^1, \ldots, q^n, p_1, \ldots, p_n)$ with the standard Poisson bracket for any two functions $F(q^i, p_i), H(q^i, p_i)$ given by

$$\{F, H\} = \sum_{i=1}^{n} \frac{\partial F}{\partial p_i}\frac{\partial H}{\partial q^i} - \frac{\partial H}{\partial p_i}\frac{\partial F}{\partial q^i} \qquad [2]$$

Then the classical Hamilton's equations are

$$\begin{aligned} \dot{q}^i &= \{q^i, H\} = \frac{\partial H}{\partial p_i} \\ \dot{p}_i &= \{p_i, H\} = -\frac{\partial H}{\partial q^i} \end{aligned} \qquad [3]$$

$i = 1, \ldots, n$. This finite-dimensional Hamiltonian system is a system of ordinary differential equations for which there are well-known existence and uniqueness theorems, that is, it has locally unique smooth solutions, depending smoothly on the initial conditions.

**Example: harmonic oscillator** As a concrete example, consider the harmonic oscillator: here $P = \mathbb{R}^2$ and the Hamiltonian (energy) is $H(q,p) = \frac{1}{2}(q^2 + p^2)$. Then Hamilton's equations are

$$\dot{q} = p, \qquad \dot{p} = -q \qquad [4]$$

### Infinite-Dimensional Classical Field Theory

Let $V$ be a Banach space and $V^*$ its dual space with respect to a pairing $\langle .,. \rangle : V \times V^* \to \mathbb{R}$ (i.e., $\langle .,. \rangle$ is a symmetric, bilinear, and nondegenerate function). On $P = V \times V^*$, the canonical Poisson

bracket for $F, H \in C^\infty(P)$, $\varphi \in V$, and $\pi \in V^*$ is given by

$$\{F,\, H\} = \left\langle \frac{\delta F}{\delta \pi}, \frac{\delta H}{\delta \varphi} \right\rangle - \left\langle \frac{\delta H}{\delta \pi}, \frac{\delta F}{\delta \varphi} \right\rangle \qquad [5]$$

where the functional derivatives $\delta F/\delta\pi \in V, \delta F/\delta\varphi \in V^*$ are the "duals" under the pairing $\langle .\,,.\rangle$ of the partial gradients $D_1F(\pi) \in V^*, D_2F(\varphi) \in V^{**} \simeq V$. The corresponding Hamilton's equations are

$$\begin{aligned} \dot\varphi &= \{\varphi,\, H\} = \frac{\delta H}{\delta \pi} \\ \dot\pi &= \{\pi,\, H\} = -\frac{\delta H}{\delta \varphi} \end{aligned} \qquad [6]$$

As a special case in finite dimensions, if $V \simeq \mathbb{R}^n$ so $V^* \simeq \mathbb{R}^n$ and $P = V \times V^* \simeq \mathbb{R}^{2n}$, and the pairing is the standard inner product in $\mathbb{R}^n$, then the Poisson bracket [5] and Hamilton's equations [6] are identical with [2] and [3], respectively.

**Example: wave equations** As a concrete example, consider the wave equations. Let $V = C^\infty(\mathbb{R}^3)$ and $V^* = \mathrm{Den}(\mathbb{R}^3)$ (densities) and the $L^2$ pairing $\langle\varphi, \pi\rangle = \int \varphi(x)\pi(x)\,\mathrm{d}x$. Take the Hamiltonian to be

$$H(\varphi,\, \pi) = \int \Big(\tfrac{1}{2}\pi^2 + \tfrac{1}{2}|\nabla\varphi|^2 + F(\varphi)\Big)\mathrm{d}x$$

where $F$ is some function on $V$. Then Hamilton's equations [6] become

$$\dot\varphi = \pi, \quad \dot\pi = \nabla^2\varphi - F'(\varphi) \qquad [7]$$

where the prime denotes differentiation with respect to $\varphi$, which imply the wave equation

$$\frac{\partial^2\varphi}{\partial t^2} = \nabla^2\varphi - F'(\varphi) \qquad [8]$$

Different choices of $F$ give different wave equations, for example, for $F = 0$ we get the linear wave equation

$$\frac{\partial^2\varphi}{\partial t^2} = \nabla^2\varphi$$

for $F = (1/2)m\varphi$, we get the Klein–Gordon equation

$$\nabla^2\varphi - \frac{\partial^2\varphi}{\partial t^2} = m\varphi$$

So, these wave equations and the Klein–Gordon equation are infinite-dimensional Hamiltonian systems on $P = C^\infty(\mathbb{R}^3) \times \mathrm{Den}\,(\mathbb{R}^3)$.

### Cotangent Bundles

The finite-dimensional examples of Poissson brackets [2] and Hamilton's equations [3] and the infinite-dimensional examples [5] and [6] are the local versions of the general case where $P = T^*Q$ is the cotangent bundle (phase space) of a manifold $Q$ (configuration space). If $Q$ in an $n$-dimensional manifold, then $T^*Q$ is a $2n$-Poisson manifold locally isomorphic to $\mathbb{R}^{2n}$ whose Poisson bracket is locally given by [2] and Hamilton's equations are locally given by [3]. If $Q$ is an infinite-dimensional Banach manifold, then $T^*Q$ is a Poisson manifold locally isomorphic to $V \times V^*$ whose Poisson bracket is given by [5] and Hamilton's equations are locally given by [6].

### Symplectic Manifolds

All the examples above are special cases of symplectic manifolds $(P, \omega)$. This means that $P$ is equipped with a symplectic structure $\omega$ which is a closed $(\mathrm{d}\omega = 0)$, (weakly) nondegenerate 2-form on the manifold $P$. Then, for any $H \in C^\infty(P)$, the corresponding Hamiltonian vector field $X_H$ is defined by $\mathrm{d}H = \omega(X_H,\, .)$ and the canonical Poisson bracket is given by

$$\{F, H\} = \omega(X_F, X_H), \quad F, H \in C^\infty(P) \qquad [9]$$

For example, on $\mathbb{R}^{2n}$ the canonical symplectic structure $\omega$ is given by $\omega = \sum_{i=1}^n \mathrm{d}p_i \wedge \mathrm{d}q^i = \mathrm{d}\theta$, where $\theta = \sum_{i=1}^n p_i \wedge \mathrm{d}q^i$. The same formula for $\omega$ holds locally in $T^*Q$ for any finite-dimensional $Q$ (Darboux's lemma). For the infinite-dimensional example $P = V \times V^*$, the symplectic form $\omega$ is given by $\omega((\varphi_1, \pi_1), (\varphi_2, \pi_2)) = \langle\varphi_1, \pi_2\rangle - \langle\varphi_2, \pi_1\rangle$. Again, these two formulas for $\omega$ are identical if $V = \mathbb{R}^n$.

#### Remarks

(i) If $P$ is a finite-dimensional symplectic manifold, then $P$ is even dimensional.
(ii) If the Poisson bracket $\{.\,,.\}$ is nondegenerate, then $\{.\,,.\}$ comes form a symplectic form $\omega$, that is, $\{.\,,.\}$ is given by [9].

### The Lie–Poisson Bracket

Not all Poisson brackets are of the from given in the above examples [2], [5], and [9], that is, not all Poisson manifolds are symplectic manifolds. An important class of Poisson bracket is the so-called Lie–Poisson bracket. It is defined on the dual of any Lie algebra. Let $G$ be a Lie group with Lie algebra $\mathfrak{g} = T_eG \simeq$ {left-invariant vector fields on $G$} and let $[.\,,.]$ denote the Lie bracket (commutator) on $\mathfrak{g}$. Let $\mathfrak{g}^*$ be the dual of a $\mathfrak{g}$ with respect to a pairing $\langle .\,,.\rangle : \mathfrak{g}^* \times \mathfrak{g} \to \mathbb{R}$. Then, for any $F, H \in C^\infty(\mathfrak{g}^*)$ and $\mu \in \mathfrak{g}^*$, the Lie–Poisson bracket is defined by

$$\{F, H\}(\mu) = \pm \left\langle \mu, \left[\frac{\delta F}{\delta\mu}, \frac{\delta H}{\delta\mu}\right] \right\rangle \qquad [10]$$

where $\delta F/\delta\mu, \delta H/\delta\mu \in \mathfrak{g}$ are the "duals" of the gradients $DF(\mu), DH(\mu) \in \mathfrak{g}^{**} \simeq \mathfrak{g}$ under the pairing $\langle .,. \rangle$. Note that the Lie–Poisson bracket is degenerate in general, for example, for $G = \mathrm{SO}(3)$ the vector space $\mathfrak{g}^*$ is three dimensional, so the Poisson bracket [10] cannot come from a symplectic structure. This Lie–Poisson bracket can also be obtained in a different way by taking the canonical Poisson bracket on $T^*G$ (locally given by [2] and [5] and then restrict it to the fiber at the identity $T_e^*G = \mathfrak{g}^*$. In this sense, the Lie–Poisson bracket [10] is induced from the canonical Poisson bracket on $T^*G$. It is induced by the symmetry of left-multiplication, as discussed in the next section.

**Example: rigid body** A concrete example of the Lie–Poisson bracket is given by the rigid body. Here $G = \mathrm{SO}(3)$ is the configuration space of a free rigid body. Identifying the Lie algebra $(\mathfrak{so}(3), [.,.])$ with $(\mathbb{R}^3, \times)$, where $\times$ is the vector product on $\mathbb{R}^3$ and $\mathfrak{g}^* = \mathfrak{so}(3)^* \simeq \mathbb{R}^3$, the Lie–Poisson bracket translates into

$$\{F, H\}(m) = -m \cdot (\nabla F \times \nabla H) \qquad [11]$$

For any $F \in C^\infty(\mathfrak{so}(3)^*)$, we have

$$\begin{aligned}\frac{\mathrm{d}F}{\mathrm{d}t}(m) &= \nabla F \cdot \dot{m} = \{F, H\}(m) \\ &= -m \cdot (\nabla F \times \nabla H) = \nabla F \cdot (m \times \nabla H)\end{aligned}$$

hence $\dot{m} = m \times \nabla H$. With the Hamiltonian

$$H = \frac{1}{2}\left(\frac{m_1^2}{I_1^2} + \frac{m_2^2}{I_2^2} + \frac{m_3^2}{I_3^2}\right)$$

we get Hamilton's equation as

$$\dot{m}_1 = \frac{I_2 - I_3}{I_2 I_3} m_2 m_3, \qquad \dot{m}_2 = \frac{I_3 - I_1}{I_3 I_1} m_3 m_1$$
$$\dot{m}_3 = \frac{I_1 - I_2}{I_1 I_2} m_1 m_2$$

These are Euler's equations for the free rigid body.

### Reduction by Symmetries

The examples discussed so far are all canonical examples of Poisson brackets, defined either on a symplectic manifold $(P, \omega)$ or $T^*Q$, or on the dual of a Lie algebra $\mathfrak{g}^*$. Different, noncanonical Poisson brackets can arise from symmetries. Assume that a Lie group $G$ is acting in a Hamiltonian way on the Poisson manifold $(P, \{..\})$. This means that we have a smooth map $\varphi : G \times P \to P : \varphi(g, p) = g \cdot p$ such that the induced maps $\varphi_g = \varphi(g, .) : P \to P$ are canonical transformations, for each $g \in G$. In terms of Poisson manifolds, a canonical transformation is a smooth map that preserves the Poisson bracket. So, the action of $G$ on $P$ is a Hamiltonian action if $\varphi_g^*\{F, H\} = \{\varphi_g^* F, \varphi_g^* H\}$ for all $F, H \in C^\infty(P)$, $g \in G$. For any $\xi \in \mathfrak{g}$, the canonical transformations $\varphi_{\exp(t\xi)}$ generate a Hamiltonian vector field $\xi_F$ on $P$ and a momentum map $J : P \to \mathfrak{g}^*$ given by $J(x)(\xi) = F(x)$, which is $\mathrm{Ad}^*$ equivariant.

If a Hamiltonian system $X_H$ is invariant under a Lie group action, that is, $H(\varphi_g(x)) = H(x)$, then we obtain a reduced Hamiltonian system on a reduced phace space (reduced Poisson manifold). We recall the Marsden–Weinstein reduction theorem:

**Reduction Theorem** *For a Hamiltonian action of a Lie group $G$ on a Poisson manifold $(P, \{.,.\})$, there is an equivariant momentum map $J : P \to \mathfrak{g}^*$, and for every regular $\mu \in \mathfrak{g}^*$ the reduced phase space $P_\mu \equiv J^{-1}(\mu)/G_\mu$ carries an induced Poisson structure $\{.,.\}_\mu$, ($G_\mu$ the isotropy group). Any $G$-invariant Hamiltonian $H$ on $P$ defines a Hamiltonian $H_\mu$ on the reduced phase space $P_\mu$ and the integral curves of the vector field $X_H$ project onto integral curves of the induced vector field $\hat{X}_{H_\mu}$ on the reduced space $P_\mu$.*

**Example: rigid body** The rigid body discussed above can be viewed as an example of this reduction theorem. If $P = T^*G$ and $G$ is acting on $T^*G$ by the cotangent lift of the left-translation $l_g : G \to G, l_g(h) = gh$, then the momentum map $J : T^*G \to \mathfrak{g}^*$ is given by $J(\alpha_g) = T_e^* R_g(\alpha_g)$ and the reduced phase space $(T^*G)_\mu = J^{-1}(\mu)/G_\mu$ is isomorphic to the coadjoint orbit $\mathcal{O}_\mu$ through $\mu \in \mathfrak{g}^*$. Each coadjoint orbit $\mathcal{O}_\mu$ carries a natural symplectic structure $\omega_\mu$ and in this case, the reduced Lie–Poisson bracket $\{.,.\}_\mu$ on the coadjoint orbit $\mathcal{O}_\mu$ is induced by the symplectic form $\omega_\mu$ on $\mathcal{O}_\mu$ as in [9]. Furthermore, $T^*G/G \simeq \mathfrak{g}^*$, and the induced Poisson bracket $\{.,.\}_\mu$ on $\mathcal{O}_\mu$ is identical with the Lie–Poisson bracket restricted to the coadjoint orbit $\mathcal{O}_\mu \subset \mathfrak{g}^*$. For the rigid body this construction is applied to $G = \mathrm{SO}(3)$.

We now discuss some infinite-dimensional examples of reduced Hamiltonian systems.

## Infinite-Dimensional Lie Groups

A general theory of infinite-dimensional Lie groups is hardly developed. Even Bourbaki only develops a theory of infinite-dimensional manifolds, but all of the important theorems about Lie groups are stated for finite-dimensional ones.

An infinite-dimensional Lie group $\mathcal{G}$ is a group and an infinite-dimensional manifold with smooth group operations

$$m : \mathcal{G} \times \mathcal{G} \to \mathcal{G}, \quad m(g, h) = g \cdot h, \qquad C^\infty \qquad [12]$$

$$i : \mathcal{G} \to \mathcal{G}, \quad i(g) = g^{-1}, \qquad C^\infty \qquad [13]$$

Such a Lie group $\mathcal{G}$ is locally diffeomorphic to an infinite-dimensional vector space. This can be a Banach space whose topology is given by a norm $\|\cdot\|$, a Hilbert space whose topology is given by an inner product $\langle.,.\rangle$, or a Frechet space whose topology is given by a metric but not by a norm. Depending on the choice of the topology on $\mathcal{G}$, the Banach, Hilbert, or Frechet Lie groups, respectively, can be treated.

The Lie algebra $\mathfrak{g}$ of $\mathcal{G}$ is defined as $\mathfrak{g} = \{\text{left-invariant vector fields on } \mathcal{G}\} \simeq T_e\mathcal{G}$, where the isomorphism is given (as in finite dimensions) by

$$\xi \in T_e\mathcal{G} \mapsto X^\xi(g) = T_e L_g(\xi) \qquad [14]$$

and the Lie bracket on $\mathfrak{g}$ is induced by the Lie bracket of left-invariant vector fields $[\xi, \eta] = [X^\xi, X^\eta](e)$, $\xi, \eta \in \mathfrak{g}$.

These definitions in infinite dimensions are identical with the definitions in finite dimensions. The big difference although is that infinite-dimensional manifolds, hence Lie groups, are not locally compact. For Frechet Lie groups, one has the additional nontrivial difficulty of defining the differentiability of functions defined on a Frechet space. Hence, the very definition of a Frechet manifold is not canonical. This problem does not arise for Banach and Hilbert Lie groups; the differential calculus extends in a straightforward manner from $\mathbb{R}^n$ to Banach and Hilbert spaces, but not to Frechet spaces.

## Finite- versus Infinite-Dimensional Lie Groups

The lack of local compactness of infinite-dimensional Lie groups causes some deficiencies of the Lie theory in infinite dimensions. Some classical results in finite dimensions are summarized below, which are not true in general in infinite dimensions:

1. The exponential map $exp : \mathfrak{g} \to G$ is defined as follows: To each $\xi \in \mathfrak{g}$ we assign the corresponding left-invariant vector field $X^\xi$ defined by [14]. We take the flow $\varphi^\xi(t)$ of $X^\xi$ and define $exp(\xi) = \varphi^\xi(1)$. The exponential map is a local diffeomorphism from a neighborhood of zero in $\mathfrak{g}$ onto a neighborhood of the identity in $G$; hence, $exp$ defines canonical coordinates on the Lie group $G$. This is not true in infinite dimensions.
2. If $f_1, f_2 : G_1 \to G_2$ are smooth Lie group homomorphisms (i.e., $f_i(g \cdot h) = f_i(g) \cdot f_i(h), i = 1, 2$) with $T_e f_1 = T_e f_2$, then locally $f_1 = f_2$. This is not true in infinite dimensions.
3. If $H$ is a closed subgroup of $G$, then $H$ is a Lie subgroup of $G$. This is not true in infinite dimensions.
4. For any finite-dimensional Lie algebra $\mathfrak{g}$, there exists a connected Lie group $G$ whose Lie algebra is $\mathfrak{g}$, that is, such that $\mathfrak{g} \simeq T_e G$. This is not true in infinite dimensions.

Some classical finite-dimensional examples of Lie groups are the matrix groups GL($n$), SL($n$), O($n$), SO($n$), U($n$), SU($n$), Sp($n$) with smooth group operations given by matrix multiplication and matrix inversion.

## Examples of Infinite-Dimensional Lie Groups

### Abelian Gauge Group $\mathcal{G} = (C^\infty(M), +)$

Let $M$ be a finite-dimensional manifold and let $\mathcal{G} = C^\infty(M)$. With group operation being addition, that is, $m(f, g) = f + g$, $i(f) = -f$, $e = 0$. $\mathcal{G}$ is an abelian $C^\infty$ Frechet Lie group with Lie algebra $\mathfrak{g} = T_e C^\infty(M) \simeq C^\infty(M)$, with trivial bracket $[\xi, \eta] = 0$, and $exp = \text{id}$. If one completes these spaces in the $C^k$-norm, $k < \infty$ then $\mathcal{G}^k$ is a Banach Lie group, and if the $H^s$-Sobolev norm is used with $s > (1/2) \dim M$ then $\mathcal{G}^s$ is a Hilbert Lie group.

**Application of $\mathcal{G} = (C^\infty(M), +)$ to Maxwell's equations** Let $E$, $B$ be the electric and magnetic fields on $\mathbb{R}^3$; then Maxwell's equations for a charge density $\rho$ are:

$$\dot{E} = \text{curl}\, B, \qquad \dot{B} = -\text{curl}\, E \qquad [15]$$

$$\text{div}\, B = 0, \qquad \text{div}\, E = \rho \qquad [16]$$

Let $A$ be the magnetic potential such that $B = -\text{curl}\, A$. As configuration space, we take $V = \text{Vec}(\mathbb{R}^3)$, vector fields (potentials) on $\mathbb{R}^3$, so $A \in V$, and as phase space, we have $P = T^*V \simeq V \times V^* \ni (A, E)$, with the standard $L^2$ pairing $\langle A, E \rangle = \int A(x)E(x)\, dx$, and canonical Poisson bracket given by [5], which becomes

$$\{F, H\}(A, E) = \int \left( \frac{\delta F}{\delta A} \frac{\delta H}{\delta E} - \frac{\delta H}{\delta A} \frac{\delta F}{\delta E} \right) dx \qquad [17]$$

As Hamiltonian, we take the total electromagnetic energy

$$H(A,\ E) = \frac{1}{2}\int (|\text{curl } A|^2 + |E|^2)\ \mathrm{d}x$$

Then Hamilton's equations in the canonical variables $A$ and $E$ are

$$\dot{A} = \frac{\delta H}{\delta E} = E \ \Rightarrow\ \dot{B} = -\text{curl}\, E$$

and

$$\dot{E} = -\frac{\delta H}{\delta A} = -\text{curl}\,\text{curl}\, A = \text{curl}\, B$$

So the first two equations of Maxwell's equations [15] are Hamilton's equations, the third one is obtained automatically from the potential $\text{div} B = -\text{div}\,\text{curl} A = 0$ and the fourth equation, $\text{div} E = \rho$, is obtained through the following symmetry (gauge invariance): the Lie group $\mathcal{G} = (C^\infty(\mathbb{R}^3), +)$ acts on $V$ by $\varphi\cdot A = A + \nabla\varphi, \varphi\in\mathcal{G}, A\in V$. The lifted action to $V\times V^*$ becomes $\varphi\cdot(A,E) = (A+\nabla\varphi, E)$, and has the momentum map $J: V\times V^* \to \mathfrak{g}^* \simeq$ {charge densities}

$$J(A,E) = \text{div}\, E \qquad [18]$$

With $\mathfrak{g} = C^\infty(\mathbb{R}^3)$ and $\mathfrak{g}^* = \text{Den}(\mathbb{R}^3)$, we identify the elements of $\mathfrak{g}^*$ with charge densities. The Hamiltonian $H$ is $\mathcal{G}$ invariant, that is, $H(\varphi\cdot(A,E)) = H(A+\nabla\varphi, E) = H(A,E)$. Then the reduced phase space for $\rho\in\mathfrak{g}^*$ is

$$(V\times V^*)_\rho = J^{-1}(\rho)/G = \{(E,\ B)|\text{div} E = \rho,\ \text{div} B = 0\}$$

and the reduced Hamiltonian is

$$H_\rho(E,\ B) = \frac{1}{2}\int (|E|^2 + |B|^2)\ \mathrm{d}x \qquad [19]$$

The reduced Poisson bracket becomes, for any functions $F$, $H$ on $(V\times V^*)_\rho$,

$$\{F,\ H\}_\rho(E,\ B) = \int\left(\frac{\delta F}{\delta E}\cdot\text{curl}\ \frac{\delta H}{\delta B} - \frac{\delta H}{\delta E}\cdot\text{curl}\ \frac{\delta F}{\delta B}\right)\mathrm{d}x \qquad [20]$$

and a straightforward computation shows that

$$\dot{F} = \{F,\ H_\rho\}_\rho \Leftrightarrow \begin{cases}\dot{E} = \text{curl}\, B, & \dot{B} = -\text{curl}\, E\\ \text{div}\, B = 0, & \text{div}\, E = \rho\end{cases} \qquad [21]$$

So, Maxwell's equations [15], [16] form an infinite-dimensional Hamiltonian system on this reduced phase space with respect to the reduced Poisson bracket.

### Abelian Gauge Group $\mathcal{G} = (C^\infty(M, \mathbb{R} - \{0\}), \cdot)$

Let $M$ be a finite-dimensional manifold and let $\mathcal{G} = C^\infty(M, \mathbb{R} - \{0\})$, the group operation being the multiplication, that is, $m(f,g) = f\cdot g$, $i(f) = f^{-1}$, $e = 1$. For $k < \infty$, $C^k(M, \mathbb{R} - \{0\})$ is open in $C^\infty(M, \mathbb{R})$, and if $M$ is compact then $C^k(M, \mathbb{R} - \{0\})$ is a Banach Lie group. If $s > (1/2)\dim M$ then $H^s(M, \mathbb{R} - \{0\})$ is closed under multiplication, and if $M$ is compact then $H^s(M, \mathbb{R} - \{0\})$ is a Hilbert Lie group.

### Nonabelian Gauge Groups $\mathcal{G} = (C^k(M, G), \cdot)$

The abelian example can be generalized by replacing $\mathbb{R} - \{0\}$ with any finite-dimensional (nonabelian) Lie group $G$. Let $\mathcal{G} = C^k(M, G)$ with pointwise group operations $m(f,g)(x) = f(x)\cdot g(x), x\in M$ and $i(f)(x) = (f(x))^{-1}$, where "$\cdot$" and "$(\,.\,)^{-1}$" are the operations in $G$. If $k < \infty$ then $C^k(M, G)$ is a Banach Lie group. Let $g$ denote the Lie algebra of $G$, then the Lie algebra of $\mathcal{G} = C^k(M, G)$ is $\mathfrak{g} = C^k(M, g)$, with pointwise Lie bracket $[\xi,\eta](x) = [\xi(x), \eta(x)], x\in M$, the latter bracket being the Lie bracket in $g$. The exponential map $exp: g\to G$ defines the exponential map $EXP: \mathfrak{g} = C^k(M, g)\to\mathcal{G} = C^k(M, G)$, $EXP(\xi) = exp\circ\xi$, which is a local diffeomorphism. The same holds for $H^s(M, G)$ if $s > (1/2)\dim M$.

Applications of these infinite-dimensional Lie groups are in gauge theories and quantum field theory, where they appear as groups of gauge transformations.

### Loop Groups $\mathcal{G} = C^k(S^1, G)$

As a special case of the example above, we take $M = S^1$, the circle. Then $\mathcal{G} = C^k(S^1, G) = \mathcal{L}^k(G)$ is called a loop group and $\mathfrak{g} = C^k(S^1, g) = l^k(g)$ its loop algebra. They find applications in the theory of affine Lie algebras, Kac–Moody Lie algebras (central extensions), completely integrable systems, soliton equations (Toda, Korteweg–de Vries (KdV), Kadomtsev–Petviashvili (KP)), quantum field theory. Central extensions of Loop algebras are examples of infinite-dimensional Lie algebras which need not have a corresponding Lie group.

### Diffeomorphism Groups

Among the most important "classical" infinite-dimensional Lie groups are the diffeomorphism groups of manifolds. Their differential structure is not the one of a Banch Lie group as defined above. Nevertheless, they have important applications.

Let $M$ be a compact manifold (the noncompact case is technically much more complicated but similar results are true) and let $\mathcal{G} = \text{Diff}^\infty(M)$ be the group of all smooth diffeomorphisms on $M$,

group operation being the composition, that is, $m(f,g)=f\circ g$, $i(f)=f^{-1}$, $e=\mathrm{id}_M$. For $C^\infty$ diffeomorphisms, $\mathrm{Diff}^\infty(M)$ is a Frechet manifold and there are nontrivial problems with the notion of smooth maps between Frechet spaces. There is no canonical extension of the differential calculus from Banach spaces (same as for $\mathbb{R}^n$) to Frechet spaces. One possibility is to generalize the notion of differentiability. For example, if we use the so-called $C^\infty_\Gamma$ differentiability, then $\mathcal{G}=\mathrm{Diff}^\infty(M)$ becomes a $C^\infty_\Gamma$ Lie group with $C^\infty_\Gamma$ differentiable group operations. These notions of differentiability are difficult to apply to concrete examples. Another possibility is to complete $\mathrm{Diff}^\infty(M)$ in the Banach $C^k$-norm, $0\le k<\infty$, or in the Sobolev $H^s$-norm, $s>(1/2)\dim M$; $\mathrm{Diff}^k(M)$ and $\mathrm{Diff}^s(M)$ become, in this case, Banach and Hilbert manifolds, respectively. Then we consider the inverse limits of these Banach and Hilbert Lie groups, respectively:

$$\mathrm{Diff}^\infty(M)=\varprojlim \mathrm{Diff}^k(M) \qquad [22]$$

becomes the so-called inverse limit of Banach (ILB) Lie group, or with the Sobolev topologies

$$\mathrm{Diff}^\infty(M)=\varprojlim \mathrm{Diff}^s(M) \qquad [23]$$

becomes the so-called inverse limit of Hilbert (ILH) Lie group. Nevertheless, the group operations are not smooth, but have the following differentiability properties. If the diffeomorphism group is equipped with the Sobolev $H^s$-topology, then $\mathrm{Diff}^s(M)$ becomes a $C^\infty$ Hilbert manifold if $s>(1/2)\dim M$ and the group multiplication

$$m:\mathrm{Diff}^{s+k}(M)\times\mathrm{Diff}^s(M)\to\mathrm{Diff}^s(M) \qquad [24]$$

is $C^k$ differentiable; hence, for $k=0$, $m$ is only continuous on $\mathrm{Diff}^s(M)$. The inversion

$$i:\mathrm{Diff}^{s+k}(M)\to\mathrm{Diff}^s(M) \qquad [25]$$

is $C^k$ differentiable; hence, for $k=0$, $i$ is only continuous on $\mathrm{Diff}^s(M)$. The same differentiability properties of $m$ and $i$ hold in the $C^k$ topology. This situation leads to the notion of nested Lie groups.

The Lie algebra of $\mathrm{Diff}^\infty(M)$ is given by $\mathfrak{g}=T_e\mathrm{Diff}^\infty(M)\simeq\mathrm{Vec}^\infty(M)$, the space of smooth vector fields on $M$. Note that the space $\mathrm{Vec}(M)$ of all vector fields is a Lie algebra only for $C^\infty$ vector fields, but not for $C^k$ or $H^s$ vector fields if $k<\infty$, $s<\infty$, because one loses derivatives by taking brackets.

The exponential map on the diffeomorphism group is given as follows: for any vector field $X\in\mathrm{Vec}^\infty(M)$ take its flow $\varphi_t\in\mathrm{Diff}^\infty(M)$, then define $EXP:\mathrm{Vec}^\infty(M)\to\mathrm{Diff}^\infty(M):X\mapsto\varphi_1$, the flow at time $t=1$. The exponential map $EXP$ is not a local diffeomorphism; it is not even locally surjective.

Applications of $\mathrm{Diff}^\infty(M)$ occur in general relativity, where the diffeomorphism group plays the role of a symmetry group of coordinate transformations. Let $(M,g)$ be a Lorentz 4-manifold. Then the vacuum Einstein's field equations are

$$\mathrm{Ric}(g)=0$$

These are invariant under coordinate transformations, that is, under the action of $\mathrm{Diff}^\infty(M)$. Moreover, Einstein's field equations form a Hamiltonian system on the space $P=\{\text{metrics on } M\}/\mathrm{Diff}^\infty(M)$.

### Subgroups of $\mathrm{Diff}^\infty(M)$

Several subgroups of $\mathrm{Diff}^\infty(M)$ have important applications.

**Group of volume-preserving diffeomorphisms** Let $\mu$ be a volume on $M$ and $\mathcal{G}=\mathrm{Diff}^\infty_\mu(M)=\{f\in\mathrm{Diff}^\infty(M)\,|\,f^*\mu=\mu\}$ the group of volume-preserving diffeomorphisms. $\mathrm{Diff}^\infty_\mu(M)$ is a closed subgroup of $\mathrm{Diff}^\infty(M)$ with Lie algebra $\mathfrak{g}=\mathrm{Vec}^\infty_\mu(M)=\{X\in\mathrm{Vec}^\infty(M)\,|\,\mathrm{div}_\mu X=0\}$ the space of divergence free vector fields on $M$. $\mathrm{Vec}^\infty_\mu(M)$ is a Lie subalgebra of $\mathrm{Vec}^\infty(M)$.

Remark: We can neither apply the finite-dimensional theorem that if $\mathrm{Vec}^\infty_\mu(M)$ is Lie algebra then there exists a Lie group whose Lie algebra it is; nor that if $\mathrm{Diff}^\infty_\mu(M)\subset\mathrm{Diff}(M)$ is a closed subgroup then it is a Lie subgroup.

Applications of $\mathrm{Diff}^\infty_\mu(M)$ occur, for example, in fluid dynamics. Euler's equations for an incompressible fluid,

$$\frac{\partial u}{\partial t}+u\cdot\nabla u=-\nabla p,\qquad \mathrm{div}\,u=0 \qquad [26]$$

are equivalent to the equations of geodesics on $\mathrm{Diff}^\infty_\mu(M)$.

**Symplectomorphism group** Let $\omega$ be a symplectic 2-from on $M$ and $\mathcal{G}=\mathrm{Diff}^\infty_\omega(M)=\{f\in\mathrm{Diff}^\infty(M)\,|\,f^*\omega=\omega\}$ the group of canonical transformations (or symplectomorphisms). $\mathrm{Diff}^\infty_\omega(M)$ is a closed subgroup of $\mathrm{Diff}^\infty(M)$ with Lie algebra $\mathfrak{g}=\mathrm{Vec}^\infty_\omega(M)=\{X\in\mathrm{Vec}^\infty(M)\,|\,L_X\omega=0\}$ the space of locally Hamiltonian vector fields on $M$. $\mathrm{Vec}^\infty_\omega(M)$ is a Lie subalgebra of $\mathrm{Vec}^\infty(M)$.

Applications of symplectomorphism groups occur, for example, in plasma physics. Maxwell–Vlasov's

equations for a plasma density $f(x, v, t)$ generating the electric and magnetic fields $E$ and $B$ are

$$\frac{\partial f}{\partial t} + v \cdot \frac{\partial f}{\partial x} + (E + v \times B)\frac{\partial f}{\partial v} = 0$$
$$\frac{\partial B}{\partial t} = -\mathrm{curl}\, E, \qquad \frac{\partial E}{\partial t} = \mathrm{curl}\, B - J_f \qquad [27]$$
$$\mathrm{div}\, E = \rho_f, \qquad \mathrm{div}\, B = 0$$

where $J_f$ and $\rho_f$ are the current and charge densities, respectively. This coupled nonlinear system of evolution equations is an infinite-dimensional Hamiltonian system of the form $\dot{F} = \{F, H\}_{\rho_f}$ on the reduced phace space

$$\mathcal{MV} = (T^*\mathrm{Diff}^{\infty}_{\omega}(\mathbb{R}^6) \times T^*V)/C^{\infty}(\mathbb{R}^6) \qquad [28]$$

($V$ is the same space as in the example of Maxwell's equations) with respect to the following reduced Poisson bracket, which is induced via gauge symmetry from the canonical Poisson bracket on $T^*\mathrm{Diff}^{\infty}_{\omega}(\mathbb{R}^6) \times T^*V$:

$$\begin{aligned}\{F, G\}_{\rho_f}(f, E, B) &= \int f\left\{\frac{\delta F}{\delta f}, \frac{\delta G}{\delta f}\right\}\mathrm{d}x\,\mathrm{d}v \\ &+ \int\left(\frac{\delta F}{\delta E}\cdot \mathrm{curl}\frac{\delta G}{\delta B} - \frac{\delta G}{\delta E}\cdot \mathrm{curl}\frac{\delta F}{\delta B}\right)\mathrm{d}x\,\mathrm{d}v \\ &+ \int\left(\frac{\delta F}{\delta E}\cdot\frac{\partial f}{\partial v}\frac{\delta G}{\delta f} - \frac{\delta G}{\delta E}\cdot\frac{\partial f}{\partial v}\frac{\delta F}{\delta f}\right)\mathrm{d}x\,\mathrm{d}v \\ &+ \int fB\cdot\left(\frac{\partial}{\partial v}\frac{\delta F}{\delta f}\times\frac{\partial}{\partial v}\frac{\delta G}{\delta f}\right)\mathrm{d}x\,\mathrm{d}v \qquad [29]\end{aligned}$$

and with Hamiltonian

$$H(f, E, B) = \frac{1}{2}\int v^2 f(x, v, t)\mathrm{d}v + \frac{1}{2}\int(|E|^2 + |B|^2)\mathrm{d}x \qquad [30]$$

More complicated plasma models are formulated as Hamiltonian systems. For example, for the two-fluid model the phase space is constituted by coadjoint orbits of the semidirect product ($\ltimes$) of the group $\mathcal{G} = \mathrm{Diff}^{\infty}(\mathbb{R}^6) \ltimes (C^{\infty}(\mathbb{R}^6) \times C^{\infty}(\mathbb{R}^6))$. For the MHD model: $\mathcal{G} = \mathrm{Diff}^{\infty}(\mathbb{R}^6) \ltimes (C^{\infty}(\mathbb{R}^6) \times \Omega^2(\mathbb{R}^3))$.

## The KdV Equation and Fourier Integral Operators

There are many known examples of PDEs which are infinite-dimensional Hamiltonian systems, such as the Benjamin–Ono, Boussinesq, Harry Dym, KdV, and KP equations and others. In many cases, the Poisson structures and Hamiltonians are given *ad hoc* on a formal level. This is illustrated here with the KdV equation, where at least one of the three known Hamiltonian structures is well understood.

The KdV equation

$$u_t + 6uu_x + u_{xxx} = 0 \qquad [31]$$

is an infinite-dimensional Hamiltonian system with the Lie group of invertible Fourier integral operators being a symmetry group. Gardner found that with the bracket

$$\{F, G\} = \int_0^{2\pi}\frac{\delta F}{\delta u}\frac{\partial}{\partial x}\frac{\delta G}{\delta u}\mathrm{d}x \qquad [32]$$

and Hamiltonian

$$H(u) = \int_0^{2\pi}\left(u^3 + \tfrac{1}{2}u_x^3\right)\mathrm{d}x \qquad [33]$$

$u$ satisfies the KdV equation [31] if and only if

$$\dot{u} = \{u, H\}$$

An important question concerns the origin of the Poisson bracket [32] and Hamiltonian [33]. It was shown earlier that this bracket is the Lie–Poisson bracket on a coadjoint orbit of Lie group $\mathcal{G} = \mathrm{FIO}$, the group of invertible Fourier integral operators on the circle $S^1$. The latter is discussed briefly in the following.

A Fourier integral operator on a compact manifold $M$ is an operator

$$A : C^{\infty}(M) \to C^{\infty}(M) \qquad [34]$$

locally given by

$$A(u)(x) = (2\pi)^{-n}\iint \mathrm{e}^{\mathrm{i}\varphi(x,y,\xi)}a(x, \xi)u(y)\mathrm{d}y\,\mathrm{d}\xi \qquad [35]$$

where $\varphi(x, y, \xi)$ is a phase function with certain properties and the symbol $a(x, \xi)$ belongs to a certain symbol class. A pseudodifferential operator is a special kind of Fourier integral operators, locally of the form

$$P(u)(x) = (2\pi)^{-n}\iint \mathrm{e}^{\mathrm{i}(x-y)\cdot\xi}p(x, \xi)u(y)\mathrm{d}y\,\mathrm{d}\xi \qquad [36]$$

Denote by FIO and ΨDO the groups under composition (operator product) of invertible Fourier integral operators and invertible pseudodifferential operators on $M$, respectively. Then we have the following results.

Both groups ΨDO and FIO are smooth infinite-dimensional ILH Lie groups. The smoothness properties of the group operations (operator multiplication and inversion) are similar to the case of diffeomorphism groups [24] and [25]. The Lie algebra of both ILH Lie groups ΨDO and FIO is the Lie algebra of all pseudodifferential operators under the commutator bracket. Moreover, FIO is a smooth infinite-dimensional principal fiber bundle

over the diffeomorphism group of canonical transformations $\mathrm{Diff}^{\infty}_{\omega}(T^*M - \{0\})$ with structure group (gauge group) $\Psi$DO.

For the KdV equation, we take the special case where $M = S^1$. Then the Gardner bracket [32] is the Lie–Poisson bracket on the coadjoint orbit of FIO through the Schrödinger operator $P \in \Psi\mathrm{DO}$. Complete integrability of the KdV equation follows from the infinite system of conserved integrals in involution given by $H_k = \mathrm{tr}(P^k)$; in particular, the Hamiltonian [33] equals $H = H_2$.

## Introduction

Let $X$ be a closed (connected, compact without boundary) smooth manifold of dimension 4, provided with a Riemannian metric denoted by $g$. Let $\Omega^p_X$ denote space of smooth $p$-forms on $X$, that is, the sections of $\wedge^p TX$. The Hodge operator acting on $p$-forms,

$$* : \Omega^p_X \to \Omega^{4-p}_X$$

satisfies $*^2 = (-1)^p$. In particular, $*$ splits $\Omega^2_X$ into two subspaces $\Omega^{2,\pm}_X$ with eigenvalues $\pm 1$:

$$\Omega^2_X = \Omega^{2,+}_X \oplus \Omega^{2,-}_X \qquad [1]$$

Note also that this decomposition is an orthogonal one, with respect to the inner product:

$$\langle \omega_1, \omega_2 \rangle = \int_X \omega_1 \wedge *\omega_2$$

A 2-form $\omega$ is said to be self-dual if $*\omega = \omega$ and it is said to be anti-self-dual if $*\omega = -\omega$. Any 2-form $\omega$ can be written as the sum

$$\omega = \omega^+ + \omega^-$$

of its self-dual $\omega^+$ and anti-self-dual $\omega^-$ components.

Now let $E$ be a complex vector bundle over $X$ as above, provided with a connection $\nabla$, regarded as a $\mathbb{C}$-linear operator

$$\nabla : \Gamma(E) \to \Gamma(E) \otimes \Omega^1_X$$

satisfying the Leibnitz rule:

$$\nabla(f\sigma) = f\nabla\sigma + \sigma \otimes \mathrm{d}f$$

for all $f \in C^\infty(X)$ and $\sigma \in \Gamma(E)$. Its curvature $F_\nabla = \nabla \circ \nabla$ is a 2-form with values in $\mathrm{End}(E)$, that is, $F_\nabla \in \Gamma(\mathrm{End}(E)) \otimes \Omega^2_X$, satisfying the Bianchi identity $\nabla F_\nabla = 0$.

The Yang–Mills equation is

$$\nabla * F_\nabla = 0 \qquad [2]$$

It is a second-order nonlinear equation on the connection $\nabla$. It amounts to a nonabelian generalization of Maxwell equations, to which it reduces when $E$ is a line bundle; the four components of $\nabla$ are interpreted as the electric and magnetic potentials.

An instanton on $E$ is a smooth connection $\nabla$ whose curvature $F_\nabla$ is anti-self-dual as a 2-form, that is, it satisfies:

$$F^+_\nabla = 0, \quad \text{that is,} \quad * F_\nabla = -F_\nabla \qquad [3]$$

The instanton equation is still nonlinear (it is linear only if $E$ is a line bundle), but it is only first-order on the connection.

Note that if $F_\nabla$ is either self-dual or anti-self-dual as a 2-form, then the Yang–Mills equation is automatically satisfied:

$$*F_\nabla = \pm F_\nabla \Rightarrow \nabla * F_\nabla = \pm \nabla F_\nabla = 0$$

by the Bianchi identity. In other words, instantons are particular solutions of the Yang–Mills equation. Furthermore, while the Yang–Mills equation [2] makes sense over any Riemannian manifold, the instanton equation [3] is well defined only in dimension 4.

A gauge transformation is a bundle automorphism $g : E \to E$ covering the identity. The set of all gauge transformations of a given bundle $E \to X$ forms a group through composition, called the gauge group and denoted by $\mathcal{G}(E)$. The gauge group acts on the set of all smooth connections on $E$ by conjugation:

$$g \cdot \nabla = g^{-1} \nabla g$$

It is then easy to see that [3] is a gauge-invariant condition, since $F_{g\cdot\nabla} = g^{-1} F_\nabla g$. The anti-self-duality equation [3] is also conformally invariant: a conformal change in the metric does not change the decomposition [1], so it preserves self-dual and anti-self-dual 2-forms.

The topological charge $k$ of the instanton $\nabla$ is defined by the integral

$$k = -\frac{1}{8\pi^2} \int_X \operatorname{tr}(F_\nabla \wedge F_\nabla) = c_2(E) - \frac{1}{2} c_1(E)^2 \qquad [4]$$

where the second equality follows from Chern–Weil theory.

If $X$ is a smooth, noncompact, complete Riemannian manifold, an instanton on $X$ is an anti-self-dual connection for which the integral [4] converges. Note that, in this case, $k$ as above need not be an integer; however, it is always expected to be quantized, that is, always a multiple of some fixed (rational) number which depends only on the base manifold $X$.

**Summary** This note is organized as follows. After revisiting the variational approach to the anti-self-duality equation [3], we study instantons over the simplest possible Riemannian 4-manifold, $\mathbb{R}^4$ with the flat Euclidean metric. In the subsequent sections, we present 't Hooft's explicit solutions, the ADHM construction, and its dimensional reductions to $\mathbb{R}^3, \mathbb{R}^2$ and $\mathbb{R}$. We conclude by explaining the construction of the central object of study in gauge theory, the instanton moduli spaces.

## Variational Aspects of Yang–Mills Equation

Given a fixed smooth vector bundle $E \to X$, let $\mathcal{A}(E)$ be the set of all (smooth) connections on $E$. The Yang–Mills functional is defined by

$$\mathrm{YM} : \mathcal{A}(E) \to \mathbb{R}$$
$$\mathrm{YM}(\nabla) = \|F_\nabla\|^2_{L^2} = \int_M \operatorname{tr}(F_\nabla \wedge *F_\nabla) \qquad [5]$$

The Euler–Lagrange equation for this functional is exactly the Yang–Mills equation [2]. In particular, self-dual and anti-self-dual connections yield critical points of the Yang–Mills functional.

Splitting the curvature into its self-dual and anti-self-dual parts, we have

$$\mathrm{YM}(\nabla) = \|F^+_\nabla\|^2_{L^2} + \|F^-_\nabla\|^2_{L^2}$$

It is then easy to see that every anti-self-dual connection $\nabla$ is an absolute minimum for the Yang–Mills functional, and that $\mathrm{YM}(\nabla)$ coincides with the topological charge [4] of the instanton $\nabla$ times $8\pi^2$.

One can construct, for various 4-manifolds but most interestingly for $X = S^4$, solutions of the Yang–Mills equations which are neither self-dual nor anti-self-dual. Such solutions do not minimize [5]. Indeed, at least for gauge group SU(2) or SU(3), it can be shown that there are no other local minima: any critical point which is neither self-dual nor anti-self-dual is unstable and must be a "saddle point" (Bourguignon and Lawson Jr. 1981).

## Instantons on Euclidean Space

Let $X = \mathbb{R}^4$ with the flat Euclidean metric, and consider a Hermitian vector bundle $E \to \mathbb{R}^4$. Any connection $\nabla$ on $E$ is of the form $d + A$, where $d$ denotes the usual de Rham operator and $A \in \Gamma(\mathrm{End}(E)) \otimes \Omega^1_{\mathbb{R}^4}$ is a 1-form with values in the endomorphisms of $E$; this can be written as follows:

$$A = \sum_{k=1}^{4} A_k \, \mathrm{d}x^k, \quad A_k : \mathbb{R}^4 \to \mathfrak{u}(r)$$

In the Euclidean coordinates $x_1, x_2, x_3, x_4$, the anti-self-duality equation [3] is given by

$$F_{12} = F_{34}, \quad F_{13} = -F_{24}, \quad F_{14} = F_{23}$$

where

$$F_{ij} = \frac{\partial A_j}{\partial x_i} - \frac{\partial A_i}{\partial x_j} + [A_i, A_j]$$

The simplest explicit solution is the charge-1 SU(2) instanton on $\mathbb{R}^4$. The connection 1-form is given by

$$A_0 = \frac{1}{1+|x|^2} \cdot \mathrm{Im}(q\,\mathrm{d}\bar{q}) \qquad [6]$$

where $q$ is the quaternion $q = x_1 + x_2\boldsymbol{i} + x_3\boldsymbol{j} + x_4\boldsymbol{k}$, while Im denotes the imaginary part of the product quaternion; we are regarding $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}$ as a basis of the Lie algebra $\mathfrak{su}(2)$; from this, one can compute the curvature:

$$F_{A_0} = \left(\frac{1}{1+|x|^2}\right)^2 \cdot \mathrm{Im}(\mathrm{d}q \wedge \mathrm{d}\bar{q}) \qquad [7]$$

We see that the action density function

$$|F_{A_0}|^2 = \left(\frac{1}{1+|x|^2}\right)^2$$

has a bell-shaped profile centered at the origin and decays like $r^{-4}$.

Let $t_{\lambda,y} : \mathbb{R}^4 \to \mathbb{R}^4$ be the isometry given by the composition of a translation by $y \in \mathbb{R}^4$ with a homothety by $\lambda \in \mathbb{R}^+$. The pullback connection $t^*_{\lambda,y}A_0$ is still anti-self-dual; more explicitly,

$$A_{\lambda,y} = t^*_{\lambda,y}A_0 = \frac{\lambda^2}{\lambda^2 + |x-y|^2} \cdot \mathrm{Im}(q\,\mathrm{d}\bar{q})$$

$$F_{A_{\lambda,y}} = \left(\frac{\lambda^2}{\lambda^2 + |x-y|^2}\right)^2 \cdot \mathrm{Im}(\mathrm{d}q \wedge \mathrm{d}\bar{q})$$

Note that the action density function $|F_A|^2$ has again a bell-shaped profile centered at $y$ and decays like $r^{-4}$; the parameter $\lambda$ measures the concentration of the energy density function, and can be interpreted as the "size" of the instanton $A_{\lambda,y}$.

Instantons of topological charge $k$ can be obtained by "superimposing" $k$ basic instantons, via the so-called 't Hooft ansatz. Consider the function $\rho : \mathbb{R}^4 \to \mathbb{R}$ given by

$$\rho(x) = 1 + \sum_{j=1}^{k} \frac{\lambda_j^2}{(x-y_j)^2}$$

where $\lambda_j \in \mathbb{R}$ and $y_j \in \mathbb{R}^4$. Then the connection 1-form $A = A_\mu \mathrm{d}x_\mu$ with coefficients

$$A_\mu = i \sum_{\nu=1}^{4} \bar{\sigma}_{\mu\nu} \frac{\partial}{\partial x_\nu} \ln(\rho(x)) \qquad [8]$$

is anti-self dual; here, $\bar{\sigma}_{\mu\nu}$ are the matrices given by ($\mu, \nu = 1, 2, 3$):

$$\sigma_{\mu\nu} = \frac{1}{4\mathrm{i}}[\sigma_\mu, \sigma_\nu] \qquad \bar{\sigma}_{\mu 4} = \frac{1}{2}\sigma_\mu$$

where $\sigma_\mu$ are the Pauli matrices.

The connection [8] correspond to $k$ instantons centered at points $y_i$ with size $\lambda_i$. The basic instanton [6] is exactly (modulo gauge transformation) what one obtains from [8] for the case $k = 1$. The 't Hooft instantons form a $5k$-parameter family of anti-self-dual connections.

SU(2) instantons are also the building blocks for instantons with general structure group (Bernard *et al.* 1977). Let $G$ be a compact semisimple Lie group, with Lie algebra $\mathfrak{g}$. Let $\phi : \mathfrak{su}(2) \to \mathfrak{g}$ be any injective Lie algebra homomorphism. If $A$ is an anti-self-dual SU(2) connection 1-form, then it is easy to see that $\phi(A)$ is an anti-self-dual $G$-connection 1-form. Using [8] as an example, we have that

$$A = \mathrm{i} \sum_{\mu,\nu} \phi(\bar{\sigma}_{\mu\nu}) \frac{\partial}{\partial x_\nu} \ln(\rho(x)) \mathrm{d}x_\mu \qquad [9]$$

is a $G$-instanton on $\mathbb{R}^4$.

While this guarantees the existence of $G$-instantons on $\mathbb{R}^4$, note that the instanton [9] might be reducible (e.g., $\phi$ can simply be the obvious inclusion of $\mathfrak{su}(2)$ into $\mathfrak{su}(n)$ for any $n$) and that its charge depends on the choice of representation $\phi$. Furthermore, it is not clear whether every $G$-instanton can be obtained in this way, as the inclusion of a SU(2) instanton through some representation $\phi : \mathfrak{su}(2) \to \mathfrak{g}$.

## The ADHM Construction

All SU($r$) instantons on $\mathbb{R}^4$ can be obtained through a remarkable construction due to Atiyah, Drinfeld, Hitchin, and Manin. It starts by considering Hermitian vector spaces $V$ and $W$ of dimension $c$ and $r$, respectively, and the following data (the so-called ADHM data):

$$B_1, B_2 \in \mathrm{End}(V), \;\; i \in \mathrm{Hom}(W, V)$$
$$j \in \mathrm{Hom}(V, W)$$

Assume, moreover, that $(B_1, B_2, i, j)$ satisfy the ADHM equations:

$$[B_1, B_2] + ij = 0 \qquad [10]$$

$$[B_1, B_1^\dagger] + [B_2, B_2^\dagger] + ii^\dagger - j^\dagger j = 0 \qquad [11]$$

Now consider the following maps

$$\alpha : V \times \mathbb{R}^4 \to (V \oplus V \oplus W) \times \mathbb{R}^4$$
$$\beta : (V \oplus V \oplus W) \times \mathbb{R}^4 \to V \times \mathbb{R}^4$$

given as follows (**1** denotes the appropriate identity matrix):

$$\alpha(z_1, z_2) = \begin{pmatrix} B_1 + z_1\mathbf{1} \\ B_2 + z_2\mathbf{1} \\ j \end{pmatrix} \qquad [12]$$

$$\beta(z_1, z_2) = (-B_2 - z_2\mathbf{1} \quad B_1 + z_1\mathbf{1} \quad \mathrm{i}) \qquad [13]$$

where $z_1 = x_1 + \mathrm{i}x_2$ and $z_2 = x_3 + \mathrm{i}x_4$ are complex coordinates on $\mathbb{R}^4$. The maps [12] and [13] should be understood as a family of linear maps parametrized by points in $\mathbb{R}^4$.

A straightforward calculation shows that the ADHM equation [10] implies that $\beta\alpha = 0$ for every $(z_1, z_2) \in \mathbb{R}^4$. Therefore, the quotient $E = \ker\beta/\mathrm{im}\,\alpha = \ker\beta \cap \ker\alpha^\dagger$ forms a complex vector bundle over $\mathbb{R}^4$ or rank $r$ whenever $(B_1, B_2, i, j)$ is such that $\alpha$ is injective and $\beta$ is surjective for every $(z_1, z_2) \in \mathbb{R}^4$.

To define a connection on $E$, note that $E$ can be regarded as a sub-bundle of the trivial bundle $(V \oplus V \oplus W) \times \mathbb{R}^4$. So let $\iota : E \to (V \oplus V \oplus W) \times \mathbb{R}^4$ be the inclusion, and let $P : (V \oplus V \oplus W) \times \mathbb{R}^4 \to E$ be the orthogonal projection onto $E$. We can then define a connection $\nabla$ on $E$ through the projection formula

$$\nabla s = P\underline{d}\iota(s)$$

where $\underline{d}$ denotes the trivial connection on the trivial bundle $(V \oplus V \oplus W) \times \mathbb{R}^4$.

To see that this connection is anti-self-dual, note that projection $P$ can be written as follows:

$$P = \mathbf{1} - \mathcal{D}^\dagger\Xi^{-1}\mathcal{D}$$

where

$$\mathcal{D} : (V \oplus V \oplus W) \times \mathbb{R}^4 \to (V \oplus V) \times \mathbb{R}^4$$
$$\mathcal{D} = \begin{pmatrix} \beta \\ \alpha^\dagger \end{pmatrix}$$

and $\Xi = \mathcal{D}\mathcal{D}^\dagger$. Note that $\mathcal{D}$ is surjective, so that $\Xi$ is indeed invertible. Moreover, it also follows from [11] that $\beta\beta^\dagger = \alpha^\dagger\alpha$, so that $\Xi^{-1} = (\beta\beta^\dagger)^{-1}\mathbf{1}$.

The curvature $F_\nabla$ is given by

$$\begin{aligned} F_\nabla &= P\Big(\underline{d}(\mathbf{1} - \mathcal{D}_\mathrm{I}^\dagger\Xi^{-1}\mathcal{D})\underline{d}\Big) = P\big(\underline{d}\mathcal{D}^\dagger\Xi^{-1}(\underline{d}\mathcal{D})\big) \\ &= P\big((\underline{d}\mathcal{D}^\dagger)\Xi^{-1}(\underline{d}\mathcal{D}) + \mathcal{D}^\dagger\underline{d}(\Xi^{-1}(\underline{d}\mathcal{D})\big) \\ &= (\underline{d}\mathcal{D}^\dagger)\Xi^{-1}(\underline{d}\mathcal{D}) \end{aligned}$$

for $P(\mathcal{D}^\dagger\underline{d}(\Xi^{-1}(\underline{d}\mathcal{D}))) = 0$ on $E = \ker\mathcal{D}$. Since $\Xi^{-1}$ is diagonal, we conclude that $F_\nabla$ is proportional to $d\mathcal{D}^\dagger \wedge d\mathcal{D}$, as a 2-form.

It is then a straightforward calculation to show that each entry of $d\mathcal{D}^\dagger \wedge d\mathcal{D}$ belongs to $\Omega^{2,-}$.

The extraordinary accomplishment of Atiyah, Drinfeld, Hitchin, and Manin was to show that every instanton, up to gauge equivalence, can be obtained in this way (see, e.g., Donaldson and Kronheimer 1990). For instance, the basic SU(2) instanton [6] is associated with the following data ($c = 1, r = 2$):

$$B_1, B_2 = 0, \quad i = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad j = (0 \quad 1)$$

**Remark** The ADHM data $(B_1, B_2, i, j)$ are said to be stable if $\beta$ is surjective for every $(z_1, z_2) \in \mathbb{R}^4$, and it is said to be costable if $\alpha$ is injective for every $(z_1, z_2) \in \mathbb{R}^4$. $(B_1, B_2, i, j)$ is regular if it is both stable and costable. The quotient:

$$\{\text{regular solutions of } (10) \text{ and } (11)\}/U(V)$$

coincides with the moduli space of instantons of rank $r = \dim W$ and charge $c = \dim V$ on $\mathbb{R}^4$ (see below). It is also an example of a quiver variety (*see* Finite Dimensional Algebras and Quivers), associated to the quiver consisting of two vertices $V$ and $W$, two loop-edges on the vertex $V$ and two edges linking $V$ to $W$, one in each direction.

## Dimensional Reductions of the Anti-Self-Dual Yang–Mills Equation

As pointed out above, a connection on a Hermitian vector bundle $E \to \mathbb{R}^4$ of rank $r$ can be regarded as 1-form

$$A = \sum_{k=1}^{4} A_k(x_1, \ldots, x_4)\mathrm{d}x^k, \quad A_k : \mathbb{R}^4 \to \mathfrak{u}(r)$$

Assuming that the connection components $A_k$ are invariant under translation in one direction, say $x_4$, we can think of

$$\underline{A} = \sum_{k=1}^{3} A_k(x_1, x_2, x_3)\mathrm{d}x^k$$

as a connection on a Hermitian vector bundle over $\mathbb{R}^3$, with the fourth component $\phi = A_4$ being regarded as a bundle endomorphism $\phi : E \to E$, called a Higgs field. In this way, the anti-self-duality equation [3] reduces to the so-called Bogomolny (or monopole) equation:

$$F_{\underline{A}} = *\mathrm{d}\phi \qquad [14]$$

where $*$ is the Euclidean Hodge star in dimension 3.

Now assume that the connection components $A_k$ are invariant under translation in two directions, say $x_3$ and $x_4$. Consider

$$\underline{A} = \sum_{k=1}^{2} A_k(x_1, x_2)\mathrm{d}x^k$$

as a connection on a Hermitian vector bundle over $\mathbb{R}^2$, with the third and fourth components combined into a complex bundle endomorphism:

$$\Phi = (A_3 + \mathrm{i} \cdot A_4)(\mathrm{d}x_1 - \mathrm{i} \cdot \mathrm{d}x_2)$$

taking values on 1-forms. The anti-self-duality equation [3] is then reduced to the so-called Hitchin's equations:

$$F_{\underline{A}} = [\Phi, \Phi^*], \qquad \bar{\partial}_{\underline{A}}\Phi = 0 \qquad [15]$$

Conformal invariance of the anti-self-duality equation means that Hitchin's equations are well defined over any Riemann surface.

Finally, assume that the connection components $A_k$ are invariant under translation in three directions, say $x_2, x_3$, and $x_4$. After gauging away the first component $A_1$, the anti-self-duality equations [3] reduce to the so-called Nahm's equations:

$$\frac{\mathrm{d}T_k}{\mathrm{d}x_1} + \frac{1}{2}\sum_{j,l} \epsilon_{kjl}[T_j, T_l] = 0, \quad j, k, l = \{2, 3, 4\} \quad [16]$$

where each $T_k$ is regarded as a map $\mathbb{R} \to \mathfrak{u}(r)$.

Readers who are interested in monopoles and Nahm's equations are referred to the survey by Murray (2002) and references therein. The best source for Hitchin's equations still are Hitchin's (1987a, b) original papers. A beautiful duality, known as Nahm transform, relates the various reductions of the anti-self-duality equation to periodic instantons; see the survey article by Jardim (2004).

It is also worth mentioning the book by Mason and Woodhouse (1996), where other interesting dimensional reductions of the anti-self-duality equation are discussed, providing a deep relation between instantons and the general theory of integrable systems.

## The Instanton Moduli Space

Now fix a rank-$r$ complex vector bundle $E$ over a four-dimensional Riemannian manifold $X$. Observe that the difference between any two connections is a linear operator:

$$(\nabla - \nabla')(f\sigma) = f\nabla\sigma + \sigma \cdot \mathrm{d}f - f\nabla'\sigma - \sigma \cdot \mathrm{d}f$$
$$= f(\nabla - \nabla')\sigma$$

In other words, any two connections on $E$ differ by an endomorphism-valued 1-form. Therefore, the set of all smooth connections on $E$, denoted by $\mathcal{A}(E)$, has the structure of an affine space over $\Gamma(\mathrm{End}(E)) \otimes \Omega^1_M$.

The gauge group $\mathcal{G}(E)$ acts on $\mathcal{A}(E)$ via conjugation:

$$g \cdot \nabla := g^{-1}\nabla g$$

We can form the quotient set $\mathcal{B}(E) = \mathcal{A}(E)/\mathcal{G}(E)$, which is the set of gauge equivalence classes of connections on $E$.

The set of gauge equivalence classes of anti-self-dual connections on $E$ is a subset of $\mathcal{B}(E)$, and it is called the moduli space of instantons on $E \to X$. The subset of $\mathcal{M}_X(E)$ consisting of irreducible anti-self-dual connections is denoted $\mathcal{M}^*_X(E)$.

Since the choice of a particular vector bundle within its topological class is immaterial, these sets are usually labeled by the topological invariants (Chern or Pontrjagyn classes) of the bundle $E$. For instance, $\mathcal{M}(r, k)$ denotes the moduli space of instantons on a rank-$r$ complex vector bundle $E \to X$ with $c_1(E) = 0$ and $c_2(E) = k > 0$. It turns out that $\mathcal{M}_X(E)$ can be given the structure of a Hausdorff topological space. In general, $\mathcal{M}_X(E)$ will be singular as a differentiable manifold, but $\mathcal{M}^*_X(E)$ can always be given the structure of a smooth Riemannian manifold.

We start by explaining the notion of a $L^2_p$ vector bundle. Recall that $L^2_p(\mathbb{R}^n)$ denotes the completion of the space of smooth functions $f : \mathbb{R}^n \to \mathbb{C}$ with respect to the norm:

$$\|f\|^2_{L^2_p} = \int_X (|f|^2 + |\mathrm{d}f|^2 + \cdots + |\mathrm{d}^{(p)}f|^2)$$

In dimension $n = 4$ and for $p > 2$, by virtue of the Sobolev embedding theorem, $L^2_p$ consists of continuous functions, i.e., $L^2_p(\mathbb{R}^n) \subset C^0(\mathbb{R}^n)$. So we define the notion of a $L^2_p$ vector bundle as a topological vector bundle whose transition functions are in $L^2_p$, where $p > 2$.

Now for a fixed $L^2_p$ vector bundle $E$ over $X$, we can consider the metric space $\mathcal{A}_p(E)$ of all connections on $E$ which can be represented locally on an open subset $U \subset X$ as a $L^2_p(U)$ 1-form. In this topology, the subset of irreducible connections $\mathcal{A}^*_p(E)$ becomes an open dense subset of $\mathcal{A}_p(E)$. Since any topological vector bundle admits a compatible smooth structure, we may regard $L^2_p$ connections as those that differ from a smooth connection by a $L^2_p$ 1-form. In other words, $\mathcal{A}_p(E)$ becomes an affine space modeled over the Hilbert space of $L^2_p$ 1-forms with values in the endomorphisms of $E$. The curvature of a connection in $\mathcal{A}_p(E)$ then becomes a $L^2_{p-1}$ 2-form with values in the endomorphism bundle $\mathrm{End}(E)$.

Moreover, let $\mathcal{G}_{p+1}(E)$ be defined as the topological group of all $L^2_{p+1}$ bundle automorphisms. By virtue of the Sobolev multiplication theorem, $\mathcal{G}_{p+1}(E)$ has the structure of an infinite-dimensional

Lie group modeled on a Hilbert space; its Lie algebra is the space of $L^2_{p+1}$ sections of End($E$).

The Sobolev multiplication theorem is once again invoked to guarantee that the action $\mathcal{G}_{p+1}(E) \times \mathcal{A}_p(E) \to \mathcal{A}_p(E)$ is a smooth map of Hilbert manifolds. The quotient space $\mathcal{B}_p(E) = \mathcal{A}_p(E)/\mathcal{G}_{p+1}(E)$ inherits a topological structure; it is a metric (hence Hausdorff) topological space. Therefore, the subspace $\mathcal{M}_X(E)$ of $\mathcal{B}_p(E)$ is also a Hausdorff topological space; moreover, one can show that the topology of $\mathcal{M}_X(E)$ does not depend on $p$.

The quotient space $\mathcal{B}_p(E)$ fails to be a Hilbert manifold because in general the action of $\mathcal{G}_{p+1}(E)$ on $\mathcal{A}_p(E)$ is not free. Indeed, if $A$ is a connection on a rank-$r$ complex vector bundle $E$ over a connected base manifold $X$, which is associated with a principal $G$-bundle. Then the isotropy group of $A$ within the gauge group

$$\Gamma_A = \{g \in \mathcal{G}_{p+1}(E) | g(A) = A\}$$

is isomorphic to the centralizer of the holonomy group of $A$ within $G$.

This means that the subspace of irreducible connections $\mathcal{A}^*_p(E)$ can be equivalently defined as the open dense subset of $\mathcal{A}_p(E)$ consisting of those connections whose isotropy group is minimal, that is,

$$\mathcal{A}^*_p(E) = \{A \in \mathcal{A}_p(E) | \Gamma_A = \text{center}(G)\}$$

Now $\mathcal{G}_{p+1}(E)$ acts with constant isotropy on $\mathcal{A}^*_p(E)$; hence, the quotient $\mathcal{B}^*_p(E) = \mathcal{A}^*_p(E)/\mathcal{G}_{p+1}(E)$ acquires the structure of a smooth Hilbert manifold.

**Remark** The analysis of neighborhoods of points in $\mathcal{B}_p(E) \backslash \mathcal{B}^*_p(E)$ is very relevant for applications of the instanton moduli spaces to differential topology. The simplest situation occurs when $A$ is an SU(2) connection on a rank-2 complex vector bundle $E$ which reduces to a pair of U(1) and such $[A]$ occurs as an isolated point in $\mathcal{B}_p(E) \backslash \mathcal{B}^*_p(E)$. Then a neighborhood of $[A]$ in $\mathcal{B}_p(E)$ looks like a cone on an infinite-dimensional complex projective space.

Alternatively, the instanton moduli space $\mathcal{M}_X(E)$ can also be described by first taking the subset of all anti-self-dual connections and then taking the quotient under the action of the gauge group. More precisely, consider the map

$$\begin{aligned} \rho : \mathcal{A}_p(E) &\to L^2_p(\text{End}(E) \otimes \Omega^{2,+}_X) \\ \rho(A) &= F^+_A \end{aligned} \qquad [17]$$

Thus, $\rho^{-1}(0)$ is exactly the set of all anti-self-dual connections. It is $\mathcal{G}_{p+1}(E)$-invariant, so we can take the quotient to get

$$\mathcal{M}_X(E) = \rho^{-1}(0)/\mathcal{G}_{p+1}(E)$$

It follows that the subspace $\mathcal{M}^*_X(E) = \mathcal{B}^*_p(E) \cap \mathcal{M}_X(E)$ has the structure of a smooth Hilbert manifold. Index theory comes into play to show that $\mathcal{M}^*_X(E)$ is finite dimensional. Recall that if $D$ is an elliptic operator on a vector bundle over a compact manifold, then $D$ is Fredholm (i.e., ker $D$ and coker $D$ are finite dimensional) and its index

$$\text{ind}\, D = \dim \ker D - \dim \text{coker}\, D$$

can be computed in terms of topological invariants, as prescribed by the Atiyah–Singer index theorem. The goal here is to identify the tangent space of $\mathcal{M}^*_X(E)$ with the kernel of an elliptic operator.

It is clear that, for each $A \in \mathcal{A}_p(E)$, the tangent space $T_A\mathcal{A}_p(E)$ is just $L^2_p(\text{End}(E) \otimes \Omega^1_X)$. We define the pairing

$$\langle a, b \rangle = \int_X a \wedge *b \qquad [18]$$

and it is easy to see that this pairing defines a Riemannian metric (the so-called $L^2$-metric) on $\mathcal{A}_p(E)$.

The derivative of the map $\rho$ in [17] at the point $A$ is given by

$$\begin{aligned} d^+_A : L^2_p(\text{End}(E) \otimes \Omega^1_X) &\to L^2_{p-1}(\text{End}(E) \otimes \Omega^2_X) \\ a &\mapsto (d_A a)^+ \end{aligned}$$

so that for each $A \in \rho^{-1}(0)$ we have

$$T_A\rho^{-1}(0) = \left\{ a \in L^2_p(\text{End}(E)) \otimes \Omega^1_X \,|\, d^+_A a = 0 \right\}$$

Now for a gauge equivalence class $[A] \in \mathcal{B}^*_p(E)$, the tangent space $T_{[A]}\mathcal{B}^*_p(E)$ consists of those 1-forms which are orthogonal to the fibers of the principal $\mathcal{G}_{p+1}(E)$ bundle $\mathcal{A}^*_p(E) \to \mathcal{B}^*_p(E)$. At a point $A \in \mathcal{A}_p(E)$, the derivative of the action by some $g \in \mathcal{G}_{p+1}(E)$ is

$$-d_A \,:\, L^2_{p+1}(\text{End}(E)) \to L^2_p(\text{End}(E) \otimes \Omega^1_X)$$

Usual Hodge decomposition gives us that there is an orthogonal decomposition:

$$L^2_p(\text{End}(E) \otimes \Omega^1_X) = \text{im}\, d_A \oplus \ker d^*_A$$

which means that:

$$T_{[A]}\mathcal{B}^*_p(E) = \left\{ a \in L^2_p(\text{End}(E) \otimes \Omega^1_X) \,|\, d^*_A a = 0 \right\}$$

Thus, the pairing [18] also defines a Riemannian metric on $\mathcal{B}^*_p(E)$. Putting these together, we conclude that the space $T_{[A]}\mathcal{M}^*_X$ tangent to $\mathcal{M}^*_X(E)$ at an equivalence class $[A]$ of anti-self-dual connections can be described as follows:

$$\begin{aligned} &T_{[A]}\mathcal{M}^*_X(E) \\ &\quad = \left\{ a \in L^2_p(\text{End}(E) \otimes \Omega^1_X) \,|\, d^*_A a = d^+_A a = 0 \right\} \end{aligned} \qquad [19]$$

It turns out that the so-called deformation operator $\delta_A = d_A^* \oplus d_A$:

$$\delta_A : L_p^2(\mathrm{End}(E) \otimes \Omega_X^1) \\ \rightarrow L_{p+1}^2(\mathrm{End}(E)) \oplus L_{p-1}^2(\mathrm{End}(E) \otimes \Omega_X^2)$$

is elliptic. Moreover, if $A$ is anti-self-dual then coker $\delta_A$ is empty, so that $T_{[A]}\mathcal{M}_X^*(E) = \ker \delta_A$. The dimension of the tangent space $T_{[A]}\mathcal{M}_X^*(E)$ is then simply given by the index of the deformation operator $\delta_A$. Using the Atiyah–Singer index theorem, we have for SU($r$) bundles with $c_2(E) = k$:

$$\dim \mathcal{M}_X^*(E) = 4rk - (r^2 - 1)(1 - b_1(X) + b_+(X))$$

The dimension formula for arbitrary gauge group $G$ can be found in Atiyah *et al.* (1978).

For example, the moduli space of SU(2) instantons on $\mathbb{R}^4$ of charge $k$ is a smooth Riemannian manifold of dimension $8k - 3$. These parameters are interpreted as the $5k$ parameters describing the positions and sizes of $k$ separate instantons, plus $3(k - 1)$ parameters describing their relative SU(2) phases.

The detailed construction of the instanton moduli spaces can be found in Donaldson and Kronheimer (1990). An alternative source is Morgan's lecture notes (Friedman and Morgan 1998). It is interesting to note that $\mathcal{M}_X^*(E)$ inherits many of the geometrical properties of the original manifold $X$. Most notably, if $X$ is a Kähler manifold, then $\mathcal{M}_X^*(E)$ is also Kähler; if $X$ is a hyper-Kähler manifold, then $\mathcal{M}_X^*(E)$ is also hyper-Kähler. One expects that other geometric structures on $X$ can also be transferred to the instanton moduli spaces $\mathcal{M}_X^*(E)$.

# Integrability and Quantum Field Theory

**T J Hollowood**, University of Wales Swansea, Swansea, UK

## Introduction

The notion of integrability plays many different rôles in quantum field theory (QFT). In this article we interpret it in a narrow sense and describe some QFTs that are completely integrable, in the sense that there are as many integrals of motion as degrees of freedom. Necessarily this implies, since we are talking about field theories, that there is an infinite number of conserved quantities. The existence of such a tower of conserved quantities of increasing Lorentz spin implies, via the Coleman–Mandula theorem, that the theories are trivial in spacetime dimensions greater than 2. On the other hand, in $1 + 1$ dimensions there is a rich menagerie of such integrable quantum field theories (IQFTs). These theories are fascinating in their own right as nontrivial QFTs for which data like the $S$-matrix and spectrum can be determined exactly. We will describe these exact $S$-matrices for a series of seminal examples. In addition, we briefly describe the applications of these theories to statistical systems in two dimensions.

## Classical Integrable Systems and Field Theories

For a field theory to be integrable it must have an infinite number of conserved charges. Necessarily these must be spacetime symmetries which extend the Poincaré symmetry in some way. It turns out that, due to a theorem of Coleman and Mandula, such

extensions are very restrictive: they are only possible in $1+1$ dimensions (one dimension of space and one of time) apart from noninteracting theories. Below we describe some of the most important examples.

### Affine Toda Theories

These theories describe the interactions of a set of scalar fields which we write as a vector $\boldsymbol{\phi}$. The action is

$$S = \int d^2x \left( \frac{1}{2} (\partial_\mu \boldsymbol{\phi})^2 - V(\boldsymbol{\phi}) \right) \qquad [1]$$

The potential has to be very specially chosen in order that the resulting theory is integrable. The resulting theories are classified by affine Lie algebras. We shall describe only the theories related to a simply laced Lie algebra $\mathfrak{g}$ (so of ADE type). In this case, for the affine version of the theory,

$$V(\boldsymbol{\phi}) = \frac{m^2}{\beta^2} \sum_{a=0}^{r} n_a \, e^{\beta \boldsymbol{\alpha}_a \cdot \boldsymbol{\phi}} \qquad [2]$$

where $\boldsymbol{\phi}$ is an $r$-rank $\mathfrak{g}$ vector and $\boldsymbol{\alpha}_a, a=1,\ldots,r$, are a set of simple roots of $\mathfrak{g}$. The fact that we are considering the affine version of the theory means that we include the term involving the extended root (the lowest root) $\boldsymbol{\alpha}_0 = -\sum_{a=1}^{r} n_a \boldsymbol{\alpha}_a$, which defines the integers $n_a (n_0 = 1)$. If this term is absent then the potential does not have a minimum. Such nonaffine theories are interesting in their own right since they include the Liouville theory, but we shall not describe them here.

One way to expose the infinite set of conserved charges at the classical level is to write the equations of motion in Lax form. This has the form of the vanishing of the field strength, or zero-curvature condition, of an auxiliary gauge connection in $\mathfrak{g}$ with components $(A_x, A_t)$:

$$\begin{aligned} A_x &= \partial_t \boldsymbol{\phi} \cdot \boldsymbol{H} + \frac{m}{2\beta} \sum_{a=0}^{r} e^{\beta \boldsymbol{\alpha}_a \cdot \boldsymbol{\phi}/2} (e_a + f_a) \\ A_t &= \partial_x \boldsymbol{\phi} \cdot \boldsymbol{H} + \frac{m}{2\beta} \sum_{a=0}^{r} e^{\beta \boldsymbol{\alpha}_a \cdot \boldsymbol{\phi}/2} (e_a - f_a) \end{aligned} \qquad [3]$$

Here, $\{e_i, f_i\}$ are related to generators of $\mathfrak{g}$ in a Cartan–Weyl basis, via

$$\begin{aligned} e_a &= z E_{\boldsymbol{\alpha}_a}, \quad f_a = z^{-1} E_{-\boldsymbol{\alpha}_a}, \qquad a = 1, \ldots, r \\ e_0 &= z^{-h} E_{\boldsymbol{\alpha}_0}, \qquad f_0 = z^h E_{-\boldsymbol{\alpha}_0} \end{aligned} \qquad [4]$$

where $z$ is a auxiliary variable known as the spectral parameter and $h$ is the Coxeter number of $\mathfrak{g}$. Using the following commutators of $\mathfrak{g}$,

$$\begin{aligned} [E_{\boldsymbol{\alpha}_a}, E_{\boldsymbol{\alpha}_b}] &= \delta_{ab} \boldsymbol{\alpha}_a \cdot \boldsymbol{H} \\ [\boldsymbol{H}, E_{\boldsymbol{\alpha}}] &= \boldsymbol{\alpha} E_{\boldsymbol{\alpha}} \\ [E_{\boldsymbol{\alpha}_a}, E_{-\boldsymbol{\alpha}_b}] &= 0 \end{aligned} \qquad [5]$$

it is straightforward to verify that the zero-curvature condition

$$F_{xt} = \partial_x A_t - \partial_t A_x + [A_x, A_t] = 0 \qquad [6]$$

is equivalent to the equations of motion which follow from extremizing the action [1].

The fact that there exists a flat connection which depends on an auxiliary parameter $z$ is sufficient to ensure integrability. In brief, the idea is that the gauge connection can be "abelianized" by a gauge transformation:

$$\tilde{A}_\mu = U \partial_\mu U^{-1} + U A_\mu U^{-1} \quad \text{with } [\tilde{A}_t, \tilde{A}_x] = 0 \qquad [7]$$

Hence, $\partial_t \tilde{A}_x - \partial_x \tilde{A}_t = 0$. This can be done in two inequivalent ways, such that $\tilde{A}_\mu$ are polynomials in $z$ and $z^{-1}$, respectively. The corresponding coefficients are then conserved currents whose integrals give conserved charges. It can be shown that for the Toda theories these conserved charges have Lorentz spin given by an exponent $\{s_a\}$ of $\mathfrak{g}$ modulo its Coxeter number $h$:

$$\begin{array}{lll} A_n: & h = n+1, & \{1,2,3,\ldots,n\} \\ D_n: & h = 2n-2, & \{1,3,5,\ldots,2n-3,n-1\} \\ E_6: & h = 12, & \{1,4,5,7,8,11\} \\ E_7: & h = 18, & \{1,5,7,9,11,13,17\} \\ E_8: & h = 30, & \{1,7,11,13,17,19,23,29\} \end{array} \qquad [8]$$

This spectrum of conserved quantities seems to be a ubiquitous feature of IQFTs. These theories can be generalized by replacing $\mathfrak{g}$, or rather its (untwisted affinization) with any affine algebra.

### The Sinh/Sine-Gordon Theory

These theories are the simplest of the Toda theories described above, associated to the Lie algebra $A_1$. In this case there is a single field and the potential has the form

$$V(\phi) = \frac{m^2}{2\beta^2} \left( e^{\beta\phi} + e^{-\beta\phi} \right) \qquad [9]$$

We have rescaled the field by $1/\sqrt{2}$ relative to the normalization in [2]. This potential defines the "sinh-Gordon theory." However, we can also take $\beta \to i\beta$ to give the sine-Gordon theory with an action

$$S = \int d^2x \left( \frac{1}{2} (\partial_\mu \phi)^2 + \frac{m^2}{\beta^2} \cos(\beta\phi) \right) \qquad [10]$$

The sine-Gordon theory is a useful paradigm for IQFTs because it exhibits most of the features of more complicated examples. To start with, it illustrates another important property of some integrable systems; namely, the existence of solitons. In the sine-Gordon case, the minima of the potential lie at $\phi = 2n\pi/\beta$, for an integer $n$, so there is a topological

kink that separates a vacuum $n$ on the left and $n+1$ on the right, as well as an antikink. The explicit solution for the kink moving with velocity $v$ is

$$\phi(x,t) = \frac{4}{\beta}\tan^{-1}\exp(m(x\cosh\theta - t\sinh\theta - \xi)) \quad [11]$$

where $\xi$ is a constant and, since we are working in $1+1$ dimensions, we have introduced the rapidity $\theta$, in terms of which the velocity is

$$v = \tanh\theta, \qquad -\infty \le \theta \le \infty \quad [12]$$

The antikink solution is simply the negative of the above. The kinks have a mass

$$M = \frac{8m}{\beta^2} \quad [13]$$

The existence of topological solitons is not a consequence of integrability, *per se*, for example, the $\phi^4$ theory in $1+1$ dimensions also has kinks; however, in the integrable setting, the solitons have special properties that survive in the quantum theory. The first property is that multisoliton solutions can be found exactly using a variety of different techniques. They are most easily written down using the tau function, which is related to the field via

$$\phi = -\frac{1}{i\beta}\log\frac{\tau}{\tau^*} \quad [14]$$

The $N$-soliton solution can then be written compactly as

$$\tau = \sum_{\{\mu_p\}=0,1}\exp\left(\sum_{p=1}^{N}\mu_p\Phi^{(p)} + \sum_{p,q=1}^{N}\mu_p\mu_q\Upsilon^{(pq)}\right) \quad [15]$$

The sum is over the $2^N$ possibilities for which $\mu_p = 0$ or 1, for each $p$, and we have introduced

$$\Phi^{(p)} = m(x\cosh\theta_p - t\sinh\theta_p - \xi_p) \pm \frac{i\pi}{2} \quad [16]$$

The rapidity of the $p$th soliton is $\theta_p$, and the choice of sign corresponds to the kink and antikink, respectively. The "interaction coefficient" is

$$\exp\Upsilon^{(pq)} = \tanh^2\left(\tfrac{1}{2}(\theta_p - \theta_q)\right) \quad [17]$$

For example, the two-soliton solution is

$$\tau = 1 + e^{\Phi^{(1)}} + e^{\Phi^{(2)}} + e^{\Upsilon+\Phi^{(1)}+\Phi^{(2)}} \quad [18]$$

The multisoliton solutions have a natural physical interpretation as the histories of a set of solitons which scatter off each other. To make this more precise, consider the two-soliton solution [18] in more detail. Suppose that $\xi_1 < \xi_2, v_1 > v_2$. Focus on the solution in the vicinity of the first soliton, that is,

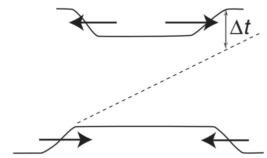

**Figure 1** Classical scattering of a kink and an antikink. The final velocities equal the initial velocities and the only effect is to introduce a velocity-dependent time delay as shown.

$x \sim v_1 t + \xi_1$. In the limit $t \to -\infty$, the solution is approximately

$$\tau \simeq 1 + e^{\Phi^{(1)}} \quad [19]$$

while, as $t \to \infty$, it is approximately

$$\tau \simeq e^{\Phi^{(2)}}\left(1 + e^{\Upsilon+\Phi^{(1)}}\right) \quad [20]$$

In both the limits, the solution represents an isolated soliton, the only difference is that the final "position offset" has been displaced: $\xi_1 \longmapsto \xi_1 - \Upsilon$. It is a consequence of integrability that the solitons interact in such a simple way. There were two solitons in the initial configuration and two in the final configuration traveling with the same velocities. The only effect is to introduce a time delay of

$$\Delta t = -\frac{\Upsilon(\theta)}{m\sinh(\theta/2)} \quad [21]$$

in the center-of-mass frame with $\theta_1 = -\theta_2 = \theta/2$, which we illustrate in Figure 1. We shall see that this kind of simple scattering is a characteristic feature of integrable field theories which extends to the quantum theory. It reflects the enormous restriction that the existence of the infinite set of integrals of motion puts on the dynamics.

## Integrability at the Quantum Level

In this section we turn to the particular implications of integrability for the field theories at the quantum level. In discussing theories in $1+1$ dimensions it is convenient, as in [12], to use the rapidity. The energy and momentum of a particle of mass $m$ are $E = m\cosh\theta$ and $p = m\sinh\theta$, respectively.

The sinh- and sine-Gordon theory, and their affine Toda generalizations, are scalar field theories with a well-behaved potential and as such they can be quantized in the conventional manner. It can be shown that integrability survives quantization and we now address its consequences. The key observation is that having an infinite set of higher-spin conserved quantities is very restrictive on the possible quantum processes. Assuming that the theory has a mass gap, the asymptotic states $|a,\theta\rangle$ are particles with rapidity

$\theta$ and additional quantum numbers needed to specify the state are indicated by the label $a$. These states are eigenstates of the conserved charges,

$$Q_s|a,\theta\rangle = q_s(a)e^{s\theta}|a,\theta\rangle \qquad [22]$$

Here, $s$ is the spin of the charge which ranges over some infinite subset of the integers. Since the charges must commute with the $S$-matrix, it follows immediately that if an incoming state of $n$ particles has a set of rapidities $\{\theta_1,\ldots,\theta_n\}$ then the outgoing state must also have $n$ particles with the same set $\{\theta_1,\ldots,\theta_n\}$: there is consequently no particle creation! For example, we have illustrated the scattering of two particles in Figure 2. The two-particle $S$-matrix element will be denoted as

$$S_{ab}^{cd}(\theta_1-\theta_2):\ |a,\theta_1;b,\theta_2\rangle \longrightarrow |c,\theta_2;d,\theta_1\rangle \qquad [23]$$

Note that masses of the incoming particles must match the outgoing ones: $m_a = m_d$ and $m_b = m_c$. We have already seen this kind of behavior with the classical scattering of solitons in the sine-Gordon theory. In spite of the fact that the scattering is purely elastic, it can be nontrivial for two reasons: if there are mass degeneracies in the theory, the quantum numbers $\{a_1,\ldots,a_n\}$ can change and, in addition, the $S$-matrix element can depend nontrivially on the momenta.

The fact that the incoming and outgoing states have the same set of momenta leads to the notion of factorizability. To see what this means, consider the case of three particles. Let us imagine that we prepare the initial state to consist of three fairly narrow wave packets in position space with momenta smeared in accordance with the uncertainty principle. The key to the following argument is the fact that the infinite set of higher-spin conserved charges (with commute with the $S$-matrix) allow one to move the positions of the three particles relative to each other in an arbitrary way. In addition, the theory has a mass gap, so interactions have a finite range. By using this freedom, we can arrange for particles 1 and 2 to interact first,

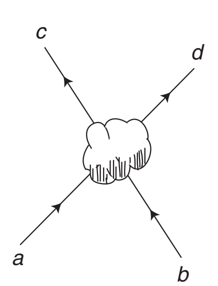

**Figure 2** The two particle $S$-matrix with particles $a$ and $b$ in the initial state and $c$ and $d$ in the final state. For consistency, $m_a = m_d$ and $m_b = m_c$.

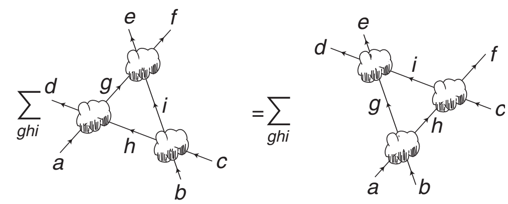

**Figure 3** The scattering of three particles can factorize in two distinct ways as illustrated, leading to a nontrivial condition: the Yang–Baxter equation.

well before they come within interaction range of the third. Subsequently, the first two particles interact with the third as on the right-hand side of Figure 3. This ability to move the wave packets around using the symmetries means that the three-particle $S$-matrix element must "factorize" into a product of three two-particle elements:

$$S_{abc}^{def}(\theta_1,\theta_2,\theta_3) = \sum_{ghi} S_{ab}^{gh}(\theta_1-\theta_2)S_{bc}^{if}(\theta_1-\theta_3)S_{gi}^{de}(\theta_2-\theta_3) \qquad [24]$$

However, we could also use the symmetries afforded by the conserved charges to shift the positions of the particles so that particle 2 and 3 interact first, as on the left-hand side of Figure 3. Since the charges commute with the $S$-matrix, the result must the same; hence, there is a nontrivial consistency condition:

$$\sum_{ghi} S_{bc}^{hi}(\theta_2-\theta_2)S_{ah}^{dg}(\theta_1-\theta_3)S_{gi}^{ef}(\theta_2-\theta_3) = \sum_{ghi} S_{ab}^{gh}(\theta_1-\theta_2)S_{bc}^{if}(\theta_1-\theta_3)S_{gi}^{de}(\theta_2-\theta_3) \qquad [25]$$

This is the celebrated Yang–Baxter equation. Notice that it is only nontrivial if there are mass degeneracies, otherwise the particles on internal lines are determined by the external particles.

The factorization of the $S$-matrix extends readily to the case of more particles in an obvious way. An $n$-body element factorizes into a two-body element for each pair of particles. One might think that considerations of the $n$-particle $S$-matrix would lead to additional constraints; however, it can readily be shown that this is not the case and that the Yang–Baxter equation acts as a basic "move" which allows one to reorder the $n$-particle $S$-matrix into an arbitrary order. Further conditions on the $S$-matrix come from the axioms of analytic $S$-matrix theory:

(i) *Unitarity*

$$\sum_{ef} S_{ab}^{ef}(\theta)S_{ef}^{cd}(-\theta) = \delta_{ac}\delta_{bd} \qquad [26]$$

(ii) *Crossing symmetry* Each particle $a$ has an antiparticle $\bar{a}$ and

$$S_{ab}^{cd}(\theta) = S_{b\bar{d}}^{\bar{a}c}(\pi i - \theta) \qquad [27]$$

(iii) *Analyticity* The $S$-matrix is a meromorphic function of $\theta$ on the physical strip, $0 \leq \mathrm{Im}\,\theta \leq \pi$. Singularities in most instances occur along the imaginary axis and the simple poles correspond to direct or cross-channel resonances. In this case, if $S_{ab}^{de}(\theta)$ has a simple pole at $\theta = \mathrm{i}u_{ab}^c$ (necessarily a nonphysical rapidity difference) in the direct channel there exists a bound state of $a$ and $b$ of mass

$$m_c^2 = m_a^2 + m_b^2 + 2m_a m_b \cos u_{ab}^c \qquad [28]$$

The situation is illustrated in Figure 4. The new particle must itself be included in the particle spectrum. The $S$-matrix elements at the pole have the form

$$S_{ab}^{de}(\theta) = \sum_c P_{ab}^c \frac{\mathrm{i}r_{ab}^c}{\theta - \mathrm{i}u_{ab}^c} P_{\bar{d}\bar{e}}^{\bar{c}} + \cdots \qquad [29]$$

where $P_{ab}^c$ can be thought of as a kind of projection operator with

$$\sum_{ab} P_{ab}^c P_{\bar{b}\bar{a}}^{\bar{d}} = \delta^{cd} \qquad [30]$$

Unitarity of the QFT requires that $r_{ab}^c$ is real and positive, although there are also examples of nonunitarity theories with exact $S$-matrices. If $ab \to c$ can occur then so can $a\bar{c} \to \bar{b}$ and $b\bar{c} \to \bar{a}$. From [28], we deduce the following identity:

$$u_{ab}^c + u_{a\bar{c}}^{\bar{b}} + u_{b\bar{c}}^{\bar{a}} = 2\pi \qquad [31]$$

The data $\{u_{ab}^c\}$ for any given scattering theory are known as the fusing angles.

(iv) *The Bootstrap equations* These give a nonlinear relation between $S$-matrix elements. The basic idea is that if particle $c$ appears as a resonance in the scattering of $a$ and $b$ then the $S$-matrix element of $c$ with another state $d$ can be deduced in terms of the scattering of $d$ with $a$ and $b$. This is illustrated in Figure 5. Using [30], we can write the resulting equation for the $S$-matrix element of $c$ and $d$ directly:

$$S_{cd}^{ef}(\theta) = \sum_{ghi} P_{\bar{a}\bar{b}}^{\bar{c}} S_{ab}^{eg}\left(\theta - \mathrm{i}\bar{u}_{a\bar{c}}^{\bar{b}}\right) S_{bd}^{hi}\left(\theta + \mathrm{i}\bar{u}_{b\bar{c}}^{\bar{a}}\right) P_{gi}^{f} \qquad [32]$$

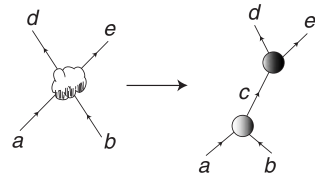

**Figure 4** Near a direct channel pole, the scattering of *a* and *b* is dominated by the bound state *c*.

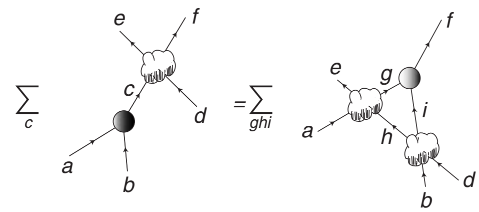

**Figure 5** The bootstrap equations result from considering the interaction of a particle *d* with the bound state *c* of *a* and *b* in two distinct ways as illustrated.

The bootstrap constraints are very powerful because they allow one to extract the $S$-matrix elements of new particles that appear as bound states. This leads to the philosophy of the “bootstrap program” where one attempts to build consistent $S$-matrices starting from the $S$-matrix for a subset of particles which act as a seed for the algorithm. The process is quite an art, but at the end one has to be satisfied that the complete analytic structure is consistent with all the axioms. The key is to be able to account for all the poles in a consistent way, either in terms of bound states, as above, or in terms of the Coleman–Thun mechanism. This allows some poles to be interpreted in ways other than the existence of a bound state. The bootstrap algorithm is very complicated in general and at the present time a complete classification of solutions is not known. However, there are a large number of known solutions which appear to be intimately related to Lie algebras and associated structures known as Yangians and quantum groups. Below we describe some of the simplest known solutions.

## Minimal *S*-Matrices

These scattering theories are in some sense the simplest. The particle spectrum is generally nondegenerate and so the Yang–Baxter equation is trivial. As is ubiquitous in the subject of IQFT, the classification of the theories is related to Lie algebras, although what seems to be important is not so much the algebra in question but rather the details of the associated root system. In this case the appropriate algebras are the simply laced algebras of ADE type. The number of particles is equal to the rank $r$ of the Lie algebra and the masses are given by the $r$ elements of one of the eigenvectors of the Cartan matrix of the algebra $\mathfrak{g}$:

$$\sum_{b=1}^{r} C_{ab} m_b = \left(2 - 2\cos\frac{\pi}{h}\right) m_a \qquad [33]$$

where $h$ is the Coxeter number of $\mathfrak{g}$. The conserved charges have spins corresponding to the exponents of $\mathfrak{g}$ modulo $h$. We briefly explain how the complete

$S$-matrix can be written down in terms of properties of the root system of $\mathfrak{g}$. Let $\boldsymbol{\Phi}$ be the set of roots of $\mathfrak{g}$, and $\boldsymbol{\alpha}_a, a=1,\ldots,r$, a set of simple roots, as in the last section. In terms of these, $C_{ab}=2\boldsymbol{\alpha}_a\cdot\boldsymbol{\alpha}_b/\boldsymbol{\alpha}_b^2$. Let $\boldsymbol{\omega}_a, a=1,\ldots,r$, be a corresponding set of fundamental weights, $\boldsymbol{\alpha}_a\cdot\boldsymbol{\omega}_b=\delta_{ab}$.

Key to defining the theories is the notation of the Weyl group of $\mathfrak{g}$, the group generated by reflections in the simple roots:

$$R_a(\boldsymbol{\alpha})=\boldsymbol{\alpha}-\frac{2\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}_a}{\boldsymbol{\alpha}_a^2}\boldsymbol{\alpha}_a \qquad [34]$$

The element $w=R_1R_2\cdots R_r$ is known as a Coxeter element of the Weyl group, and it has special properties that are significant in the present context. In particular, its eigenvalues are of the form $\exp(2\pi i s_a/h)$, where $h$ is the Coxeter number of $\mathfrak{g}$ and the integers $s_a$ are the exponents of the algebra as in [8]. Note that there is always a pair with $s_1=1$ and $s_r=h-1$. Clearly, $w$ acts as a rotation in the two-dimensional space spanned by the two corresponding eigenvectors. We can define an antisymmetric function $u(\boldsymbol{\alpha},\boldsymbol{\beta})$ on roots to be $h/\pi$ times the (signed) angle between the projections of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ onto this two-dimensional eigenspace. In preparation for what follows, it is useful to also define the roots

$$\boldsymbol{\phi}_a=R_rR_{r-1}\cdots R_{a+1}(\boldsymbol{\alpha}_a) \qquad [35]$$

We can now present P Dorey's amazingly compact formula for the complete $S$-matrix. For the scattering of particle $a$ with particle $b$,

$$S_{ab}(\theta)=\prod_{\boldsymbol{\beta}\in\Gamma_b}\{1+u(\boldsymbol{\phi}_a,\boldsymbol{\beta})\}^{\boldsymbol{\omega}_a\cdot\boldsymbol{\beta}} \qquad [36]$$

In this formula $\Gamma_b$ is the set of positive roots of $\mathfrak{g}$ which lie in the orbit of $\boldsymbol{\phi}_b$ under $w$. We have also defined the building block

$$\{x\}=(x+1)(x-1)$$
$$(x)=\frac{\sinh\left(\dfrac{\theta}{2}+\dfrac{i\pi x}{h}\right)}{\sinh\left(\dfrac{\theta}{2}-\dfrac{i\pi x}{h}\right)} \qquad [37]$$

The fusing rules are also particularly elegant in the language of root systems. There is a three-point coupling between $a_i, i=1,2,3$, if there exist three roots $\boldsymbol{\alpha}^{(i)}\in\Gamma_{a_i}$ such that $\boldsymbol{\alpha}^{(1)}+\boldsymbol{\alpha}^{(2)}+\boldsymbol{\alpha}^{(3)}=0$. Furthermore, the fusing occurs in the $a_1, a_2$ channel at rapidity difference

$$iu_{a_1a_2}^{\bar{a}_3}=\frac{i\pi}{h}u(\boldsymbol{\alpha}^{(1)},\boldsymbol{\alpha}^{(2)}) \qquad [38]$$

This is Dorey's fusing rule.

For the case of $A_{n-1}$, the $S$-matrices are particularly simple. The mass spectrum is

$$m_a=m\sin\frac{\pi a}{n}, \quad a=1,\ldots,n-1 \qquad [39]$$

and Dorey's rule gives the possible fusings as $ab\to(a+b)\mathrm{mod}\ n$, which occur at the rapidity values

$$\theta=iu_{ab}=\begin{cases} i\dfrac{a+b}{n}\pi & a+b<n \\ i\left(2-\dfrac{a+b}{n}\right)\pi & a+b\geq n \end{cases} \qquad [40]$$

The charge conjugation operator maps $a\to\bar{a}=n-a$ and the explicit form for the $S$-matrix elements is

$$S_{ab}(\theta)=\{a+b-1\}\{a+b-3\}\cdots\{|a-b|+1\} \qquad [41]$$

The element $S_{ab}(\theta)$ has one direct channel pole at $\theta=iu_{ab}$ corresponding to the exchange of the particle $a+b \bmod n$, and a cross-channel pole at $\theta=iu_{a\bar{b}}$ corresponding to the exchange of particle $a-b \bmod n$.

## Affine Toda Theories

The bootstrap program has been solved for all the affine Toda theories. For the simply laced theories described earlier, the result is directly related to the minimal $S$-matrices constructed above. The only difference is that there are additional factors which depend on the coupling $\beta$ of the Toda theory but which do not introduce any additional poles onto the physical strip. These CDD factors are included by simply changing the basic building block [37]:

$$\{x\}\to\{x\}_{\mathrm{Toda}}=\frac{(x+1)(x-1)}{(x-1+B)(x+1-B)} \qquad [42]$$

where

$$B=\frac{1}{2\pi}\cdot\frac{\beta^2}{1+\beta^2/4\pi} \qquad [43]$$

The $S$-matrix structure for the Toda theories based on the nonsimply laced algebras is a good deal more complicated. Integrability is only maintained in the quantum theory if the ratios of the physical masses of the particles depend on the coupling constant $\beta$ is some very special way.

## The Sine-Gordon Theory

We have seen that the sine-Gordon theory has solitons at the classical level. At the quantum level,

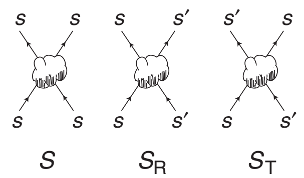

**Figure 6** Soliton scattering processes. *s* and *s*′ are the kink and antikink, respectively, or vice versa.

we expect that these kinks become *bona fide* particle states, in addition to the particle corresponding to the quantum fluctuations of the field $\phi$. Focusing on the solitons, we expect a degenerate doublet corresponding to the kink and antikink. For the scattering of two solitons, there are six allowed processes illustrated in **Figure 6**. Unitarity [26] leads to the constraints

$$\begin{aligned} &S(\theta)S(-\theta) = 1 \\ &S_{\mathrm{T}}(\theta)S_T(-\theta) + S_{\mathrm{R}}(\theta)S_{\mathrm{R}}(-\theta) = 1 \\ &S_{\mathrm{T}}(\theta)S_{\mathrm{R}}(-\theta) + S_{\mathrm{R}}(\theta)S_{\mathrm{T}}(-\theta) = 0 \end{aligned} \qquad [44]$$

while crossing symmetry [27] (using the fact that the soliton and antisoliton are antiparticles) gives

$$S(\mathrm{i}\pi-\theta) = S_T(\theta), \qquad S_{\mathrm{R}}(\mathrm{i}\pi-\theta) = S_R(\theta) \qquad [45]$$

By themselves, these constraints are rather mild; however, the complete soliton *S*-matrix must also satisfy the Yang–Baxter equation [25]. The solution to all the constraints is not unique, however, the Zamolodchikovs conjectured that the exact answer is

$$\begin{aligned} S(\theta) &= \frac{1}{\mathrm{i}\pi}\sinh\left(\frac{8\pi}{\gamma}(\mathrm{i}\pi-\theta)\right)U(\theta) \\ S_{\mathrm{T}}(\theta) &= \frac{1}{\mathrm{i}\pi}\sinh\left(\frac{8\pi}{\gamma}\theta\right)U(\theta) \\ S_{\mathrm{R}}(\theta) &= \frac{1}{\pi}\sin\left(\frac{8\pi^2}{\gamma}\right)U(\theta) \end{aligned} \qquad [46]$$

with

$$\begin{aligned} U(\theta) &= \Gamma\left(\frac{8\pi}{\gamma}\right)\Gamma\left(1+\mathrm{i}\frac{8\theta}{\gamma}\right)\Gamma\left(1-\frac{8\pi}{\gamma}-\mathrm{i}\frac{8\theta}{\gamma}\right) \\ &\quad\times\prod_{n=1}^{\infty}\frac{R_n(\theta)R(\mathrm{i}\pi-\theta)}{R_n(0)R_n(\mathrm{i}\pi)} \\ R_n(\theta) &= \frac{\Gamma\left(2n\frac{8\pi}{\gamma}+\mathrm{i}\frac{8\theta}{\gamma}\right)}{\Gamma\left((2n+1)\frac{8\pi}{\gamma}+\mathrm{i}\frac{8\theta}{\gamma}\right)} \\ &\quad\times\frac{\Gamma\left(1+2n\frac{8\pi}{\gamma}+\mathrm{i}\frac{8\theta}{\gamma}\right)}{\Gamma\left(1+(2n-1)\frac{8\pi}{\gamma}+\mathrm{i}\frac{8\theta}{\gamma}\right)} \end{aligned} \qquad [47]$$

where $\gamma = \beta^2(1-\beta^2/8\pi)^{-1}$. The reason for confidence in the conjecture is that from the soliton *S*-matrix one can complete the bootstrap program and account for all the poles in terms of particles in the theory. In particular, there is a finite set of bound states of the soliton and antisoliton, called breathers, with masses

$$m_k = 2M\sin\frac{k\gamma}{16}, \quad k = 1,2,\ldots < \frac{8\pi}{\gamma} \qquad [48]$$

Here, $M$ is the soliton mass. The bootstrap equations give the *S*-matrix for the scattering of a soliton or antisoliton with the $k$th breather,

$$S_k(\theta) = \frac{\sinh\theta+\mathrm{i}\cos\frac{k\gamma}{16}}{\sinh\theta-\mathrm{i}\cos\frac{k\gamma}{16}} \times\prod_{j=1}^{k-1}\frac{\sin^2\left(\frac{k-2j}{32}\gamma-\frac{\pi}{4}+\mathrm{i}\frac{\theta}{2}\right)}{\sin^2\left(\frac{k-2j}{32}\gamma-\frac{\pi}{4}-\mathrm{i}\frac{\theta}{2}\right)} \qquad [49]$$

while, for the scattering of breather $k$ with $l$,

$$S_{kl}(\theta) = \frac{\sinh^2\theta+\mathrm{i}\sin\left(\frac{k+l}{16}\gamma\right)\sinh\theta+\mathrm{i}\sin\left(\frac{k-l}{16}\gamma\right)}{\sinh^2\theta-\mathrm{i}\sin\left(\frac{k+l}{16}\gamma\right)\sinh\theta-\mathrm{i}\sin\left(\frac{k-l}{16}\gamma\right)} \times\prod_{j=1}^{l-1}\frac{\sin^2\left(\frac{k-l-2j}{32}\gamma+\mathrm{i}\frac{\theta}{2}\right)\cos^2\left(\frac{k+l-2j}{32}\gamma+\mathrm{i}\frac{\theta}{2}\right)}{\sin^2\left(\frac{k-l-2j}{32}\gamma-\mathrm{i}\frac{\theta}{2}\right)\cos^2\left(\frac{k+l-2j}{32}\gamma-\mathrm{i}\frac{\theta}{2}\right)} \qquad [50]$$

where we assume, without loss of generality, that $k \geq l$. The remarkable thing is that the scattering of the lowest-mass breather $m_1$ with itself,

$$S_{11}(\theta) = \frac{\sinh\theta + \mathrm{i}\sin\frac{\gamma}{8}}{\sinh\theta - \mathrm{i}\sin\frac{\gamma}{8}} \qquad [51]$$

is precisely the Toda $S$-matrix for $A_1$ with $\beta \to \mathrm{i}\beta/\sqrt{2}$ (the origin of the factor of $\sqrt{2}$ is mentioned after eqn [9]). This uniquely identifies the lowest-mass breather as being the quantum of the $\phi$ field.

The quantum structure that we have described above can be directly related to the classical scattering of solitons. In order to implement the classical limit, we can reintroduce $\hbar$ which is achieved by replacing $\beta^2$ by $\beta^2\hbar$. In this limit, the $S$-matrix elements have the form

$$S(\theta) = \exp\frac{2\mathrm{i}}{\hbar}(\delta(\theta) + \mathcal{O}(\hbar)) \qquad [52]$$

The phase $\delta(\theta)$ is related via the WKB approximation to the time delay in the classical theory of soliton scattering via

$$\delta(\theta) = \text{const.} + \int_0^\theta \mathrm{d}\theta' M\sinh(\theta/2)\Delta t(\theta) \qquad [53]$$

where $\Delta t(\theta)$ is the time delay in the center of mass (21). It is possible to verify [53] for the processes $S(\theta)$ and $S_{\mathrm{T}}(\theta)$. Note that the reflection process has no classical analogue.

## IQFT, Conformal Field Theories and Statistical Systems

We have described some IQFTs and their factorizable $S$-matrices in theories with a mass gap. We can ask the question, "what happens at very high energies compared with all the mass scales?" For a generic QFT such a limit may not exist, however, for a special class of theories the limit is a massless scale-invariant theory corresponding to a fixed point of the renormalization group. The massive theory can be thought of as a deformation of the massless theory by a particular relevant operator. At the fixed point, the Poincaré symmetry is enhanced to the full conformal group in the appropriate number of dimensions and the resulting theory is known as a conformal field theory (CFT). In $1+1$ dimensions the conformal group is infinite dimensional and so many CFTs are themselves integrable, in the sense that the complete spectrum of fields is known and their correlation functions can be constructed. Hence, an alternative way of thinking about many IQFTs is as a perturbation of a CFT by a specific relevant operator:

$$S_{\mathrm{IQFT}} = S_{\mathrm{CFT}} + g\int \mathrm{d}^2x\mathcal{O}(x) \qquad [54]$$

We will suppose that the operator has conformal dimensions $(\Delta, \bar{\Delta})$. This description of the theory can be turned around to ask the following question: which relevant deformations of a given CFT lead to IQFTs? Remarkably, since CFTs are so well understood, the question can often be answered exactly. The idea is that the conserved quantities of a CFT are all (anti-)holomorphic with respect to a holomorphic coordinate $z = x + \mathrm{i}t$. Conserved quantities include the stress tensor of spin 2 but include, in addition, an infinite tower of currents of ever increasing spin $\{T_s\}$. After perturbation, one has

$$\bar{\partial}T_s = gR^{(1)} + \cdots + g^nR^{(n)} + \cdots \qquad [55]$$

The conformal dimensions of the $R^{(n)}$ are $(s - n(1-\Delta), 1 - n(1-\Delta))$. Since the conformal dimensions of fields in a CFT are bounded below by zero, it follows that the series on the right-hand side truncates. The question of whether $T_s$ remains conserved away from the CFT boils down to the question as to whether the right-hand side has the form $\partial\Theta$, for some $\Theta$. Zamolodchikov found an ingenious counting argument which showed in certain circumstances that the right-hand side has precisely this form for some $s > 2$. This is sufficient to establish that the perturbed theory is an IQFT. In certain cases the spectrum of spins of the conserved quantities that are established by the counting argument is enough to make a connection with a known factorizable $S$-matrix.

This way of viewing IQFT as perturbations of CFTs is especially fruitful when we make the connection of the Euclidean QFT with the classical statistical mechanics of a two-dimensional system. In this connection, the Feynman path integral is reinterpreted as the sum over the configurations in the canonical ensemble with the Euclidean action interpreted as the energy. Usually, we consider statistical systems which are discrete, so typically defined on a lattice. The Euclidean QFTs are to be thought of as these statistical systems in the continuum limit where the lattice spacing is taken to zero keeping the long-range physics fixed. CFTs which have no massive degrees of freedom are identified with points of second-order phase transitions in the statistical system where correlation lengths are infinite. Perturbations of CFTs by relevant operators correspond to taking the statistical system away from criticality by changing some external parameter.

The prototypical example of such a statistical system is the Ising model. In the lattice version of

this model, there are a set spins $\{\sigma_i\}$ at each lattice site which can take the discrete values $\pm 1$. The partition function of the theory is

$$Z(H,T) = \sum_{\{\sigma_i\}} \exp\left( - T^{-1} \sum_{\langle i,j \rangle} \sigma_i \sigma_j - H \sum_i \sigma_i \right) \quad [56]$$

The Ising model is the simplest model of a ferromagnet, where $T$ is the temperature and $H$ is the external applied field. The theory has a second-order phase transition for $T = T_c$, the Curie temperature, and $H = 0$ when the competition between the energy, which favors aligning the spins, and entropy, which favors disorder, exactly balance. In the two-dimensional neighborhood of the critical point, the lattice theory admits a continuum limit which can be described as the perturbation of a CFT, describing the critical Ising model, by a pair of relevant operators with couplings $T - T_c$ and $H$. In the case of the Ising model, the CFT is simply the theory of a free massless fermion in two-dimensional Euclidean space.

It turns out that in the two-dimensional space of relevant perturbations, there are two directions which lead to IQFTs. The most obvious is changing the temperature away from $T_c$ while keeping $H = 0$. This leads to a particularly simple IQFT, that of a free massive fermion. More unexpectedly, the direction for which $H$ varies away from 0, but $T = T_c$, also leads to an IQFT. In this case, Zamolodchikov's counting argument shows that there are higher-spin conserved charges of spin including

$$s = 1, 7, 11, 13, 17, 19, \ldots \quad [57]$$

This is remarkable because, as we have described previously, there is a minimal solution of the bootstrap program that describes the scattering of eight particles which has a spectrum of conserved charges that includes these spins. It is the minimal scattering theory related to the algebra $E_8$.

The fact that the scattering theory of the off-critical Ising model in the magnetic field direction has been identified is remarkable. From the $S$-matrix one can proceed to investigate the off-critical correlation functions using a technique known as the "form factor programe." Detailed simulation of the original lattice model [56] has provided strong support for the veracity of the $E_8$ scattering theory. For instance, the two lightest masses in the scattering theory determine the ratio of the two longest correlation lengths $m_2/m_1 = 2\cos(\pi/5)$.

In general, the identification of an IQFT and the CFT at its ultraviolet limit can be more difficult to establish. One way to proceed is to use the thermodynamic Bethe ansatz. This technique involves considering the thermodynamics of a gas of the particles in a periodic box. Since the scattering is purely elastic, thermodynamic quantities can be calculated, albeit in terms of a set of coupled nonlinear integral equations. If the box is small enough, ultraviolet effects dominate and various features of the CFT can be recovered.

## Other IQFTs

There is a rich menagerie of other IQFTs that we have no space to discuss in detail. One is sigma models, whose fields take values in a Riemannian target space $\mathfrak{M}$ with an action

$$S = \int d^2x g_{ab} \partial_\mu X^a \partial^\mu X^b \quad [58]$$

where $g_{ab} dX^a\, dX^b$ is the metric of $\mathfrak{M}$. These theories are integrable at the classical level if the target space is either a group manifold of a compact simple group $G$ or a symmetric space coset $G/H$, where $H$ is a suitable subgroup of $G$. The former are known as the "principal chiral models." There are two kinds of conserved quantities, both local and nonlocal. At the quantum level, the conserved currents which imply classical integrability can be subject to quantum anomalies. An analysis of these anomalies proves that the principal chiral models are all integrable at the quantum level, while only the subset of symmetric space coset models, namely

$$\begin{array}{ll} SO(n+1)/SO(n), & SU(n)/SO(n) \\ SU(2n)/Sp(n), & SO(2n)/SO(n) \times SO(n) \\ Sp(2n)/Sp(n) \times Sp(n) & \end{array} \quad [59]$$

are quantum integrable. $S$-matrices have been proposed for all these integrable sigma models. They have a more complicated structure than most of the cases discussed here, because the particles fall into representations of the associated Lie groups and the Yang–Baxter equation, such as for the sine-Gordon solitons, is now nontrivial. Remarkably, gross features of the $S$-matrices, such as the mass spectrum fusing rules, are identical to the Toda theories or the minimal $S$-matrices.

Returning to IQFTs that are associted with deformations of CFTs, there are more general classes which are associated with the renormalization group trajectories between two nontrivial fixed points. These theories have both massless and massive degrees of freedom. Even more remarkable are the staircase models of Zamolodchikov that exhibit an infinite series of crossover behavior where the renormalization group trajectory passes close to an infinite series of fixed points in sequence.

For all of the theories described above, one might have thought more generally that integrability is a very rigid property of a theory. In general, for example, the number of external coupling constants is very limited and the mass ratios are all fixed. For

example, in Toda theories there is only an overall mass scale $m$ and the coupling $\beta$. If the form of the potential is altered in any way then integrability is lost. However, in certain circumstances, integrability appears to be a looser constraint that allows more flexibility. One class of such theories is known as the homogeneous sine-Gordon theories. These are integrable deformations of gauged WZW models associated with the coset $G/\mathrm{U}(1)^r$, where $r$ is the rank of a simple compact group $G$. In these theories there is a rich spectrum of both stable and unstable particles with masses and an $S$-matrix that depends continuously on a set of $r$ coupling constants.

# Integrable Discrete Systems

**O Ragnisco**, Università "Roma Tre", Rome, Italy

## Discrete Dynamical Systems

The expression "dynamical system" usually refers to a coupled system of ordinary differential equations (ODEs), namely,

$$\dot{x}_j(t) = f_j(t, x_1, \ldots, x_N), \quad j = 1, \ldots, N \qquad [1]$$

where $t$ belongs to some set of nonzero measure $I$ of the real line $\mathbb{R}$, typically an interval $[a, b]$ or a semiline or the whole line, and $x_j$ are sufficiently smooth functions from $I$ to $\mathbb{R}$ or to $\mathbb{C}$.

The system [1] is complemented by initial or boundary conditions that make it into an "initial-value" or a "boundary-value" problem. Under suitable regularity assumptions on the RHS, the existence and uniqueness of the solution of the initial-value problem is guaranteed, but in most cases the solution can be known only "approximately" either through perturbation theory or just through numerical integration. This is not the proper place to discuss finite-difference schemes for systems of ODEs: what is relevant is that such numerical schemes (think, e.g., of Euler or Runge–Kutta schemes) "discretize" the continuous independent variable $t$ by replacing it by an integer variable $n \in \mathbb{Z}$: in the simplest case, the interval $[a, b]$ is replaced by a set of $L$ equally spaced points $t_n = a + n(b-a)/L (n = 1, \ldots, L)$, the first derivative is approximated by a (forward) difference, and the system [1] is converted into a system of "difference" equations of the form

$$x_j(n+1) = x_j(n) + hF(n, x_1(n), \ldots, x_N(n)) \qquad [2]$$

where $h$ denotes the time step $(b-a)/L$.

The coupled system [2] is an example of a "discrete dynamical system," explicit (because the updated variables only depend upon the values taken

at previous discrete times), first order (only "nearest-neighbor" discrete times, $n$, $n+1$ are involved), but nonautonomous, as the RHS is allowed to depend explicitly upon the independent variable $n$, analogously to its continuum counterpart.

In the following, "autonomous" but not necessarily explicit discrete dynamical systems of a special type will be considered: in fact, we will require them to be equipped with a Hamiltonian structure, and we will define the notion of complete integrability (in the Arnol'd–Liouville sense) for such systems.

This article emphasizes on some aspects and properties of integrable discrete systems, neglecting others that could be equally important. In particular, as no nonautonomous discrete systems will be considered, discrete analogs of Painleve' equations will never be discussed in this article, and consequently the intriguing issues concerning "singularity confinement" in the discrete and "algebraic entropy" will not be touched upon (see, e.g., Grammaticos *et al.* (2004)). Similarly, neither the integrability for discrete systems in multidimensional space nor "quantum integrable mappings" will be discussed.

## Lagrangian and Hamiltonian Formulations

Following the historical path along which modern classical mechanics has been developed, first the concept of a Lagrangian map is introduced, and then Hamiltonian (in fact, symplectic) maps are defined through a proper discrete version of the Legendre transformation.

Let $x_j(n)\,(j=1,\ldots,N, n\in\mathbb{Z})$ be $N$ sequences of real numbers and let $\mathcal{L}(\boldsymbol{x},\boldsymbol{y})$ be a smooth function from $\mathbb{R}^N\times\mathbb{R}^N$ into the reals, $\boldsymbol{x}$ denoting the $N$-tuple $x_1,\ldots,x_N$. $\mathcal{L}$ is regarded as a "discrete Lagrange function": corresponding to each discrete time $n$, it is assigned a certain value $\mathcal{L}_n := \mathcal{L}(\boldsymbol{x}(n),\boldsymbol{x}(n+1))$. The corresponding discrete action functional $S[\mathcal{L}]$ is defined in a natural way:

$$S[\mathcal{L}] = \sum_{n=N_a}^{N_b} \mathcal{L}_n \qquad [3]$$

The actual "discrete trajectory" will be given by the sequence $\boldsymbol{x}(n)$ that corresponds to a "critical point" of the action [3] subject to the constraints $\delta\boldsymbol{x}(N_a)=\delta\boldsymbol{x}(N_b)=0$. Note that the values $N_a\,(N_b)$ may well possibly coincide with $-\infty\,(+\infty)$. Such "critical points" are given by the solution of the discrete Euler–Lagrange equations:

$$\left.\frac{\partial\mathcal{L}}{\partial x_j}\right|_{x_j=x_j(n),y_j=x_j(n+1)} + \left.\frac{\partial\mathcal{L}}{\partial y_j}\right|_{x_j=x_j(n-1),y_j=x_j(n)} = 0 \qquad [4]$$

It is worthwhile to remark the intrinsic nature of eqns [4], whose form turns out to be independent of the choice of a coordinate chart. In fact, by omitting the explicit dependence on $n$ and simply denoting $\boldsymbol{x}(n)=\boldsymbol{x}$, $\boldsymbol{x}(n+1)=\tilde{\boldsymbol{x}}$, $\boldsymbol{x}(n-1)=\underset{\sim}{\boldsymbol{x}}$, [4] can be cast in the form

$$\nabla_1\mathcal{L}(\boldsymbol{x},\tilde{\boldsymbol{x}}) + \nabla_2\mathcal{L}(\underset{\sim}{\boldsymbol{x}},\boldsymbol{x}) = 0 \qquad [5]$$

which makes its "implicit" nature for the updated variable $\tilde{\boldsymbol{x}}$ more transparent. Clearly, as a map from the pair $(\underset{\sim}{\boldsymbol{x}},\boldsymbol{x})$ to the pair $(\boldsymbol{x},\tilde{\boldsymbol{x}})$, it is in general a multivalued map, or a "correspondence", as it is called in the literature (Suris 2003, Veselov 1991). In order that [5] be solvable for $\tilde{\boldsymbol{x}}$, the Hessian matrix $H_{jk}=\partial^2\mathcal{L}/\partial x_j\partial y_k$ should be nondegenerate.

As will be noted shortly, the Lagrangian map [4] (or [5]) is in fact a canonical, or better a symplectic transformation on a suitably defined cotangent bundle $T^*X$ to the configuration space $X\in\mathbb{R}^N$. Namely, one defines the conjugate momentum to $\boldsymbol{x}$ as

$$\boldsymbol{p} := \nabla_2\mathcal{L}(\underset{\sim}{\boldsymbol{x}},\boldsymbol{x}) \qquad [6]$$

so that [5] can be rewritten as the following system:

$$\boldsymbol{p} = -\nabla_1\mathcal{L}(\boldsymbol{x},\tilde{\boldsymbol{x}}) \qquad [7]$$

$$\tilde{\boldsymbol{p}} = \nabla_2\mathcal{L}(\boldsymbol{x},\tilde{\boldsymbol{x}}) \qquad [8]$$

This system defines a correspondence $(\boldsymbol{x},\boldsymbol{p})\to(\tilde{\boldsymbol{x}},\tilde{\boldsymbol{p}})$, which is indeed a "symplectic" one, as it preserves the standard symplectic form $\omega(\boldsymbol{x},\boldsymbol{p})=\sum_{j=1}^N \mathrm{d}p_j\wedge \mathrm{d}x_j$, and, of course, the associated Poisson brackets. The simplest way to recognize this property is by constructing the generating function of the corresponding canonical transformation. To this end, let us introduce

$$\mathcal{S}(\boldsymbol{x},\tilde{\boldsymbol{p}}) = -\mathcal{L} + \sum_{j=1}^N \tilde{p}_j(\tilde{x}_j - x_j) \qquad [9]$$

The discrete Euler–Lagrange equation then takes the form

$$\tilde{x}_j - x_j = \frac{\partial\mathcal{S}}{\partial\tilde{p}_j} \qquad [10]$$

$$p_j - \tilde{p}_j = \frac{\partial\mathcal{S}}{\partial x_j} \qquad [11]$$

which is canonically generated by $\mathcal{S}+\sum_j x(j)\tilde{p}(j)$. A strict analog of the Hamiltonian formulation for continuous-time Lagrangian systems does not indeed exist in the discrete-time case. One of the main consequences, well known to the specialists but worth emphasizing in the present context, is that even a symplectic map in one degree of freedom

(two-dimensional $T^*X$) is generically not integrable: the existence of an invariant function $F(\boldsymbol{x},\boldsymbol{p}) = F(\tilde{\boldsymbol{x}},\tilde{\boldsymbol{p}})$ is not entailed by the symplectic structure, so that, as discussed later, integrable maps of the standard type are indeed exceptional. On the other hand, note that invariant functions do exist whenever a Lagrangian has some additional symmetry: this is the case when a Lie group acts on the configuration space $X$ and the Lagrange function is invariant under its induced action on $X \times X$, so that a discrete version of the Noether theorem applies (Suris 2003).

## Complete Integrability

The definition of a "completely integrable" discrete-time system is now in order. Let $\Phi$ be a symplectic map on the $2N$-dimensional phase space $\mathcal{M} := (\mathbb{R}^{2N}, \mathrm{d}p \wedge \mathrm{d}q)$, equipped with $N$ smooth invariant functions $F_j$, such that

- $F_1, \ldots, F_N$ are functionally independent, that is, their gradients $\nabla F_j$ are linearly independent of $\mathcal{M}$;
- $F_1, \ldots, F_N$ are in involution:

$$\{F_j, F_k\} = 0, \quad j,k = 1,\ldots,N$$

Let $\mathcal{T}$ be a connected component of the common level set

$$\{(\boldsymbol{x},\boldsymbol{p}) \in \mathcal{T}:\ F_k(\boldsymbol{x},\boldsymbol{p}) = c_k,\ k = 1,\ldots,N\}$$

Then $\mathcal{T}$ is diffeomorphic to $\mathbb{T}^l \times \mathbb{R}^{N-l}$, for some $0 \le l \le N$; if $\mathcal{T}$ is compact, then it is diffeomorphic to an $N$-dimensional torus $\mathbb{T}^N$.

In the compact case, there exists an open ball $\Omega \in \mathbb{R}^N$ such that, in $\mathcal{T} \times \Omega$, there exist new canonical coordinates $(I_k, \phi_k), k = 1,\ldots,N;\ I_k \in \mathcal{T}, \phi_k \in \Omega$, the so-called action-angle coordinates, enjoying the following properties:

- the actions $I_k$ depend just on the $F_j$'s
- in action-angle coordinates the map is a linear shift on the $N$-dimensional torus:

$$\tilde{I}_k := \Phi(I_k) = I_k$$
$$\tilde{\phi}_k := \Phi(\phi_k) = \phi_k + \nu_k(I_1, I_2, \ldots, I_N)$$

Hence, in action-angle variables a completely integrable map is a canonical transformation from $(I,\phi)$ to $(\tilde{I}\,(=I), \tilde{\phi})$, whose generating function $W$ only depends on the action variables. It takes the form

$$\tilde{I}_k - I_k = 0 \qquad [12]$$

$$\tilde{\phi}_k - \phi_k = \frac{\partial W}{\partial I_k} := \frac{\partial}{\partial I_k} \sum_{j=1}^{N} \int_x^{\tilde{x}} \mathrm{d}x_j\ p_j(\boldsymbol{I},\boldsymbol{x}) \qquad [13]$$

## Integrable Maps of the Standard Type

As the simplest integrable models, first consider some highly nontrivial examples of "standard maps," that is, scalar discrete second-order difference equations of the following type (Suris 2003):

$$x_{n+1} - 2x_n + x_{n-1} = G(x_n; h) \qquad [14]$$

with $h$ a real parameter, which exhibit an invariant function, say

$$J(x_{n-1}, x_n) = J(x_n, x_n + 1) \qquad [15]$$

Clearly, [14] can serve as a discretization of the Newtonian equation:

$$\ddot{x} = f(x) \qquad [16]$$

if $\lim_{h\to 0} h^2 G(x;h)$ exists and is equal to $f(x)$.

All "standard maps" are Lagrangian, being stationary points of the discrete action:

$$S = \sum_{n\in\mathbb{Z}} \left( \tfrac{1}{2}\left[x_{n+1} - x_n\right]^2 + V(x_n; h) \right) \qquad [17]$$

with $G(x;h) = \partial V(x;h)/\partial x$. A point in the phase space is a pair $x_n, p_n = x_n - x_{n-1}$, and [14] is symplectic for $\mathrm{d}p \wedge \mathrm{d}x$, reading

$$x_{n+1} - x_n = p_{n+1} \qquad [18]$$

$$p_n - p_{n+1} = G(x_n; h) \qquad [19]$$

The corresponding generating function is given by $S = V(x;h) + (1/2)p_{n+1}^2$. Integrability of [19] means the existence of a function $F$ from $\mathcal{M}$ into itself such that

$$F(x_{n+1}, p_{n+1}) = F(x_n, p_n) \qquad [20]$$

where [15] and [20] are equivalent provided $J(x, x - y) = F(x,y)$.

Suris has found three families of functions $G$ that ensure integrability: a rational family, a trigonometric family, and a hyperbolic family. There is no room here to display the relevant formulas, nor to explain why, under natural analiticity assumptions both in $h$ and $x$, no other integrable family exists. However, it is worth mentioning that they turn out to be integrable discretizations of the scalar second-order differential equations [16] for the following "force" functions $f(x)$:

$$f_{\mathrm{rat}}(x) = A + Bx + Cx^2 + DX^3 \qquad [21]$$

$$f_{\mathrm{trig}}(x) = A\sin(\omega x) + B\cos(\omega x) + C\sin(\omega 2x) + D\cos(\omega 2x) \qquad [22]$$

$$f_{\mathrm{hyp}}(x) = A\exp(x) + B\exp(-x) + C\exp(2x) + D\exp(-2x) \qquad [23]$$

A curious fact is that those Newton forces that one can "discretize" in order to get integrable maps

are exactly the external forces that one can add to the internal two-body interactions of the Calogero–Moser or Calogero–Sutherland models to preserve complete integrability.

## Integrable Discrete Systems and the Lax Approach

Since, in a seminal paper, Lax (1968) introduced it for the Korteweg–de Vries (KdV) equation, the search for a "Lax representation" played a crucial role in the construction of integrable systems, both finite and infinite dimensional. In particular, the continuous time dynamical system [1] (assumed to be autonomous) is said to be equipped with a Lax representation if there exist two matrices $L$, $M$ whose entries depend upon the coordinates $x_j$, whenceforth upon the time $t$, such that the time evolution [1] can be cast in the form

$$\dot{L}(t) = [L(t), M(t)] \qquad [24]$$

Hence, the one-parameter family of matrices $L(t)$ undergoes the "isospectral" deformation:

$$L(t) = U(t)L(0)(U(t))^{-1} \qquad [25]$$

$U(t)$ being the unique solution of the linear matrix differential equation:

$$\dot{U}(t) = M(t)U(t) \qquad [26]$$

with the initial condition $U(0) = I$. Then, the existence of a Lax representation in term of, say, $k \times k$ matrices entails the existence of $k$ integrals of motion, given, for instance, by the eigenvalues of $L(t)$, or by the traces $t_l := \mathrm{tr}(L(t))^l$.

Some remarks are in order:

- In the case of a Hamiltonian system, the matrices $L$, $M$ depend, of course, on the point in the phase space.
- No guarantee exists, *a priori*, that the eigenvalues of $L$, or equivalently the traces $t_l$, be "sufficiently many" and in involution. Note, however, that in many examples the Lax matrices $L$, $M$ depend on an extra scalar parameter $\lambda$ (so that they are elements of an affine or "loop" Lie algebra), which might increase the number of integrals of motion well beyond the dimension of the matrix.

The $N$-body systems of Calogero type and Toda type are celebrated examples of integrable dynamical systems equipped with a Lax representation.

How this description can be adapted to the discrete-time case? The isospectral equation [25] suggests the proper way. One has to look for two matrices depending on the coordinates (or on the phase-space variables) $\boldsymbol{x}$ (again, they can be called $L$, $M$), such that the discrete-time evolution, modeled, for instance, by [2], can be cast in the form of a similarity transformation:

$$\tilde{L} = MLM^{-1} \qquad [27]$$

where $L = L(\boldsymbol{x})$, $\tilde{L} = L(\tilde{\boldsymbol{x}})$, and $M = M(\boldsymbol{x}, \tilde{\boldsymbol{x}})$. As usual, by denoting by $n$ the discrete time (i.e., the number of iterations), so that $\boldsymbol{x} = \boldsymbol{x}(n), \tilde{\boldsymbol{x}} = \boldsymbol{x}(n+1)$, eqn [27] implies that a discrete version of [25] holds:

$$L(n) = U(n)L(0)[U(n)]^{-1} \qquad [28]$$

where $U(n) := M(n)M(n-1)\cdots M(1)$.

As in the continuous case, the existence of a discrete Lax representation entails the existence of conserved quantities (invariants of the map or of the correspondence) but by itself it does not say anything about completeness and involutivity of such invariants. There is, however, an approach that incorporates the involutivity property in the very construction of Lax equations, both discrete and continuous, namely the "$R$-matrix approach." Indeed, from the experimental observation of a number of examples, both finite and infinite dimensional, one can assert that the matrix $M$ taking part in the "continuous" Lax representation [24] may be presented in the form (Suris 2003)

$$M = R(f(L)) \qquad [29]$$

In [29], $L$, $M$ are element of some matrix Lie algebra $\boldsymbol{g}$, $R$ is a linear map from $\boldsymbol{g}$ into itself, and $f$ is a conjugation-covariant function, namely

$$f(ALA^{-1}) = Af(L)A^{-1} \qquad [30]$$

$A$ being an arbitrary element of the group $\boldsymbol{G}$ with Lie algebra $\boldsymbol{g}$.

Polynomials in the variable $L$ with scalar coefficients are typical examples of conjugation-covariant functions. Moreover, in a matrix Lie algebra, one can identify $\boldsymbol{g}$ with its dual space $\boldsymbol{g}^*$ through the nondegenerate bilinear form provided by the trace: $(L_1, L_2) := \mathrm{tr}(L_1 L_2)$. Then, the trace $F$ of a conjugation-covariant function $f$ will be a typical example of a conjugation-invariant function, and, conversely, the gradient of a conjugation-invariant function $F$, defined as

$$\langle \nabla F, X \rangle = \frac{\mathrm{d}}{\mathrm{d}\epsilon} F(L + \epsilon X)|_{\epsilon=0} \qquad [31]$$

will be a typical example of a conjugation-covariant function. In the above setting, one can define the following Lie–Poisson bracket on $\boldsymbol{g}$:

$$\{F, G\}(L) := (L, [\nabla F, \nabla G]) \qquad [32]$$

where $F$, $G$ are arbitrary (i.e., not necessarily invariant) functions from $\boldsymbol{g}$ into $\mathbb{C}$, so that the Hamilton equation

$$\dot{L} = \{H, L\} \quad [33]$$

takes the Lax form

$$\dot{L} = [L, \nabla H] \quad [34]$$

It is immediate to check that invariant functions of $L$ are Casimir functions of [32] so that they will not generate any nontrivial flow.

Assume now that the linear mapping $R$, usually called $r$-matrix, introduced in [29], is such that it defines a new Lie bracket on $\boldsymbol{g}$, through the formula

$$[L_1, L_2]_R = \tfrac{1}{2}([L_1, R(L_2)] + [R(L_1), L_2]) \quad [35]$$

and consequently a new Lie–Poisson bracket

$$\{F, G\}_R(L) := (L, [\nabla F, \nabla G]_R) \quad [36]$$

Then the following theorem holds:

*Let $H$ be an invariant function on $\boldsymbol{g}$. Then*:

(i) *The Hamilton equations on $\boldsymbol{g}$ generated by $H$ with respect to the Poisson bracket [36] have the Lax form*

$$\dot{L} = [L, R(\nabla H)] \quad [37]$$

(ii) *The invariants of $\boldsymbol{g}$, that is, the Casimir function of the standard Lie–Poisson bracket [32], are in involution for [36] so that the corresponding flows are mutually commuting.*

A particular realization of such $R$ operator, very important for the application, arises in the so-called Adler–Kostant–Symes (AKS) construction (Adler 1979, Kostant 1979, Symes 1980), where the Lie algebra $\boldsymbol{g}$ admits a decomposition in two subalgebras, $\boldsymbol{g}_+$ and $\boldsymbol{g}_-$, so that, as linear spaces, it holds that

$$\boldsymbol{g} = \boldsymbol{g}_+ \oplus \boldsymbol{g}_- \quad [38]$$

Denoting by $\pi_\pm$ the corresponding projections, the linear mapping

$$R := \pi_+ - \pi_- \quad [39]$$

defines a new Lie bracket on $\boldsymbol{g}$, and the corresponding Lax equations take the two equivalent forms:

$$\dot{L} = [L, \pi_+(f(L))] = -[L, \pi_-(f(L))] \quad [40]$$

For the present purposes, it is of paramount importance that the AKS construction has a discrete-time version (Suris 2003).

In fact, let $\boldsymbol{G}$ be a Lie group with Lie algebra $\boldsymbol{g}$, and let $\boldsymbol{G}_+, \boldsymbol{G}_-$ be its subgroups having $\boldsymbol{g}_+, \boldsymbol{g}_-$ as Lie algebras. Then, in a certain component of the identity element $I$, any element $g$ of $\boldsymbol{G}$ is uniquely factorizable as

$$g = \Pi_+(g)\Pi_-(g), \quad \Pi_\pm(g) \in \boldsymbol{G}_\pm \quad [41]$$

Moreover, let $F: \boldsymbol{g} \to \boldsymbol{G}$ be a conjugation-covariant function. Consider now the map

$$\begin{aligned} L \to \tilde{L} &:= \Pi_+^{-1}(F(L)) \cdot L \cdot \Pi_+(F(L)) \\ &= \Pi_-(F(L)) \cdot L \cdot \Pi_-^{-1}(F(L)) \end{aligned} \quad [42]$$

and regard it as a difference equation, yielding $\tilde{L} = L(n+1)$ in terms of $L = L(n)$. Then, the following properties hold:

- For whatever function $F$, the map [42] commutes with any continuous flow [40], mapping solutions into solutions.
- It can be "explicitly integrated" with respect to the discrete time $n$, yielding

  $$L(n) = \Pi_+^{-1}(F^n(L_0)) \cdot L_0 \cdot \Pi_+(F^n(L_0)) \quad [43]$$

  or the equivalent expression in terms of the complementary projection $\Pi_-$.
- It is interpolated by the continuous flow [40] with time step $h$ if

  $$\exp(hf(L)) = F(L) \leftrightarrow f(L) = h^{-1} \log(F(L)) \quad [44]$$

  In other words, the discrete-time systems that one derives through this approach are just a sequence of pictures taken at equally spaced times of some continuous flow pertaining to the hierarchy [40]: so, by construction they are Poisson maps with an involutive family of integrals given by the conjugation-invariant functions of $L$ (typically, $\operatorname{tr} L^n$).
- As far as

  $$F(L) = I + hf(L) + o(h^2) \quad [45]$$

  the map [42] serves as an integrable exact discretization of the flow [40], sharing both its Poisson structure and its constants of the motion.

## An Integrable Discretization of the Toda Lattice

Consider a simple but an illuminating example of the above construction, showing an integrable discretization of the "open-end Toda lattice," which is described (Suris 2003) by the Newtonian equations of motion:

$$\begin{aligned} \ddot{x}_j &= \exp(x_{j+1} - x_j) - \exp(x_j - x_{j-1}) \\ j &= 1, \ldots, N \end{aligned} \quad [46]$$

and can be cast into a Hamiltonian form by setting $p_j = \dot{x}_j$; $q_j = x_j$. If, according to H Flaschka (1974), one introduces the variables

$$b_j = \dot{x}_j, \qquad a_j = \exp(x_{j+1} - x_j) \qquad [47]$$

eqn [46] takes the form

$$\dot{b}_j = a_j - a_{j-1}, \qquad \dot{a}_j = a_j(b_{j+1} - b_j) \qquad [48]$$

and enjoys the Lax representation [24] in terms of the $N \times N$ matrices:

$$L(a,b) = \sum_{k=1}^{N} a_j E_{j,j+1} + \sum_{k=1}^{N} b_j E_{j,j} + \sum_{k=1}^{N} E_{j+1,j} \qquad [49]$$

$$M(a,b) = A := \sum_{k=1}^{N} a_j E_{j,j+1} \quad \text{or}$$
$$M(a,b) = -B := \sum_{k=1}^{N} b_j E_{j,j} + \sum_{k=1}^{N} E_{j+1,j} \qquad [50]$$

In the above formula, $E_{j,k}$ is the matrix having 1 in the $jk$ position and 0 elsewhere, so that, obviously, $E_{N,N+1} = E_{N+1,N} = 0$. An inspection to [49] and [50] shows that $A$ is just the strictly upper triangular part of $L(a,b)$, while $B$ is its lower triangular part. The pair $(A,B)$ constitutes the so-called $LU$ decomposition of $L(a,b)$. One is clearly in the AKS setting, the Lie algebra $\boldsymbol{g}$ being just the algebra of $N \times N$ matrices, and the Lie subalgebras $\boldsymbol{g}_\pm$ being the strictly upper and lower triangular matrices. The tridiagonal matrix $L(a,b)$ belongs to a Poisson submanifold of $\boldsymbol{g}$, invariant under the flows [40], and a complete family of commuting integrals of motion is given, for instance, by $I_k = \mathrm{tr} L^k$.

Now, the elements of the group $\mathrm{GL}_N$, realized as the group of invertible $N \times N$ matrices, uniquely factorize into a product of an invertible lower-triangular matrix times an upper-triangular matrix with units on the diagonal, and the Lie algebras of those subgroups are just the aforementioned subalgebras $\boldsymbol{g}_\pm$. Then, one is naturally tempted to look for an integrable discretization provided by a conjugation-covariant function of the type [45], starting with the simplest possible choice, namely

$$F(L) = I + hf(L)$$

Setting

$$\begin{aligned}\tilde{L}(a,b) &:= L(\tilde{a},\tilde{b})\\ &= \Pi_+^{-1}(I+hL)\cdot L\cdot \Pi_+(I+hL)\\ &= \Pi_-(I+hL)\cdot L\cdot \Pi_-^{-1}(1+hL) \qquad [51]\end{aligned}$$

it turns out that the matrix equation [51] is equivalent to the map

$$(a,b) \to (\tilde{a},\tilde{b})$$

described by the following equations:

$$\tilde{b}_k = b_k + h\left(\frac{a_k}{\beta_k} - \frac{a_{k-1}}{\beta_{k-1}}\right)$$
$$\tilde{a}_k = a_k(\beta_{k+1} - \beta_k)$$

where $\beta_k$, which are the "field variables" entering into the $LU$ factorization [51], are explicitly and uniquely defined by the recurrent relation (amounting to a finite continued fraction):

$$\beta_k = 1 + hb_k - h^2\frac{a_{k-1}}{\beta_{k-1}}, \quad k = 1,\ldots,N \qquad [52]$$

As $a_0 = 0$, the initial condition is simply $\beta_1 = 1 + hb_1$.

It follows from the general results of the previous section that [51] is an integrable Poisson map, sharing with the continuous Toda hierarchy both the Poisson structure and the integrals of motion. Its initial-value problem can be uniquely solved in terms of the $LU$ factorization of the group element $(I + hL_0)^n$, the initial condition $L_0$ being any matrix pertaining to the tridiagonal submanifold [49]. According to [44], the interpolating Hamiltonian flow is provided by the function $f(L) = h^{-1}\log(1 + hL)$. To make contact with the discussion in the section "Lagrangian and Hamiltonian formulations," we observe that, in terms of the canonical variables $x_j$, $p_j$, the discrete Toda [51] lattice becomes the following symplectic map:

$$1 + hp_j = \exp(\tilde{x}_j - x_j) + h^2\exp(x_j - \tilde{x}_{j-1}) \qquad [53]$$

$$1 + h\tilde{p}_j = \exp(\tilde{x}_j - x_j) + h^2\exp(x_{j+1} - \tilde{x}_j) \qquad [54]$$

It can evidently be written in the discrete Newtonian form:

$$\begin{aligned}&\exp(\tilde{x}_j - x_j) - \exp(x_j - \underset{\sim}{x}_j)\\ &\quad = h^2\exp(\underset{\sim}{x}_{j+1} - x_j) - \exp(x_j - \tilde{x}_{j-1}) \qquad [55]\end{aligned}$$

whose Lagrangian function is given by

$$\mathcal{L} = \sum_{k=1}^{N}\psi(\tilde{x}_k - x_k) - h\sum_{k=1}^{N}\exp(x_{k+1} - \tilde{x}_k) \qquad [56]$$

with

$$\psi(\xi) = h^{-1}(\exp(\xi) - 1 - \xi) \qquad [57]$$

The variables $\beta_j$ acquire the following extremely simple expression in the Lagrangian coordinates $x_j, \tilde{x}_j$:

$$\beta_j = \exp(\tilde{x}_j - x_j)$$

For integrable Hamiltonian systems with long-range two-body interaction, such as Calogero–Moser type systems, and their so-called relativistic version (Ruijsenaars systems), an exact integrable discretization has also been found. However, at least

in the more natural Lax representation, the related $R$-matrix is dynamical (namely, it depends on the phase-space coordinates), and the simple factorization scheme holding for the Toda lattice system (and for the related ones) is not available.

Further knowledge on the intriguing subject of "discrete integrable systems" can be acquired by looking at the monographs and papers listed in the "Further Reading" section. In particular, the excellent book by Y B Suris, which also provides an exhaustive list of references (updated to 2003), is recommended.

# Integrable Systems and Algebraic Geometry

**E Previato**, Boston University, Boston, MA, USA

## Historical Overview

The relevance of algebraic geometry in the theory of dynamical systems has a long history. Three models may serve as guiding threads from old to the current state of the theory. Each time algebraic geometry is used to integrate an evolution equation; this is achieved by an underlying addition rule. The very origin for this seems to be Fagnano's addition rule for the arc of a lemniscate (see Siegel (1969)). In analogy to the addition of two arcs on a circle $x^2+y^2=1$, or the duplication formula for

$$\arcsin r = \int_0^r \frac{\mathrm{d}r}{\sqrt{1-r^2}}$$

namely

$$\int_0^r \frac{\mathrm{d}r}{\sqrt{1-r^2}} = 2\int_0^u \frac{\mathrm{d}u}{\sqrt{1-u^2}}$$

if $r=2u\sqrt{1-u^2}$ (a restatement of the trigonometric identity $r=\sin(2x)=2\sin x\cos x$), Fagnano found, and proved, by substitution, a geometric rule for duplicating the arc of a lemniscate:

$$x^4+2x^2y^2+y^4=x^2-y^2$$

The length of the arc is now given by

$$s=\int_0^r \frac{\mathrm{d}r}{\sqrt{1-r^4}}$$

and later Gauss designated the limit of integration by $r=\operatorname{sinlemn}(s)$. Fagnano was able to show that

$$\int_0^r \frac{\mathrm{d}r}{\sqrt{1-r^4}} = 2\int_0^u \frac{\mathrm{d}u}{\sqrt{1-u^4}}$$

with the substitution

$$r^2=\frac{4u^2(1-u^4)}{(1+u^4)^2}$$

which is remarkable not only because it doubles the length, but also because it does so by rational functions, and in fact shows that the arc of the lemniscate can be halved by straightedge and compass. Gauss showed that the constructible fractions of an arc of a lemniscate are the same as the ones for the circle.

Thanks to subsequent work by Euler, and to the theory of abelian functions due to Abel, Jacobi, and others in the nineteenth century, we now realize that Fagnano's discovery revealed the algebraic group structure of the singular quartic curve (or of a smooth cubic, if preferred, an elliptic curve).

This is the key fact that provides the "integration by quadratures" for the simple pendulum. We follow McKean and Moll (1997) to sketch this prototype example of a system which is algebraically completely integrable (ACI), defined in the section

"Hitchin systems." Newton's law gives the equation of motion $\ddot{\theta} + \sin\theta = 0$, where $\theta$ parametrizes the position of the bob in terms of the angle the pendulum makes with the vertical axis, as it rotates about its pivot (the length has been normalized so as to match the gravitational constant). The energy is a first integral, $I = \cos\theta - 1/2\dot{\theta}^2$, and the substitution

$$x = \sqrt{\frac{2}{1-I}} \times \sin\frac{\theta}{2}$$

linearizes the motion:

$$t = \int_0^x \frac{1}{\sqrt{(1-x^2)(1-k^2x^2)}}\,\mathrm{d}x$$

with $k^2 = (1-I)/2$ between 0 and 1, precisely because of Fagnano's and Euler's addition rule.

The second striking example of addition rule, yielding solutions to a nonlinear partial differential equation (PDE), together with this first will provide the two themes of this article, and embed into an infinite-dimensional family of conservation laws that will accommodate the representation-theoretic aspect of the symmetries. In their 1895 article, Korteweg and de Vries (KdV) gave official status to the (then controversial) representation of solitary waves in shallow water:

$$u_t = 6uu_x - u_{xxx}$$

(again up to normalization) is by now the well-known KdV equation, where $u$ represents the amplitude of the wave and $x$ the direction along a canal. It so happens that by integrating twice the ordinary differential equation (ODE) obtained by the one-wave ansatz, $z = x - ct$ (where $c$ is the constant velocity), one sees that the solution $u$ and its derivative $u_z = u'$ satisfy identically an algebraic equation:

$$\begin{aligned} -cu' - 6uu' + u''' &= 0 \\ (-cu - 3u^2 + u'' + a)u' &= 0 \\ \frac{(u')^2}{2} &= u^3 + c\frac{u^2}{2} - au + b \end{aligned}$$

$$u = 2\wp + \text{const.} \quad \text{(up to a linear transformation)}$$
$$(\wp')^2 = 4\wp^3 - g_2\wp - g_3 = 4(\wp - e_1)(\wp - e_2)(\wp - e_3)$$

In disguise, then, the PDE and the Hamiltonian evolutions are the same; the motion becomes linear (and quasiperiodic) on the torus $\mathbb{C}/\Lambda$, where $\Lambda$ is the period lattice of the $\wp$ function. It took considerably greater effort to generalize this correspondence to higher genus. This article is devoted to such a correspondence as well as some of the surprising connections between complete integrability and other areas of mathematics such as: representation theory (the corresponding geometric objects are Grassmann manifolds as opposed to Jacobians); differential algebras (Weyl algebras, commutative rings of differential operators, and differential Galois theory); and reduction in symplectic geometry.

It is often helpful to highlight the relevant features in the simplest example, even if it is of special kind. The KdV equation and, as Hamiltonian counterpart, Neumann's system (see Neumann (1859)) will serve best. The abelian sum identified by Fagnano cannot be defined on points of a curve $X$ of genus $g > 0$; what one can add are points of the $g$-fold symmetric product $X^{(g)}$ up to linear equivalence, defining (up to noncanonical isomorphism) an abelian variety, the Jacobian $\mathrm{Jac}(X) = \mathbb{C}^g/\Lambda$; analytically, the Jacobian is described by abelian coordinates $z_1, \ldots, z_g$: if $\alpha_1, \ldots, \alpha_g, \beta_1, \ldots, \beta_g$ is a basis of 1-cycles on $X$ with standard intersection matrix and $\omega_1, \ldots, \omega_g$ is the dual basis of holomorphic differentials, then $z_j = \sum_{i=1}^{g} \int_{P_0}^{P_i} \omega_j$ is defined in terms of a fixed base point $P_0 \in X$ and of $(P_1, \ldots, P_g) \in X^{(g)}$ up to the period lattice $\Lambda$. It is in these coordinates that the Hamiltonian flows become linear. In canonical coordinates $q_1, \ldots, q_{g+1}, p_1, \ldots, p_{g+1}$, the harmonic oscillator

$$\begin{aligned} \dot{q}_i &= p_i \\ \dot{p}_i &= -e_i q_i \end{aligned}$$

when constrained to the unit sphere $\sum_{i=1}^{g+1} q_i^2$ has equations

$$\begin{aligned} \dot{q}_i &= p_i \\ \dot{p}_i &= -e_i q_i + q_i \sum_j (e_j q_j^2 - p_j^2) \end{aligned}$$

This system is completely integrable in the sense that there exist enough involutory invariants, $g$ generically (in the $(q_i, p_i)$ variables) independent functions on the $2g$-dimensional tangent bundle of the unit sphere with canonical symplectic structure; in fact the coefficients of the polynomial

$$f(\lambda) = \prod_{i=1}^{g+1} (\lambda - e_i)^2 \left( \left( \sum_{k=1}^{g+1} \frac{q_k^2}{\lambda - e_k} \right) \left( \sum_{k=1}^{g+1} \frac{p_k^2}{\lambda - e_k} + 1 \right) - \left( \sum_{k=1}^{g+1} \frac{q_k p_k}{\lambda - e_k} \right)^2 \right)$$

are invariant and the hyperelliptic Riemann surface $X$ whose model in the affine plane is given by $\mu^2 = f(\lambda)$ is called the spectral curve of the system. Since the polynomial $f(\lambda)$ is monic of degree $2g+1$ and has generically simple roots, $X$ has

genus $g$. A change of variables permits integration by quadratures,

$$q_i(t) = \frac{\vartheta[\eta_{2i-1}](0)\vartheta[\eta_{2i-1}](z_0 - \Delta + 2\sqrt{-1}tU)}{\vartheta[0](0)\vartheta[0](z_0 - \Delta + 2\sqrt{-1}tU)}$$

where $z_0$, $U \in \mathbb{C}^g$ are constant vectors, $\vartheta$ denotes the Riemann theta function of $X$, $\eta_k (k = 1, \ldots, 2g)$ are theta characteristics and $\Delta$ is the Riemann constant. While these are technical objects of classical Riemann function theory whose detailed definition is best found in a textbook (see, e.g., Mumford (1984)), the point here is that the motion is linearized along the line with direction $U$, on the hyperelliptic Jacobian Jac($X$), which is a $2^{g+1} : 1$ cover of the phase space.

A yet deeper fact links the integrable Hamiltonian motion and the (soliton) PDE, namely the statement that $\sum_{i=1}^{g+1}(e_i q_i^2 + p_i^2) = u(t_1, t_3)$ solves the KdV equation, where the variables are renamed as $x = t_1, t = t_3$ to denote two of the $g$ commuting Hamiltonian flows.

The Neumann system as well allows us to uncover another deep relation between dynamics and geometry, namely the moduli aspect: on the one hand, Mumford (1984) used the Neumann system to recover the equation of the spectral curve from a vanishing property of theta functions with characteristics, thereby giving the first characterization of the moduli subvariety of hyperelliptic curves in terms of thetanulls (for any genus). On the other hand, Françoise (1987) explored the relevance of the integrable system to the Picard–Fuchs equations. The fundamental link is provided by Arnol'd's theory, according to which a set of action-angle variables $(q_i, p_i)$, $i = 1, \ldots, n$, for a completely integrable Hamiltonian system can be calculated in terms of a basis $\gamma_i$ of the first homology of the fibers, which are $n$-dimensional tori, $\int_{\gamma_j} \mathrm{d}q_i = \delta_{ij}$; hence, in the case of an algebraically integrable system such as the Neumann example (or, in Françoise's paper, the Kowalevski top), in principle one can express the (coefficients of the) differential equations satisfied by the periods in terms of the commuting Hamiltonians, despite the fact that periods and Hamiltonians are transcendental functions the ones of the others. A more general family of period matrices is subject to the Gauss–Manin connection, and the question of whether its general abelian variety is Lagrangian with respect to a holomorphic symplectic structure on the family yields a cubic condition on the periods (Donagi and Markman 1996).

These are two major applications of PDEs to algebraic geometry: characterizing subvarieties of moduli spaces (of curves) and expressing the Gauss–Manin connection acting on sections of a Hodge-theoretic bundle over the moduli space in terms of the evolution equations of a completely integrable system. In the former case, the flows of the system act on the theta functions of a (fixed) curve; in the latter, the Hamiltonians are related, via the action variables, to computing the monodromy over the branch points of the base of the system. The generalization of specific (e.g., hyperelliptic) cases is very difficult to work out and remains largely open 40 years after the field of integrable equations started being actively investigated.

Before concluding this historical overview, a beautiful theory that escaped attention is worth mentioning. In the late nineteenth century, for example, Baker (1907) constructed the first genus-2 solutions of the KdV equation, although he was apparently not aware of the equation itself; in the process, he also defined what is known as the Hirota bilinear operator, a device introduced by R Hirota in the 1970s to capture an equivalent version of the KdV, or the more general Kadomtsev–Petviashvili (KP) equation,

$$(u_t - 6uu_x + u_{xxx})_x = u_{yy}$$

Just as the Lax pair allows for a linearization of the isospectral deformations, Hirota's bilinear form reveals the representation-theoretic (and algebro-geometric) nature of the equations, via the vanishing of a natural pairing on a pair of solutions, besides providing a formula for exact solutions; the definition of the bilinear operation is the following: for functions $F$ and $G$,

$$D_{t_n} F \cdot G = \left(\frac{\partial}{\partial t'_n} - \frac{\partial}{\partial t_n}\right) F(\underline{t}) G(\underline{t}') \big|_{\underline{t} = \underline{t}'}$$
$$\underline{t} = (t_1, t_2, \ldots)$$

so that Hirota's direct method gives the following solution: set $u = 2(\partial^2/\partial x^2) \log F$, then

$$\text{KdV} \Leftrightarrow \left(D_x D_t + D_x^4\right) F \cdot F = 0$$
$$\text{KP} \Leftrightarrow D_x^2 \frac{\left(D_x^4 + 3D_y^2 - 4D_x D_t\right) F \cdot F}{2F^2} = 0$$

Baker was intent on generalizing the properties of the Weierstrass $\wp$ function. He focused on genus 2 (and obtained partial results for general genus), in which case any curve is hyperelliptic,

$$f : \mu^2 = \lambda^{2g+1} + a_{2g}\lambda^{2g} + \cdots + a_0$$

and used a suitable basis of holomorphic differentials particular to the hyperelliptic case, whose

integrals give abelian coordinates $z_i$ that happen to be dual to the KdV flows,

$$\omega_1 = \frac{d\lambda}{2\mu},\ \omega_2 = \frac{\lambda d\lambda}{2\mu},\ \ldots,\ \omega_g = \frac{\lambda^{g-1}d\lambda}{2\mu}$$

to characterize the genus-2 theta function by differential equations (equivalent to the KdV hierarchy), as well as give the quartic equation for the Kummer surface in $\mathbb{P}^3$, namely the 2:1 image of the Jacobian of the curve mapped by the divisor $2\Theta$, that is, by a basis of the space of theta functions with second-order characteristics, simply as the determinant of

$$\begin{bmatrix} -a_0 & \frac{1}{2}a_1 & 2\wp_{11} & -2\wp_{12} \\ \frac{1}{2}a_1 & -(a_2+4\wp_{11}) & \frac{1}{2}a_3+2\wp_{12} & 2\wp_{22} \\ 2\wp_{11} & \frac{1}{2}a_3+2\wp_{12} & -(a_4+4\wp_{22}) & 2 \\ -2\wp_{12} & 2\wp_{22} & 2 & 0 \end{bmatrix}$$

where

$$\wp_{ij}(z) = -\frac{\partial^2}{\partial z_i \partial z_j}\log\sigma(z)$$

and the $\sigma$ function, defined in analogy to the genus-1 case, is proportional to the Riemann theta function.

To summarize this introduction, the exchange between algebraic geometry (the classification of algebraic varieties) and dynamical systems has been extremely fruitful in either direction: algebraic geometry surprisingly provides exact solutions to evolution equations that have special algebraic symmetries (and arise in nature!), and conversely those very evolutionary equations yield the structure of particularly complicated varieties, by characterizing their (rational) functions.

## Isospectral Deformations

The isospectral deformations in question have been encoded by Lax-pair equations, which take their name from Peter D Lax, who gave a version of the KdV equation in such form.

Lax pairs enter in two essentially different ways in the theory of integrable systems. The evolution equations take the form: $\partial_{t_n}L=[B,L]$, where $t_1,t_2,t_3,\ldots$ is a sequence of commuting time flows, $L$ is an operator whose coefficients depend on time, and $B$ is another operator of the same kind; since heuristically this is the infinitesimal version of the equation $L(t)=U(t)^{-1}L(0)U(t)$ (with $B=U^{-1}\partial_t U$), the spectrum of $L$ is preserved and provides conserved quantities; in fact, Moser (1980) speculated that every completely integrable system might have such a form.

In the form that immediately yields a hierarchy of PDEs, the (hierarchy of) deformations pertain to a ring of (formal) pseudodifferential operators, where the variable $x=t_1$ is singled out and $\partial$ denotes differentiation with respect to $x$:

$$L(t) \in \mathcal{D} = \left\{ \sum_{j=0}^{n} u_j(x)\partial^j, u_j \text{ analytic near } x=0 \right\}$$

$$\subset \mathcal{P} = \left\{ \sum_{-\infty}^{n} u_j(x)\partial^j \right\}$$

The multiplication rule that makes $\mathcal{P}$ into a ring (in fact, a $\mathbb{C}$-algebra) is composition:

$$\partial \circ u = u\partial + u'$$
$$\partial^{-1} \circ u = u\partial^{-1} - u'\partial^{-2} + u''\partial^{-3} - \cdots$$

We normalize $L$ by an automorphism of $\mathcal{D}$ (generated by a change of variable and conjugation by a function)

$$L = \partial^n + u_{n-2}(x)\partial^{n-2} + \cdots + u_0(x)$$

In $\mathcal{P}$ any (normalized) $L$ has a unique $n$th root, $n=\operatorname{ord} L$, of the form $\mathcal{L}=\partial+u_{-1}(x)\partial^{-1}+u_{-2}(x)\partial^{-2}+\cdots$. Finally, the deformation equations,

$$\partial_{t_n}\mathcal{L} = [(\mathcal{L}^n)_+, \mathcal{L}]$$

define the KP hierarchy, which takes its name from the first nontrivial deformation equation, known as the KP equation encountered above, if we set $x=t_1, y=t_2, t=t_3$ (notice that this reduces to KdV, up to rescaling, when the solution is independent of $y$). The algebro-geometric solutions are those with the property that only a finite number of time evolutions are independent. This turned out to be equivalent to a classical problem of elementary differential algebra, known as the Burchnall–Chaundy problem after the two co-authors who solved it in the 1920s.

The Burchnall–Chaundy problem: which $L(x)$'s have centralizer $\mathcal{C}_{\mathcal{D}}(L)$ that is larger than a polynomial ring $\mathbb{C}[L_1]$, $L_1 \in \mathcal{D}$? The key to the solution is the following fact (which clearly does not hold for operators in more than one variable, or finite-dimensional operators such as matrices): if $\operatorname{ord} L>0$ and $A,B\in\mathcal{D}$ both commute with $L$, then $[A,B]=0$; in particular, $\mathcal{C}_{\mathcal{D}}(L)$ is commutative, hence every maximal-commutative subalgebra of $\mathcal{D}$ is a centralizer. It was proved in the early 1900s by I Schur that $\mathcal{C}_{\mathcal{D}}(L)=\{\sum_{-\infty}^{N} c_j\mathcal{L}^j, c_j\in\mathbb{C}\}\cap\mathcal{D}$. It follows that centralizers are rings of affine curves: their transcendence degree over the field of coefficients is 1, and $\operatorname{Spec}\mathcal{C}(L)$ can be regarded as an affine curve $X_0$ (with natural compactification

$X$ by a smooth point at infinity). Burchnall and Chaundy proceeded to show that the rings of operators whose orders are not all multiples of a fixed integer >1, and having the same spectral curve $X$ (up to isomorphism), correspond to line bundles over $X$ (more precisely, rank-1 torsion-free sheaves); thus, the hierarchy of evolutions linearizes on Jac $X$, as indicated by the examples treated above.

In this setting, it has been very challenging to generalize the integrable flows, both to the higher-rank and to the higher-dimensional case. When all the operators in the commutative ring have order divisible by an integer $r > 1$, their common kernel defines a rank-$r$ vector bundle over the spectral curve, and although the theory in principle is similar to the case of line bundles, there are no explicit formulas for solution. On the other hand, in order that the spectrum be a variety $X$ of dimension $d > 1$ rather than a curve, it is natural to seek commutative rings of partial differential operators in $d$ variables; but again, while some constructions work in principle, explicit formulas are elusive.

The form in which Lax pairs occur for finite-dimensional Hamiltonian systems is quite different: here what is preserved is the spectrum of a finite-dimensional linear operator, a matrix. The first examples, from which the theory took off, were inspired guesses. The Neumann system described above fits in the following theory: Moser (1980) showed that the Neumann system together with other important classical examples are special cases of rank-2 perturbations (since $(2 = \dim\langle \boldsymbol{p}, \boldsymbol{q}\rangle)$) which preserve the spectrum of a matrix

$$L = A + a\boldsymbol{q} \otimes \boldsymbol{q} + b\boldsymbol{q} \otimes \boldsymbol{p} + c\boldsymbol{p} \otimes \boldsymbol{q} + d\boldsymbol{p} \otimes \boldsymbol{p}$$

where $A$ is a fixed constant matrix which can be normalized to a diagonal, $\mathrm{diag}(e_1, \ldots, e_{g+1})$,

$$\det\begin{bmatrix} a & b \\ c & d \end{bmatrix} \neq 0$$

and $\boldsymbol{u} \otimes \boldsymbol{v}$ denotes the matrix $[u_i v_j]$. The symplectic structure is the standard $\omega = \sum \mathrm{d}p_i \wedge \mathrm{d}q_i$ so that a Hamiltonian $H$ defines a flow

$$\dot{q}_i = \frac{\partial H}{\partial p_i}, \qquad \dot{p}_i = -\frac{\partial H}{\partial q_i}$$

and

$$\frac{\partial G}{\partial t} = -\{H, G\} = \sum \frac{\partial H}{\partial p_i}\frac{\partial G}{\partial q_i} - \frac{\partial G}{\partial p_i}\frac{\partial H}{\partial q_i}$$

The Hamiltonian flow of

$$H = \frac{1}{2}\left( a\langle B\boldsymbol{q}, \boldsymbol{q}\rangle + (b + c)\langle B\boldsymbol{q}, \boldsymbol{p}\rangle + d\langle B\boldsymbol{p}, \boldsymbol{p}\rangle - \frac{ad - bc}{2}\sum_{i \neq j} \frac{b_i - b_j}{e_i - e_j}(q_i p_j - q_j p_i)^2 \right)$$

(where $B = \mathrm{diag}(b_1, \ldots, b_{g+1})$ is any fixed diagonal matrix) is equivalent to the Lax-pair equation $\dot{L} = [M, L]$, where $M$ is a suitable matrix:

$$M = \frac{1}{2}(b - c)[b_i \delta_{ij}] + (ad - bc)\left[\frac{b_i - b_j}{e_i - e_j}(q_i p_j - q_j p_i)\right]$$

The Weinstein–Aronszajn formula

$$\det\left( I_n - \sum_{i=1}^{r} \xi_i \otimes \eta_i \right) = \det\Big( I_r - [\langle \xi_i, \eta_j\rangle] \Big)$$

(where each of the $\xi_1, \ldots, \xi_r, \eta_1, \ldots, \eta_r$ is a $(g + 1 = n)$-vector) gives for the spectral invariants

$$\begin{aligned}\frac{l(\lambda)}{e(\lambda)} &= \frac{\det(\lambda - L)}{\det(\lambda - A)} \\ &= \det(I - ((\lambda - A)^{-1}\boldsymbol{q}) \otimes (a\boldsymbol{q} + b\boldsymbol{p}) \\ &\quad - ((\lambda - A)^{-1}\boldsymbol{p}) \otimes (c\boldsymbol{q} + d\boldsymbol{p})) \\ &= \det(I_2 - W_\lambda(\boldsymbol{q}, \boldsymbol{p}))\end{aligned}$$

with

$$W_\lambda(\boldsymbol{q}, \boldsymbol{p}) = \begin{bmatrix} \langle (\lambda - A)^{-1}\boldsymbol{q}, \boldsymbol{q}\rangle & \langle (\lambda - A)^{-1}\boldsymbol{q}, \boldsymbol{p}\rangle \\ \langle (\lambda - A)^{-1}\boldsymbol{q}, \boldsymbol{p}\rangle & \langle (\lambda - A)^{-1}\boldsymbol{p}, \boldsymbol{p}\rangle \end{bmatrix} \times \begin{bmatrix} a & b \\ c & d \end{bmatrix}$$

and $\det(I - W_\lambda(\boldsymbol{q}, \boldsymbol{p})) = 1 - \mathrm{tr}\, W_\lambda + \det W_\lambda = 1 - \phi_\lambda(\boldsymbol{q}, \boldsymbol{p})$, defining the rational function $\phi_\lambda$.

Moser also showed that the system is completely integrable and linearizes on the (generalized) Jacobian of the curve $\mu^2 = e^2(\lambda)\phi_\lambda(x, y)$. Letting $a = -1$, $b = -c = 1, d = 0$ gives the Neumann system.

The dilation $\boldsymbol{q} \mapsto \lambda\boldsymbol{q}$ gives a Lax pair with a parameter, $A \mapsto A + \lambda^2 \boldsymbol{q} \otimes \boldsymbol{q} + \lambda(\boldsymbol{q} \otimes \boldsymbol{p} - \boldsymbol{p} \otimes \boldsymbol{q})$, which makes the spectral curve look more natural. Indeed,

**Remark** (Adler and van Moerbeke 1980). The Neumann flow is equivalent to the Lax pair: $\dot{L}_1 = [M_1, L_1]$, where $L_1 = A\mu^2 + \mu(\boldsymbol{q} \otimes \boldsymbol{p} - \boldsymbol{p} \otimes \boldsymbol{q}) + \boldsymbol{q} \otimes \boldsymbol{q}$ and $M_1 = A\mu + \boldsymbol{q} \otimes \boldsymbol{p} - \boldsymbol{p} \otimes \boldsymbol{q}$. Moreover, the Hamiltonians are of Adler–Kostant–Symes (AKS) type, namely projections (with respect to an ad-invariant inner product) of gradients of orbit-invariant functions to half of the splitting of a Lie algebra.

Specifically, $\{\sum_{-\infty}^{N} A_j\mu^j | A_j \in \mathrm{gl}(n, \mathbf{C})\} = K \oplus N$, with $K = \{\sum_0^N A_j\mu^j\}$ and $N = \{\sum_{-\infty}^{-1} A_j\mu^j\}$; if the inner product is $\langle A, B\rangle = \sum_{i+j=-1} \operatorname{tr} A_iB_j$, the dual of $N$ can be identified with $K = K^{\perp}$, and the Hamiltonian for the Neumann flow can be taken to be $H = \langle (1/2)(L_1\mu^{-2})^2,\ \mu^3 I_{g+1}\rangle$ under the Lie–Poisson brackets and suitable reduction. The flows linearize on the Jacobian of the (hyperelliptic) curve $\det(L_1 - \eta) = 0$.

It is possible to recover the link between the finite and infinite integrable systems (Neumann and KdV) mentioned in the introductory overview, if we notice that squared eigenfunctions for the Lax operator $L = \mathcal{L}^2 = \partial^2 + u$ become algebraic on the spectral curve: Dubrovin *et al.* (2001) introduced the Baker function, namely the unique function $\psi(x, P)$ with the following properties:

(i) For $|x|$ sufficiently small it is meromorphic on $X \setminus \{P_\infty\}$, with pole divisor bounded by $\delta = P_1 + \cdots + P_g$, independent of $x$, such that $h^0(\delta - P_\infty) = 0$, and near $P_\infty \psi(x, P)e^{-xz} = 1 + O(z^{-1})$ is holomorphic, with $z$ chosen to be $\lambda^{1/2}$ in our case.

(ii) We let $\Omega$ be the unique meromorphic differential with zeros on $\delta$ and a double pole of the form $(-\lambda + \text{holomorphic})dz^{-1}$ at $P_\infty$. Note: (1) that Riemann–Roch show that $\Omega$ is unique. (2) We also get a characterization of the dual Baker function, defined as $\psi(x, \iota P)$ in the hyperelliptic case where $\iota$ is the involution $(\lambda, \mu) \mapsto (\lambda, -\mu)$, as meromorphic on $X \setminus \{P_\infty\}$ with poles bounded by $\delta'$ and behavior $e^{-xz}(1 + O(z^{-1}))$ near $P_\infty$, where $\delta + \delta'$ are the $2g$ zeros of $\Omega$. (3) Furthermore, $\Omega = d\lambda/\mathcal{W}(\psi,\ \phi)$, where $\mathcal{W}$ is the Wronskian (with respect to the variable $x$). Then, upon fixing a meromorphic function $h$, normalized at $P_\infty, h = \lambda^{-1/2} + \text{entire}$, with $g + 1$ fixed poles distinct from $\delta$, we have:

*If* $\rho_j = \operatorname{Res}_{e_j} h\Omega,\ q_j = \sqrt{\rho_j}\psi(x, e_j),\ p_j = \sqrt{\rho_j}\phi(x, e_j),$ *then* $\Sigma_{j=1}^{g+1} q_j^2 = 1,\ \Sigma_{j=1}^{g+1} q_jp_j = 0,\ \Sigma_{j=1}^{g+1}(e_jq_j^2 + p_j^2) = u(x)$ *and* $\{q_j, p_j\}$ *satisfy the Neumann system.*

Indeed, the constraints follow from the "residue theorem" applied to the differential $h\Omega\psi\phi$ (it has a residue of $-1$ at $P_\infty$); the differential equations $\ddot{q}_j = e_jq_j - uq_j$ follow from the assumption $L\psi = \lambda\psi$.

The function $u = -2\sum_{k=1}^{g+1}(\sum_{l\neq k} e_l)q_k^2$, evolving under suitable abelian flows, is a solution of the KdV equation; the "times" of the KdV hierarchy are linear combinations of the Neumann Hamiltonians; more precisely, of the invariant vector fields determined by the tangent directions to the image of $X$ in Jac$X$, with Abel map normalized at $P_\infty$, at some point $P$: $D_P = \sum_{k=1}^{g} \lambda(P)^{g-k} D_k$.

The other way around (Moser–Trubowitz, McKean–van Moerbeke),

> *If* $L = \partial^2 + u(x)$ *is a finite-gap operator and* $e_1, \ldots, e_{g+1}$ *are among the* $2g + 1$ *edges of the gaps, there exist constants* $\rho_1, \ldots, \rho_{g+1}$ *so that the functions* $p_j(x) = \sqrt{\rho_j}\psi(x, e_j)$ *satisfy* $\sum_1^{g+1} p_j^2(x) \equiv 1$. *Since* $L\psi_j = e_j\psi_j$, *the* $p_j(x)$ *solve the Neumann system.*

The squared eigenfunctions also provide a natural interpretation for Moser's Lax pair. If $V_\lambda$ is the kernel of $L - \lambda$, then the Baker function $\psi(x, P)$ and its dual $\phi(x, P)$ give a basis of $V_\lambda$ except at the branch points $(e_i, 0)$ where $\psi = \phi$. But then the normalized basis of $V_\lambda$ is related to $\psi$, $\phi$ by a constant matrix:

$$\begin{bmatrix} y_0 \\ y_1 \end{bmatrix} = C\begin{bmatrix} \psi \\ \phi \end{bmatrix}$$

while

$$B\begin{bmatrix} \psi \\ \phi \end{bmatrix} = \begin{bmatrix} \mu & 0 \\ 0 & -\mu \end{bmatrix}\begin{bmatrix} \psi \\ \phi \end{bmatrix}$$

if $B$ is the differential operator of the Burchnall–Chaundy ring corresponding to multiplication by $\mu$, so that

$$\begin{bmatrix} -V & U \\ W & V \end{bmatrix}^{\mathrm{T}} = M_B = C\begin{bmatrix} \mu & 0 \\ 0 & -\mu \end{bmatrix}C^{-1}$$

By evaluating at $x = 0$, we find:

$$C = \frac{1}{\mathcal{W}}\begin{bmatrix} \phi' & -\psi' \\ -\phi & \psi \end{bmatrix}\Bigg|_{x=0}$$

with $\mathcal{W} = \psi\phi' - \psi'\phi$. Finally, we calculate:

$$C\begin{bmatrix} \mu & 0 \\ 0 & -\mu \end{bmatrix}C^{-1} = \frac{\mu}{\mathcal{W}}\begin{bmatrix} \psi\phi' + \psi'\phi & 2\psi'\phi' \\ -2\psi\phi & -(\psi\phi' + \psi'\phi) \end{bmatrix}$$

so that $U(\lambda) = \psi\phi' + \psi'\phi, V(\lambda) = -2\psi\phi, W(\lambda) = 2\psi'\phi'$ are polynomials like the entries of $W_\lambda(\boldsymbol{q}, \boldsymbol{p}) \cdot e^2(\lambda)$, and the fact that $UW + V^2$ does not depend on $x$ expresses the fact that $\mathcal{W} = \text{constant}$.

An object that links the two distinct occurrences of Lax pairs is Sato's infinite-dimensional Grassmann manifold. One particular model will serve as illustration, with more general settings covered by Dickey (2003). Sato defined a one-to-one correspondence between cyclic $\mathcal{D}$-submodules $\mathcal{I}$ of $\mathcal{P}$, namely of the type $\mathcal{I} = \mathcal{D}S$ (which turns out to be equivalent to the property: $\mathcal{P} = \mathcal{I} \oplus \mathcal{P}^{(-1)}$), and subspaces of a ring of formal power series, which make up an infinite-dimensional Grassmann manifold, more

precisely elements of $\mathrm{Gr}^{\emptyset}$, the "big cell." This way, KP can be viewed as deformation of $\mathcal{D}$ modules.

There are two ways to set up the Grassmannian: (1) more direct as a limit of finite-dimensional Grassmannians; (2) more intrinsic, using the rings $\mathcal{D} \subset \mathcal{P}$.

1. Let $\dim V = m + n = N, \mathrm{Gr}(m, V) = \{m - \text{frames in } V\}/\mathrm{GL}(m) \hookrightarrow \mathbb{P}(\wedge^m V)$ via $\xi^{(0)}, \ldots, \xi^{(m-1)} \mapsto \xi^{(0)} \wedge \cdots \wedge \xi^{(m-1)}$.

If we fix a basis $e_0, \ldots, e_{N-1}$ of $V$, and write a frame in coordinates, $\xi^{(i)} = \xi_{0,i} e_0 + \cdots + \xi_{N-1,i} e_{N-1}$, then

$$\xi^{(0)} \wedge \cdots \wedge \xi^{(m-1)} = \sum_{0 \le \ell_0 < \cdots < \ell_{m-1} < N} \xi_{\ell_0 \ldots \ell_{m-1}} e_{\ell_0} \wedge \cdots \wedge e_{\ell_{m-1}}$$

with $\xi_{\ell_0 \ldots \ell_{m-1}} = \det(\xi_{\ell_i, j})_{i,j=0,\ldots,m-1}$

A point in the ambient $\mathbb{P}(\wedge^m V)$ lies in the embedded $\mathrm{Gr}(m, V) \Leftrightarrow$ its projective coordinates $\xi_{\ell_0 \ldots \ell_{m-1}} (0 \le \ell_i < N)$ satisfy the Plücker relations (PRs):

$$\sum_{i=0}^{m} (-1)^i \xi_{k_0 \ldots k_{m-2} \ell_i} \xi_{\ell_0 \ldots \hat{\ell}_i \ldots \ell_m} = 0$$

Therefore,

$$\mathrm{Gr}(m, V) = (\widetilde{\mathrm{Gr}}(m, V) \backslash \{0\})/\mathrm{GL}(1)$$

where $\widetilde{\mathrm{Gr}}(m, V) = \{(\xi_Y)_{Y \subset \Delta_{mN}}$ satisfying the PRs$\}$ is a line bundle over $\mathrm{Gr}(m, V)$, $Y$ is a Young diagram consisting of rows

$$\begin{array}{l} \boxed{\ell_{m-1} - (m-1)} \\ \vdots \\ \boxed{\ell_1 - 1} \\ \boxed{\ell_0} \end{array}$$

so it is contained in the rectangle $\Delta_{mN}$.

For the commutative diagram:

$$\begin{array}{ccc} \widetilde{\mathrm{Gr}}(m', N') & \overset{\text{project}}{\longrightarrow} & \widetilde{\mathrm{Gr}}(m, N) \\ \downarrow \text{identity} & & \downarrow \text{identity} \\ \widetilde{\mathrm{Gr}}(m', N') & \overset{\text{embed}}{\hookleftarrow} & \widetilde{\mathrm{Gr}}(m, N) \end{array}$$

the following facts can be checked. Let $m \le m', n \le n', N' = m' + n'$:

(i) if $(\xi'_Y)_{Y \subset \Delta_{m'N'}}$ satisfies PRs, so does its restriction to $Y$'s within $\Delta_{mN}$;

(ii) if $(\xi_Y)_{Y \subset \Delta_{mN}}$ satisfies PRs, so does $(\xi'_Y)_{Y \subset \Delta_{m'N'}}$ where $\xi'_Y = 0$ unless $Y \subset \Delta_{mN}$.

These facts make it possible to define: $\mathrm{Gr} = (\widetilde{\mathrm{Gr}} \backslash \{0\})/\mathrm{GL}(1)$, where $\widetilde{\mathrm{Gr}} = \{(\xi_Y)_{Y \text{ all Young diagrams}}$ satisfying all PRs$\}$

$$\begin{array}{ccc} \widetilde{\mathrm{Gr}} & \overset{\text{project}}{\longrightarrow} & \widetilde{\mathrm{Gr}}(m, N) \\ \uparrow \text{dense} & & \downarrow \text{identity} \\ \widetilde{\mathrm{Gr}}^{\text{fin}} & \overset{\text{embed}}{\hookleftarrow} & \widetilde{\mathrm{Gr}}(m, N) \end{array}$$

and

$$\begin{aligned} \widetilde{\mathrm{Gr}}^{\text{fin}} &= \{(\xi) \in \widetilde{\mathrm{Gr}} : \xi_Y = 0 \text{ for almost all } Y\} \\ &= \bigcup_{m,N} \widetilde{\mathrm{Gr}}(m, N) \end{aligned}$$

The KP time deformations are defined as follows:

$$\xi_Y(t) := \sum_{\text{all } Y'} \chi_{Y'/Y}(t) \xi_{Y'} \text{ where } \chi_{Y'/Y}(t) := \det(p_{\ell'_i - \ell_j}(t))$$

$$p_0(t) = 1, p_n(t) := \sum_{\nu_1 + 2\nu_2 + 3\nu_3 + \cdots = n} t_1^{\nu_1} t_2^{\nu_2} \ldots / (\nu_1! \nu_2! \ldots)$$

Write $\chi_{Y/\emptyset}$ as $\chi_Y$, where $\chi_Y(t) = \det(p_{\ell_i - j}(t))$ are the Schur functions.

To connect with the KP hierarchy, let

$$w_n(x, t) := (-1)^n \frac{\xi_{\Delta_{n,1}}(x + t)}{\xi_\emptyset(x + t)}$$

where $x + t = (x + t_1, t_2, \ldots)$, and $S := 1 + w_1(x, t) \partial^{-1} + \cdots$. Then $\mathcal{L} = S \partial S^{-1}$ satisfies the KP hierarchy, namely $\partial_{t_n} S = B_n S - S \partial^n$, where $B_n := (S \partial^n S^{-1})_+, \Longleftrightarrow [\partial_{t_n} - B_n, \partial_{t_k} - B_k] = 0 \Longleftrightarrow \partial_{t_n} \mathcal{L} = [(\mathcal{L}^n)_+, \mathcal{L}]$.

**Note** The Plücker coordinate $\xi_\emptyset(t) = \sum_{\text{all } Y} \chi_Y(t) \xi_Y = \tau(\xi, t)$ is a generating function for the Plücker coordinates, $\xi_Y(t) = \chi_Y(\partial_t) \xi_\emptyset(t)$, where

$$\partial_t := \left( \frac{\partial}{\partial t_1}, \frac{1}{2} \frac{\partial}{\partial t_2}, \frac{1}{3} \frac{\partial}{\partial t_3}, \ldots \right)$$

Now by reducing to $\mathrm{Gr}(m, N)$ and checking that every $\xi_Y(t)$ satisfies PRs, we have a dynamical system on $\widetilde{\mathrm{Gr}}$.

**Conclusion** (Sato). Although any $f(t) \in \mathbb{C}[[t_1, t_2, \ldots]]$ admits a formal expression of the form $\sum_Y c_Y \chi_Y(t)$, where the coefficients are

$$c_Y = \chi_Y(\partial_t) f(t)|_{t=0}$$

it represents the $\tau$ function for some $\xi \in \widetilde{\mathrm{Gr}} \Longleftrightarrow$ its coefficients satisfy the following PRs:

$$\sum_{i=0}^{m} (-1)^i \chi_{k_0 \ldots k_{m-1} \ell_i} \left( \frac{\partial_t}{2} \right) \chi_{\ell_o \ldots \hat{\ell}_i \ldots \ell_m} \left( -\frac{\partial_t}{2} \right) \tau \cdot \tau = 0$$

which is the KP hierarchy in Hirota bilinear form.

2. Let

$$V := \frac{\mathcal{P}}{\mathcal{P}x} \cong \mathcal{P}_{\text{const}} = \left\{ \sum_{-\infty<i<<\infty} a_i \partial^i, \ a_i \in \mathbb{C} \right\}$$

equipped with the induced filtration $V^{(i)}$ by order, induced by

$$\mathcal{P}^{(i)} = \left\{ \sum_{-\infty<k\leq i} a_k \partial^k, \ a_k \in \mathbb{C} \right\}$$

and define

$$\begin{aligned} \text{Gr} = \{&\text{vector subspaces } W \text{ of } V \\ &\text{s.t.} \dim(W \cap V^{(0)}) = \dim V/(W + V^{(0)}) < \infty\} \end{aligned}$$

"same size" as the reference subspace $\{\sum_{\nu\leq 0} c_\nu e_\nu : c_\nu \in \mathbb{C}\} = V^{(0)}$.

The correspondence between such a $W$ and a cyclic submodule of $\mathcal{P}$ is given as follows:

$$\mathcal{I} \mapsto W = S^{-1}V^{(0)} = \{v \in V : \mathcal{I}v \subset V^{(0)}\}$$
$$W \mapsto \mathcal{I} = \{A \in \mathcal{P} : AW \subset V^{(0)}\}$$

Generic points of particular interest in constructing KP solutions make up the "big cell":

$$\begin{aligned} \text{Gr}^{\emptyset} \underset{\text{open dense}}{\subset} \text{Gr} &\Longleftrightarrow V = W \oplus V^{(0)} \\ &\Longleftrightarrow \xi_{\emptyset} \neq 0 \text{ and a } \tau \text{ function can} \\ &\qquad \text{be defined as above} \end{aligned}$$

In standard basis of $V, e_i := \partial^{-i-1} \bmod \mathcal{P}x, \ i \in \mathbb{Z}$, the action

$$\begin{aligned} xe_i &= (i+1)e_{i+1} \\ \partial e_i &= e_{i-1} \end{aligned}.$$

gives $V$ a $\mathcal{P}$-module structure. Let $\Lambda$ be the shift operator: $\partial e_i = e_{i-1}$; then

$$\xi(t) = \mathrm{e}^{(t_1\Lambda + t_2\Lambda^2 + \cdots)} \cdot \xi$$

so, this linearizes the flows!

This survey would not be complete without an example of the formula that links the $\tau$ and the theta function; more general statements and groups of symmetries can be found in Dickey (2003). A solution of the KP hierarchy can be expressed in terms of the $\tau$ function $\tau_W$ associated with an element $W$ of $\text{Gr}(H)$, in the model $\text{Gr}(H)$, where $H = L^2(S^1), H = H_+ \oplus H_-$ with standard basis $H_+ = \langle 1, z, z^2, \ldots \rangle, H_- = \langle z^{-1}, z^{-2}, \ldots \rangle$ and $p_\pm$ the projections, $\tau_W(g) = \det(\mu_g \circ p_+ \circ \mu_{g^{-1}} \circ (p_+|_W)^{-1})$, where $g = \mathrm{e}^{\Sigma t_i z^i}$. The associated Baker function $\psi_W(g, z)$ is a function of the form

$$\psi_W(g, z) = g(z)\left(1 + \sum_{i=-\infty}^{-1} a_i z^i\right)$$

with $a_i \in \mathbb{C}[[t_1, t_2, \ldots]]$ for each $i$, such that the map $z \mapsto \psi_W(g, z)$ is an element of $g^{-1}W$. If $\phi = 1 + \sum_{i=-\infty}^{-1} a_i z^i$, then $L = \phi\partial\phi^{-1}$ is a solution of the KP hierarchy.

Moreover,

$$g^{-1}\psi_W(g, \zeta) = \frac{\tau_W\left(\left(t_\alpha - \dfrac{1}{\alpha\zeta^\alpha}\right)\right)_\alpha}{\tau_W((t_\alpha))_\alpha}$$

This is the analog of the expression for the Baker function in terms of the theta function, when $W$ corresponds to an element of the Jacobian of the spectral curve $\Gamma$ via the Krichever map

$$\psi(x, P) = \exp\left(x \int \eta - xa\right) \times \frac{\vartheta(Ux + A(P) - A(D) - \Delta)\vartheta(A(D) + \Delta)}{\vartheta(A(P) - A(D) - \Delta)\vartheta(Ux - A(D) - \Delta)}$$

where $P \in \Gamma, A(-)$ is the Abel map, $\Delta$ the Riemann constant, $U \in \mathbf{C}^g$ a suitable vector, $D$ a generic divisor of points $P_1, \ldots, P_g \in \Gamma, \eta$ a differential of the second kind, and $a$ a constant depending on the curve. For the KdV solutions, the condition on $W \in \text{Gr}^{\emptyset}$ is that $z^2 W \subset W$ and the solution is

$$u_W(x, t_2, t_3, \ldots) = 2\partial \log \tau_W(x, t_2, t_3, \ldots)$$

In the Grassmannian formulation, the Hirota bilinear operator mentioned in the introductory overview makes its third and most general appearance (we regard Baker's and Hirota's definitions as the first two – the one based on a residue formula in algebraic geometry, the other on the vanishing of a differential form):

**Definitions**

(i) In $\mathcal{P}$, it is possible to conjugate any $\mathcal{L} = \partial + u_{-1}(x)\partial^{-1} + \cdots$ into $\partial$ by a $K = 1 + v_{-1}(x)\partial^{-1} + \cdots$, determined up to elements of $\mathbf{C}[\partial] = \mathcal{C}_{\mathcal{D}}(\partial)$: $K^{-1}\mathcal{L}K = \partial$.

(ii) We define a formal Baker function for $\mathcal{L}$ as the element of the module $M$ (the free, rank-1 $\mathcal{P}$-module = space of formal expressions $f = \mathrm{e}^{xz}\tilde{f}$ where $\tilde{f} = \sum_{-\infty}^{N} f_j(x)z^j$, with generator $\mathrm{e}^{xz}$) such that $\mathcal{L}\psi = z\psi$; so that $\psi = K\mathrm{e}^{xz}$ for $K$ as in (i).

(iii) We say that the formal adjoint $A^\dagger$ of a (formal pseudo) differential operator $A = \sum_{j=-\infty}^{N} u_j(x)\partial^j$ is $A^\dagger = \sum_{j=-\infty}^{N} (-\partial)^j u_j(x)$, and that the dual Baker function $\psi^\dagger$ to $\psi = K\mathrm{e}^{\Sigma t_j z^j}$ is the Baker function of $(\mathcal{L}^\dagger)$; the operator which corresponds to $K$ in (i) is $(K^\dagger)^{-1}$, that is, $(K^\dagger)^{-1}\mathcal{L}^\dagger K^\dagger = -\partial$.

Then, the KP hierarchy is equivalent to the following formula:

$$\text{Res}_z \psi(t', z)\psi^\dagger(t, z) = 0$$

Moreover, as proved in Dickey (2003), if $\psi_1$ and $\psi_2$ are formal power series of the form $\psi_1 = Ke^{\Sigma t_i z^i}, \psi_2 = Je^{-\Sigma t_i z^i}$, for $K, J \in 1 + \mathcal{P}^{(-1)}$, satisfying the condition

$$\mathrm{Res}_z \left( \partial_{i_1}^{\alpha_1} \partial_{i_2}^{\alpha_2} \cdots \partial_{i_m}^{\alpha_m} \psi \right) \cdot \phi = 0$$

then there exists an operator $\mathcal{L}$ satisfying the Lax equations, whose wave function and adjoint wave function are $\psi_1, \psi_2$, respectively.

To conclude this overview of Lax equations, we point out that they can be viewed as zero-curvature condition for a (formal) connection (on the trivial bundle over the formal deformation space whose fiber is $\mathcal{P}$), rephrasing the fact that the time flows commute and hence define time deformations; such formulation can be found in Mulase (1984).

## Symplectic Reduction and $r$ Matrices

While the Lax-pair presentation provides natural spectral invariants, the group/representation-theoretic nature of integrability (sometimes referred to as hidden symmetries) is best seen in the context of Marsden–Weinstein reduction. We perform it in the example of a generalization of Moser's rank-2 perturbation; we extract the basic construction from Adams *et al.* (1988). A more comprehensive treatment can be found in Babelon *et al.* (2003).

**Definition** We let $M_{n,r}$ denote the space of $n \times r$ complex matrices, with $n \geq r$ and give $M = M_{n,r} \times M_{n,r}$ the symplectic structure $\omega(F, G) = \mathrm{tr}(\mathrm{d}F \wedge \mathrm{d}G^{\mathrm{T}})$ for $F, G \in M$. A rank-$r$ perturbation of a fixed $n \times n$ matrix $A$ is $L = A + FG^{\mathrm{T}}$.

**Definition** We split the formal loop algebra $\widetilde{\mathrm{gl}(r)} = \widetilde{\mathrm{gl}(r)}^+ \oplus \widetilde{\mathrm{gl}(r)}^-$ where $\widetilde{\mathrm{gl}(r)}^+$ consists of $r \times r$ matricial polynomials in $\lambda$ and $\widetilde{\mathrm{gl}(r)}^-$ of strictly negative formal power series. Under the pairing $\langle X(\lambda), Y(\lambda)\rangle = \mathrm{tr}(X(\lambda)Y(\lambda))_-$ (where the subscript $-$ means the coefficient of $\lambda^{-1}$), the dual of $\widetilde{\mathrm{gl}(r)}^+$ is identified with $\widetilde{\mathrm{gl}(r)}^-$, which therefore admits a Lie–Poisson structure.

In sketch, we consider an action on $M$ whose moment map lands in $\widetilde{\mathrm{gl}(r)}^-$; we check that the AKS flows on $\widetilde{\mathrm{gl}(r)}^-$ correspond to isospectral deformations of $L = A + FG^{\mathrm{T}}$ for flows on $M_A$; finally, we perform a Marsden–Weinstein reduction for an (equivariant) $\mathrm{GL}(r)$ action to obtain a completely integrable system on a symplectic leaf, whose flows are linear on the Jacobian of the spectral curve. We recall very briefly the general definitions.

### Moment Map

1. A smooth group action of $G$ on a symplectic manifold $(M, \omega)$ is said to be Hamiltonian if there exists a "moment map" $J : M \to g^*$ such that the Hamiltonian vector field associated with $J$ and a fixed element $\xi \in g$ is the same as the infinitesimal action associated with $\xi$. However, an infinitesimal definition is given because in the formal setup the group of a Lie algebra is often delicate to define. We recall that:
2. The Lie–Poisson structure of $g^*$ is defined by

$$\{\phi, \psi\}_{g^*}(\mu) = < \mu, [\mathrm{d}\phi(\mu), \mathrm{d}\psi(\mu)] >$$
$$\text{for } \phi, \psi \in \mathcal{C}^\infty(g^*), \quad \mu \in g^*$$

where $\mathrm{d}\phi : g^* \to g^{**}$ (which in our situation will always be identified with $g$) is defined by

$$< \mathrm{d}\phi(\mu), \nu > = \frac{\mathrm{d}}{\mathrm{d}t} \phi(\mu + t\nu)\Big|_{t=0}, \quad \mu, \nu \in g^*$$

Now we say that $J : M \to g^*$ is a moment map if

3. its linear dual $j : g \to \mathcal{C}^\infty(M)$ is a Lie-algebra homomorphism; or if
4. it is a Poisson map with respect to the Lie–Poisson structure: $\phi, \psi \in \mathcal{C}^\infty(g^*) \Rightarrow \{J^*\phi, J^*\psi\} = J^*\{\phi, \psi\}_{g^*}$. In case we do have a Hamiltonian $G$-action, then the subspace $\mathcal{C}_G^\infty(M)$ of $G$-invariant functions is a Lie subalgebra of $\mathcal{C}^\infty(M)$. If $G$ acts freely and properly on $M$, then $M/G$ is a manifold with a Poisson structure inherited from the one on $M$ through the identification $\mathcal{C}^\infty(M/G) \cong \mathcal{C}_G^\infty(M)$. The symplectic leaves of $M/G$ have the form $M_\mu = J^{-1}(\mu)/G_\mu = J^{-1}(\mathcal{O}_\mu)/G$, where $\mu \in g^*$, $G_\mu$ is the isotropy group of $\mu$ in $G$ and $\mathcal{O}_\mu$ is the $G$-orbit through $\mu$. The reduced manifold $M_\mu$ has a natural symplectic structure $\omega_\mu$ such that $i^*\omega = \pi^*\omega_\mu$, where $i : J^{-1}(\mu) \to M$ is inclusion and $\pi : J^{-1}(\mu) \to M_\mu$ is the natural projection taking points to their $G_\mu$-orbits.

This class of examples can be treated with the technique of a (classical) $r$-matrix, as follows. Given a linear map $R : g \to g$, the alternating bilinear form $[X, Y]_R = (1/2)([RX, Y] + [X, RY])$ satisfies the Jacobi identity $\Leftrightarrow$ certain quadratic conditions on $R$ are satisfied. Assuming they are, for all pairs of invariant functions $I, J$ on $g^*$, we have $\{I, J\}_R = 0$ (where $\{\,,\,\}_R$ is the attendant (Lie–Poisson) structure). Indeed, $\{I, J\}_R(\mu) = \langle [\mathrm{d}I(\mu), \mathrm{d}J(\mu)]_R, \mu\rangle = (1/2)\langle [R\mathrm{d}I(\mu), \mathrm{d}J(\mu)], \mu\rangle + (1/2)\langle [\mathrm{d}I(\mu), R\mathrm{d}J(\mu)], \mu\rangle$, but, for example, $\langle [R\mathrm{d}I(\mu), \mathrm{d}J(\mu)], \mu\rangle = \langle R\mathrm{d}I(\mu), \mathrm{ad}^*\mathrm{d}J(\mu)(\mu)\rangle = 0$.

**Remark** As is clear from the proof above, our definition of invariant need only be infinitesimal, that is, $f \in I(g^*)$ iff $< \mu, [\mathrm{d}f(\mu), X] > = 0 \ \forall \mu \in g^*$, $X \in g$. Of course, when we have a corresponding Lie group the invariants are the functions which are

invariant under the natural action, such as the symmetric functions of the eigenvalues of a matrix.

### AKS Flows

For a splitting $g = K \oplus N$, as given above, with $g^* = N^* \oplus K^*$, an example of $r$-matrix is given by $R(X) = X_+ - X_-$ (where $+, -$ denote projection to $K$, $N$): the Jacobi identity is straightforward to check. As a consequence, invariants on $g^*$ are in involution with respect to $\{,\}_R$ and these are called AKS flows, after work done independently by AKS: $\dot{X} = [\mathrm{d}f(\tilde{X})_+, X] = -[\mathrm{d}f(\tilde{X})_-, X]$, given here for the special case in which we can identify $K$ with $K^*$ and $\tilde{X}$ is the element in $K^*$ that corresponds to $X \in K$.

We now proceed to the appropriate moment maps. We generalize the constant matrix $A$ introduced above (isospectral deformations) by allowing multiple eigenvalues $\alpha_i$ of multiplicities $n_i \le r, n_1 + \cdots + n_k = n$, so that $\det(A - \lambda I) = \prod_{i=1}^k (\alpha_i - \lambda)^{n_i}$. Let $a(\lambda) = \prod_{i=1}^k (\alpha_i - \lambda)$. We split an $n \times r$ matrix $F$ into $k$ blocks $F_i$ accordingly.

**Definition/statement**

(i) $J_r^n(F, G)(x_1, \ldots, x_n) = -\sum_{j=1}^n \mathrm{tr}(F_j X_j G_j^{\mathrm{T}})$ is the moment map of the action $[(g_1, \ldots, g_n)(F, G)]_i = (F_i g_i^{-1}, G_i g_i^{\mathrm{T}})$, where $g_i \in \mathrm{GL}(r)$ so that under standard identifications $J_r^n(F, G) = -(G_1^{\mathrm{T}} F_1, \ldots, G_n^{\mathrm{T}} F_n)$ and restricting the action to the diagonal subgroup $\{(g, \ldots, g)\}$, $J_r(F, G) = -G^{\mathrm{T}} F$.

(ii) For $X(\lambda) \in \widetilde{\mathrm{gl}(r)}^+$ we define $\alpha(X(\lambda)) = (X(\alpha_1), \ldots, X(\alpha_r))$ and obtain the exact sequence

$$0 \to a(\lambda)\widetilde{\mathrm{gl}(r)}^+ \xrightarrow{\iota} \widetilde{\mathrm{gl}(r)}^+ \xrightarrow{\alpha} g_r^n \to 0$$

By dualizing, and identifying $g_r^n$ to its dual by using the trace componentwise, we get

$$\alpha^*(Y_1, \ldots, Y_n) = \sum_{i=1}^k \frac{Y_i}{\lambda - \alpha_i}$$

and finally check that $\tilde{J}_r = \alpha^* \circ J_r^n$ is a moment map. By combining (i) and (ii), we get a moment map

$$\tilde{J}_r(F, G) = \sum_{i=1}^k \frac{G_i^{\mathrm{T}} F_i}{\alpha_i - \lambda} = G^{\mathrm{T}}(A - \lambda)^{-1} F$$

which becomes injective on $\mathcal{M}/H$, where $\mathcal{M}$ is a suitable open submanifold of $M$ and $H = \mathrm{GL}(n_1) \times \cdots \times \mathrm{GL}(n_k)$ acts blockwise by $(h_i F_i, h_i^{-1\mathrm{T}} G_i)$.

(iii) We also notice that the "Moser space" $M_A = \{A + FG^{\mathrm{T}} | F, G \in \mathcal{M}\}$ of rank-$r$ perturbations can be identified with the orbit space $\mathcal{M}/G_r, G_r = \mathrm{GL}(r)$ acting as in (i).

To finish, we turn on the obvious AKS flows on $\widetilde{\mathrm{gl}(r)}^-$: the key observation is that they are isospectral for the rank-$r$ perturbation $A + FG^{\mathrm{T}}$: we see that the Poisson-commutative ring $\mathcal{F}_+$ of projected invariants defines, by composition with $\tilde{J}_r$, a Poisson-commutative ring $\mathcal{F}$ of isospectral flows on $M_{n,r} \times M_{n,r}$.

## Hitchin Systems

The Hitchin system, introduced in the late 1980s, 20 years later still encompasses the most general class of "algebraically completely integrable" systems, which we now discuss. In its most basic form, the concept of "algebraic completely integrable" (ACI) Hamiltonian system, is an extra condition on the integrability of classical mechanics, in the following sense.

A Hamiltonian system with $n$ degrees of freedom, that is, defined on a symplectic manifold $M$ of (real) dimension $2n$ is (Arnol'd–Liouville) completely integrable if it admits $n$ functions in involution whose differentials are linearly independent (possibly, generically on $M$). When $M$ is a component of the set of real points of an algebraic variety $M_{\mathbb{C}}$ and the symplectic form $\omega$ and Hamiltonian function $H$ are rational without poles on $M$, the concept of algebraic complete integrability can be introduced. For this condition to hold, we require that the vector fields corresponding to the Hamiltonians in involution still have no poles on a compactification of the fibers on $M_{\mathbb{C}}$.

**Nonexample** (Mumford 1984, §4). Consider

$$M = \mathbb{R}^2, \quad \omega = \mathrm{d}x \wedge \mathrm{d}y, \quad H = x^4 + y^4$$

Here a compactification of the fiber, the affine curve $x^4 + y^4 = c$, is the projective curve $X^4 + Y^4 = cZ^4$, which is smooth (provided $c \neq 0$) and has four points at infinity. The vector field $X_H$ defined by $H$, $X_H \rfloor \omega = -\mathrm{d}H$, is tangent to the fiber in the affine plane, but has a pole at infinity as can be checked by a change of coordinates; 4 is the lowest exponent for which this simple nonexample works!

**Note** In the algebraically completely integrable situation, the fibers are abelian varieties or extensions of such by $\mathbb{C}^{*k}$ for some power $k$. This gives rise to the issues of variations of periods over the base mentioned in the introductory overview.

The Neumann system is ACI, with integral tori given by the Jacobians of the spectral curves:

$$\Gamma : \mu^2 = g(\lambda) = \prod_1^{2g+1} (\lambda - e_i) = UW + V^2$$

where

$$L = e(\lambda)\begin{bmatrix} \sum \frac{q_i p_i}{\lambda - e_i} & \sum \frac{p_i^2}{\lambda - e_i} \\ 1 + \sum \frac{q_i^2}{\lambda - e_i} & -\sum \frac{q_i p_i}{\lambda - e_i} \end{bmatrix} = \begin{bmatrix} V & U \\ W & -V \end{bmatrix}, \qquad e(\lambda) = \prod_1^{g+1}(\lambda - e_i)$$

$U = \prod_{i=1}^{g}(\lambda - \lambda_i), \quad (\lambda_1, \ldots, \lambda_g)$ "elliptical spherical coordinates"

$$\psi = \left(1, \frac{U}{V+\mu}\right) \text{ eigenvector: } L\psi = \mu\psi$$

$$\text{divisor: } \sum_{i=1}^{g}(\lambda_i, V(\lambda_i))$$

Hitchin (1982) devised a geometrical model of the spectral curve, a compact algebraic curve contained in the surface $\mathcal{T}^*\mathbb{P}^1$, and its line bundles. He also provided subsequently (1987) a dramatic generalization.

Hitchin's construction, in the Neumann-system example, highlights the following objects:

- $L \in H^0(\mathbb{P}^1, \mathrm{End}(E) \otimes \mathcal{O}(g+1))$, $E$ rank $(r=)2$ bundle over $\mathbb{P}^1$;
- $T =$ total space of the line bundle $\mathcal{O}(g+1)$ over $\mathbb{P}^1$;
- $\mu =$ tautological section: $\mathbb{P}^1 \to T$, where $\tilde{L} - \tilde{\mu}I \in H^0(T, \mathrm{End}(\tilde{E}) \otimes \tilde{\mathcal{O}}(g+1))$ (tildes denote pullback);
- $\Gamma$: $\det(\tilde{L} - \tilde{\mu}I) = 0$. The line bundle $\psi$ (eigenvectors) is defined as the kernel of $\tilde{L} - \tilde{\mu}I$; and
- the moduli space of spectral curves is a linear system on the surface $T$. Fixing $\{e_1, \ldots, e_{g+1}\}$ in the above example gives constraints that define it as subsystem of a complete linear system, as well as providing a Poisson structure on the whole $((2g-1)+g)$-dimensional manifold (base = curves, fiber = Jacobians) which reduces to the standard $\sum \mathrm{d}p_i \wedge \mathrm{d}q_i$. Equivalent to choosing a section $s \in H^0(\mathbb{P}^1, \mathcal{O}(g-1) \otimes K_{\mathbb{P}^1}^{-1})$,

$$\begin{array}{ll} \Gamma & s \leftrightarrow (e_1, \ldots, e_{g+1}) \\ \downarrow r:1 & E \to E \otimes \mathcal{O}_{\mathbb{P}^1}(g+1) \leftrightarrow L \\ \mathbb{P}^1 & (\lambda:1) \in \mathbb{P}^1 \end{array}$$

### Generalizations

- $\mathbb{P}^1 \to$ Riemann surface $X$ of genus $g > 1$;
- $E$ stable rank-$r$ vector bundle over $X$. To give a concrete example, we will take $r = 2$ and fix $\det\ E = \mathcal{O}_X$.

### Hitchin's Abelianization Program

**Fact** (Hitchin). *Every such bundle $E$ over $X$ can be realized as the direct image of a line bundle over a spectral curve $\Gamma \overset{r:1}{\to} X$.*

We introduce the moduli space $\mathcal{M} = \mathcal{SU}_X(2, \mathcal{O}_X) = S$-equivalence classes of $E$'s, $E$ semistable rank-2 bundle over $X$, $\det E = \mathcal{O}_X$. The dimension of $\mathcal{M}$ is $3g-3$.

Hitchin (1987) proved that $\mathcal{T}^*\mathcal{M}$ is ACI (generically, there exist $3g-3$ regular functions in involution with respect to the standard symplectic structure, with invariant manifolds isomorphic to Prym $\Gamma$, where $\Gamma =$ spectral curve).

To recognize the analog of the features highlighted above, we recall that Kodaira–Spencer deformation theory gives the following description of the cotangent bundle: since a rank-$r$ vector bundle over $X$ is determined by a 1-cocycle with values in $\mathrm{GL}(r, \mathcal{O}_X)$, a first-order deformation of $E$ is given by a 1-cocycle with values in the associated bundle of Lie algebras, hence by a class in $H^1(X, \mathrm{End}(E))$, so the cotangent bundle has Serre-dual fiber $H^0(X, E \otimes E^* \otimes K)$.

**Hitchin map** $(E, \phi) \in \mathcal{T}^*\mathcal{M}$ (Higgs field, trace zero, $\phi \in H^0(X, \mathrm{End}_0(E) \otimes K)$):

$H: \phi \mapsto \det\phi$ (more generally for any $r \geq 2$, $\mathrm{tr} \wedge^i \phi \in H^0(X, K^{\otimes i})$ $i = 2, \ldots, r$;
$\mu \mapsto -\mu$ defines Prym $\Gamma, \mu^2 = \det\phi \in H^0(X, K^{\otimes 2})$ defines $\Gamma$.

### Explicit Hamiltonians for the Hitchin System

The cases in which $X$ is genus 0 and 1 were solved explicitly by Nekrasov (1996) using explicit parametrizations of the moduli spaces; this includes the case of insertions (singular curves), yielding (elliptic) Gaudin models. We report the solution for the genus-2 case (van Geemen and Previato 1996).

**Remark** The map $H$ projectivizes,

$$\bar{H}: \mathbb{P}H^0(X, \mathrm{End}_0(E) \otimes K) \to \mathbb{P}H^0(X, K^{\otimes 2})$$
$$\det(c\phi) = c^2 \det\phi$$

Coordinates on $\mathcal{T}^*\mathcal{M}$ can be given as follows:
$\Theta \subset \mathrm{Pic}^{g-1}X =$ canonical theta divisor

$$\Delta: \mathcal{M} \to |2\Theta| = \mathbb{P}^{2^g-1}$$

$$E \mapsto D_E = \{\xi \in \mathrm{Pic}^{g-1}X : h^0(E \otimes \xi) > 0\}$$

$X$ hyperelliptic $\Rightarrow \Delta$ is 2:1 except for $g = 2$ (every point of $\mathcal{M}$ is fixed under the hyperelliptic

involution), where $\mathcal{M} \cong \mathbb{P}^3$. For a vector space $V$ the Euler sequence gives

$$\mathbb{P}\mathcal{T}^*\mathbb{P}V \cong I = \{(x, h) \in \mathbb{P}V \times \mathbb{P}V^* : x \in h\}$$

In our case,

$$\mathbb{P}V \times \mathbb{P}V^* = |2\Theta| \times |2\Theta_0|$$

Define six polynomial functions $H_i$ on $\mathbb{P}^3 \times \mathbb{P}^{3*}$ by the requirement: for generic $q \in \mathbb{P}^3, (H_i = 0) \cap \mathbb{P}T_q\mathbb{P}^3 = \ell_i \cup \ell_i'$, the six pairs of bitangents to $\mathcal{K} \cap \mathbb{P}T_q^*\mathbb{P}^3$, where $\mathcal{K}$ is the Kummer surface (the remaining 16 bitangents are cut out by the tropes.)

Recall that the Grassmannian of lines in $\mathbb{P}^3, \mathrm{Gr}(2,4)$, is defined by an equation $\sum_1^6 X_i^2 = 0$ in Klein's coordinates

$$(X_1 : \ldots : X_6) \in \mathbb{P}^5$$

$$X_1 = p_{01} + p_{23}, \qquad X_2 = i(p_{01} - p_{23})$$

$$X_3 = i(p_{02} - p_{13}), \qquad X_4 = p_{02} + p_{13}$$

$$X_5 = p_{03} + p_{12}, \qquad X_6 = i(p_{03} - p_{12})$$

where $p_{ij} = Z_i W_j - W_j Z_i$ are Plücker's coordinates on the line

$$\langle (Z_0 : \ldots : Z_3)(W_0 : \ldots : W_3) \rangle \subseteq \mathbb{P}^{3*}$$

Using coordinates on the incidence variety $I$ given by the sections $\Phi_i$ of the bundle projection $\mathbb{P}\mathcal{T}^*\mathbb{P}^3 \to \mathbb{P}^3$, $\phi_i : \mathbb{P}^3 \to \mathbb{P}\mathcal{T}^*\mathbb{P}^3 = I \subset \mathbb{P}^3 \times \mathbb{P}^{3*}, q \mapsto (q, \epsilon_i(q)) = (q, X_i(q, -))$, explicitly given, for $q = (x : y : z : t)$, by

$$\epsilon_1 = (y : -x : t : -z), \quad \epsilon_2 = (y : -x : -t : z)$$

$$\epsilon_3 = (z : t : -x : -y), \quad \epsilon_4 = (z : -t : -x : y)$$

$$\epsilon_5 = (t : z : -y : -x), \quad \epsilon_6 = (t : -z : y : -x)$$

$$x_j = X_j(\langle \epsilon_i(q), p \rangle)$$

**Fact** *For a point $q \in \mathbb{P}^3, p \in \mathbb{P}T_q^*\mathbb{P}^3, p \notin \epsilon_i(q)$, the ith Klein coordinate of the line $\langle \epsilon_i(q), p \rangle$ is zero and*

$$p \in \ell_i \cup \ell_i' \Leftrightarrow H_i(p, q) = \sum_{j \neq i} \frac{x_j^2}{\lambda_i - \lambda_j} = 0$$

*with $x_j = X_j(\langle \epsilon_i(q), p \rangle)$.*

**Conclusion** In an affine patch $\mathbb{C}^3 \times \mathbb{C}^{3*} \ni (q, p) = ((x : y : z : 1), (u : v : w : -(xu + yv + zw)))$

$$H_i^a(p, q) = \sum_{j \neq i} \frac{X_j(\epsilon_i(q), p)^2}{\lambda_i - \lambda_j}$$

give six Hitchin Hamiltonians, any three of which are generically independent. The $H_i^a$ have degree $\leq 4$ in $x, y, z$ and are homogeneous of degree 2 in $u, v, w$; they Poisson-commute with respect to $\mathrm{d}x \wedge \mathrm{d}u + \mathrm{d}y \wedge \mathrm{d}v + \mathrm{d}z \wedge \mathrm{d}w$.

**Example** An example is constituted by

$$\mu^2 = (\lambda^2 - 1)(\lambda^2 - 4)(\lambda^2 - 9)$$
$$((x : y : z : 1), (u : v : w : -(xu + yv + zw)))$$
$$\in \boldsymbol{A}^3 \times \boldsymbol{A}^{3*}$$

$$\begin{aligned} H_1 = {} & uv(-70xy - 32x^3y - 18xy^3 - 10z - 32x^2z \\ & + 18y^2z) + v^2(-9 - 30y^2 - 16x^2y^2 - 9y^4 - 32xy^2 \\ & - 16z^2) + u^2(-16 - 40x^2 - 16x^4 - 9x^2y^2 + 18xyz \\ & - 9z^2) + vw(-18x + 10xy^2 + 10yz - 32x^2yz \\ & - 18y^3z - 32xz^2) + uw(32y + 10x^2y - 10xz \\ & - 32x^2z - 18xy^2z + 18yz^2) + w^2(-9x^2 - 16y^2 \\ & + 10xyz - 16x^2z^2 - 9y^2z^2) \end{aligned}$$

The concept of reduction and $r$-matrix have been generalized to Hitchin systems. Notably, Hitchin later showed that the Hamiltonians of the system appear as symbols of a heat operator that corresponds to a projectively flat connection, the quantization of the moduli space of bundles, obtained by changing the complex structure of the Riemann surface $X$.

## Other Aspects

### Special Functions

Special functions have also been traditionally significant in both algebraic geometry and integrable systems. Within the examples presented, elliptic functions gave rise to surprisingly sophisticated theories. The 1-wave solution encountered in the introduction, $u = 2\wp + \text{const.}$ in the limit when one or both periods of the Weierstrass function go to zero, becomes exponential or rational, respectively. The higher-genus analogs give rise to solitons, or rational solutions. On the other hand, the KP solutions which are doubly periodic in the $x$ variable ("elliptic solitons") were classified by Krichever (cf. Dubrovin *et al.* (2001)), as forming an ACI Hamiltonian system ("elliptic Calogero–Moser"), which, 25 years later, is still generating important work, with Hamiltonian

$$H = \sum_{i=1}^{n} p_1^2 + \frac{1}{2} \sum_{i \neq j} \wp(q_i - q_j)$$

(where $\wp$ is the Weierstrass function of a lattice $L$ with associated elliptic curve $X = \mathbb{C}/L$, $q \in X$ the origin) and $u = 2\sum_{i=1}^{n} \wp(x - x_i(t_2, t_3, \ldots))$ is a solution of the KP hierarchy for suitable time flows $t_j$ of the system $(t_1 = x)$ and KP Baker function

$$\psi(x; \alpha) = \frac{\sigma(\alpha - x)}{\sigma(\alpha) - \sigma(x)} \mathrm{e}^{(\zeta(\alpha) \cdot x)}$$

The associated spectral curves have been classified in moduli by Treibich and Verdier (cf. Treibich (2001)); Krichever produced a two-field model as

well as a universal Poisson structure for the system; Donagi and Markman (1996) realized it as a generalized Hitchin system.

More classically, elliptic potentials were the subject of much study, in particular by Lamé and Hermite in the nineteenth century and Ince in the twentieth; a sample result due to Ince makes one feel like Alice in Wonderland, who "knelt down and looked along the passage into the loveliest garden you ever saw": the Lamé operator $L = -\partial^2 + a(a+1)\wp(x - x_0)$ with real, smooth potential is finite gap (namely, almost all the periodic eigenvalues are double) iff $a \in \mathbb{Z}$ (if $a$ is positive the number of gaps is $a$). A generalization to several variables (due to Chalykh and Veselov),

$$L = -\Delta + \sum_{\alpha \in R_+} g_\alpha \wp(\langle \alpha, x \rangle)$$

where $R_+$ is the set of positive roots for a simple complex Lie algebra of rank $n$, $\langle -, - \rangle$ is some scalar product in $\mathbb{R}^n$, invariant under the action of the Weyl group, and $g_\alpha = m_\alpha(m_\alpha + 1)\langle \alpha, \alpha \rangle$ for some $m_\alpha \in \mathbb{Z}$, provides one of the few known examples of quantum completely integrable rings of differential operators in several variables. Roughly speaking, this means that the centralizer of $L$ contains $n$ operators with functionally independent symbols, where $n$ is the number of variables.

What is more, Chalykh *et al.* (2003) combine differential Galois theory and elliptic function theory to characterize (under some mild assumptions) the generalized Lamé operators that are algebraically completely integrable: the differential Galois group of the solutions is abelian.

### Duality, Fourier–Mukai Transform, and Bispectrality

Duality is a concept imported from mathematical physics; as a mathematical phenomenon, it has not reached theoretical maturity. First observed in examples, as in Fock *et al.* (2000), where different definitions of dual ACI Hamiltonian systems were given (action-angle, action–action, and quantum), it resurfaced for the Hitchin system, in more than one guise, whether it be an interchange of position and momentum variables (Gawędzki and Tran-Ngoc-Bich 1998) or a duality between the Lagrangian tori that fiber two such systems, coming from a Fourier–Mukai transform, namely a twist by the (universal) Picard line bundle:

$$\begin{array}{c} \mathcal{P} \\ \downarrow \\ \mathrm{Jac}(X) \times (H^0(X,K) = T^*\mathrm{Jac}(X)) \end{array}$$

Notably, the Picard bundle was used by Nakayashiki to give a spectacular generalization of the Burchnall–Chaundy result for a genus-2 curve $X$ (more generally, Jac($X$) is replaced by a generic abelian variety in the statement): the coordinate ring of $\mathrm{Jac}(X) - \Theta_X$ is the common spectrum of a ring of commuting $(g! \times g!)$ matrix partial differential operators in $g$ variables. The Fourier transform allowed him to extend Sato's correspondence $\partial^{-1} \leftrightarrow z$ and give $\mathcal{F}$ a unique (free, rank-$g!$) $D_{\mathrm{Jac}(X)}$-module structure, where $\mathcal{F}$ is a suitable coherent sheaf over Jac($X$) generalizing the Baker function.

In this model, the interchange of the $x$ and $z$ variables is known as bispectrality (cf. Grünbaum (2001)): a somewhat narrower question is a characterization of the differential operators $L$ in $x$ for which there exists a differential operator $B$ in $k$ and a common eigenfunction:

$$\begin{cases} L\psi(x,k) = f(k)\psi(x,k) \\ B\psi(x,k) = \theta(x)\psi(x,k) \end{cases}$$

for some functions $f, \theta$, typically polynomial. This question proved to be related with the KP hierarchy and isomonodromy deformations. When to a hierarchy there is associated an ACI Hamiltonian system (as in the Neumann case shown above), bispectrality may produce a dual system, in a sense related to the ones discussed, but somewhat mysteriously so.

## Conclusion

Many important mathematical topics and individual contributions regrettably have to go unmentioned in an article of this length. The aim was to illustrate by simplest examples the geometric nature of integrable systems and equations, in the areas of spectral curves, moduli of vector bundles over them, Grassmann manifolds, special functions, Poisson geometry, representation theory, as well as mention constructions that are not yet complete, such as spectral varieties of higher dimension, dualities sweeping vaster moduli spaces, and quantization.

# Integrable Systems and Discrete Geometry

**A Doliwa**, University of Warmia and Mazury in Olsztyn, Olsztyn, Poland

**P M Santini**, Università di Roma "La Sapienza," Rome, Italy

## Introduction

Although the main subject of this article is the connection between integrable discrete systems and geometry, we feel obliged to begin with the differential part of the relation.

### Classical Differential Geometry and Integrable Systems

The oldest (1840) integrable nonlinear partial differential equation recorded in literature is the Lamé system

$$\frac{\partial^2 H_i}{\partial u_j \partial u_k} - \frac{1}{H_j}\frac{\partial H_j}{\partial u_k}\frac{\partial H_i}{\partial u_j} - \frac{1}{H_k}\frac{\partial H_k}{\partial u_j}\frac{\partial H_i}{\partial u_k} = 0, \quad i, j, k \quad \text{distinct} \qquad [1]$$

$$\frac{\partial}{\partial u_k}\left(\frac{1}{H_k}\frac{\partial H_j}{\partial u_k}\right) + \frac{\partial}{\partial u_j}\left(\frac{1}{H_j}\frac{\partial H_k}{\partial u_j}\right) + \frac{1}{H_i^2}\frac{\partial H_j}{\partial u_i}\frac{\partial H_k}{\partial u_i} = 0 \qquad [2]$$

describing orthogonal coordinates in the three-dimensional Euclidean space $\mathbb{E}^3$ (indices $i, j, k$ range from 1 to 3). Already in 1869, it was found by Ribaucour that the nonlinear Lamé system possesses a discrete symmetry enabling to construct, in a linear way, new solutions of the system from the old ones. He gave also a geometric interpretation of this symmetry in terms of certain spheres tangent to the coordinate surfaces of the triply orthogonal system. In 1918, Bianchi showed that the result of superposition of the Ribaucour transformations is, in a certain sense, independent of the order of their composition.

Such properties of a nonlinear equation are hallmarks of its integrability, and indeed, the Lamé system was solved using soliton techniques in 1997–98. The above example illustrates the close connection between the modern theory of integrable partial differential equations and the differential geometry of the turn of the nineteenth and twentieth centuries. A remarkable property of certain parametrized submanifolds (and then of the corresponding equations) studied that time is that they allow for transformations which exhibit the so-called "Bianchi permutability property." Such transformations called, depending on the context, the Darboux, Calapso, Christoffel, Bianchi, Bäcklund, Laplace,

Koenigs, Moutard, Combescure, Lévy, Goursat, Ribaucour, or the fundamental transformation of Jonas, can be geometrically described in terms of certain families of lines called line congruences.

In the connection between integrable systems and differential geometry, a distinguished role is played by the multidimensional conjugate nets, described by the Darboux system, which is just the first part [1] of the Lamé system with indices ranging form 1 to $N \geq 3$. On the level of integrable systems, this dominant role has the following explanation: the Darboux system, together with equations describing isoconjugate deformations of the net, forms the multicomponent Kadomtsev–Petviashvilii (KP) hierarchy, which is viewed as a master system of equations in soliton theory. In fact, in appropriate variables, the whole multicomponent KP hierarchy can be rewritten as an infinite system of the Darboux equations.

### Transition to the Discrete Domain

The recent progress in studying discrete integrable systems showed that, in many respects, they should be considered as more fundamental than their differential counterparts. Consequently, the natural problem of extending the geometric interpretation of integrable partial differential equations to the discrete domain arose, leading not only to the transition to the discrete domain of many results on the connection between the differential geometry and integrable systems, but also – and this seems to be even more important – to the description of integrability in a very elementary and purely geometric way.

At the level of integrable equations, the transition "from differential to discrete" often makes formulas more complicated and longer. On the contrary, at the geometric level, in such a transition the properties of discrete submanifolds, relevant to their integrability, become simpler and more transparent. Indeed, the mathematics necessary to understand the basic ideas of the integrable discrete geometry does not exceed the "ruler and compass constructions," and many proofs can be performed using elementary incidence geometry.

We will concentrate our attention on the multidimensional lattice made from planar quadrilaterals, which is the discrete analog of a conjugate net. Together with the discussion of its properties, which are the core of the geometric integrability, we briefly present the analytic methods of construction of these lattices and we also describe some basic multidimensional integrable reductions of them. Then we discuss integrable discrete surfaces; some of them have been found in the early period of the "case-by-case" studies. We shall however try to present them, from a unifying perspective, as reductions of the quadrilateral lattice (QL).

## Multidimensional Integrable Lattices

### The Quadrilateral Lattice

An $N$-dimensional lattice $\boldsymbol{x}:\mathbb{Z}^N \to \mathbb{R}^M$ is a lattice made from planar quadrilaterals, or a quadrilateral lattice (QL) in short, if its elementary quadrilaterals $\{\boldsymbol{x}, T_i\boldsymbol{x}, T_j\boldsymbol{x}, T_iT_j\boldsymbol{x}\}$ are planar; that is, iff the following system of discrete Laplace equations is satisfied:

$$\Delta_i\Delta_j\boldsymbol{x} = (T_iA_{ij})\Delta_i\boldsymbol{x} + (T_jA_{ji})\Delta_j\boldsymbol{x}, \quad i \neq j, \; i,j = 1,\dots,N \qquad [3]$$

where $A_{ij}:\mathbb{Z}^N \to \mathbb{R}$ are functions of the discrete variable; here $T_i$ is the translation operator in the $i$th direction, and $\Delta_i = T_i - 1$ is the corresponding difference operator. For simplicity, we work here in the affine setting neglecting projective geometric aspects of the theory.

**The geometric integrability scheme** In the case $N = 2$ the definition [3] allows one to uniquely construct, given two discrete curves intersecting in a common vertex and two functions $A_{12}, A_{21}: \mathbb{Z}^2 \to \mathbb{R}$, a quadrilateral surface. For $N > 2$ the planarity constraints [3] are instead compatible if and only if the geometric data $A_{ij}$ satisfy the nonlinear system

$$\Delta_kA_{ij} + (T_kA_{ij})A_{ik} = (T_jA_{jk})A_{ij} + (T_kA_{kj})A_{ik} \quad i,j,k \quad \text{distinct} \qquad [4]$$

This constraint has a very simple interpretation: in building the elementary cube (see Figure 1), the seven points $\boldsymbol{x}, T_i\boldsymbol{x}, T_j\boldsymbol{x}, T_k\boldsymbol{x}, T_iT_j\boldsymbol{x}, T_iT_k\boldsymbol{x}$, and $T_jT_k\boldsymbol{x}$ ($i,j,k$ are distinct) determine the eighth point $T_iT_jT_k\boldsymbol{x}$ as the unique intersection of three planes in the three-dimensional space.

The connection of this elementary geometric point of view with the classical theory of integrable systems is transparent: the planarity constraint corresponds to the set of linear spectral problems [3] and the resulting QL is characterized by the nonlinear equations [4], arising as the compatibility conditions for such spectral problems. Since the QL equations [4] are a master system in the theory of integrable equations, planarity can be viewed as the elementary geometric root of integrability. The idea

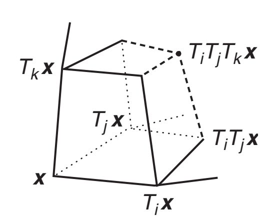

**Figure 1** The geometric integrability scheme.

that integrability be associated with the consistency of a geometric (and/or algebraic) property when increasing the dimensionality of the system is recurrent in the theory of integrable systems.

**Other forms of the Darboux system** The $i \leftrightarrow j$ symmetry of the RHS of eqns [4] implies the existence of the potentials $H_i : \mathbb{Z}^N \to \mathbb{R}$ (the Lamé coefficients) such that

$$A_{ij} = \frac{\Delta_j H_i}{H_i}, \quad i \neq j \qquad [5]$$

and then eqns [4] take the form

$$\Delta_k \Delta_j H_i - \left( T_j \frac{\Delta_k H_j}{H_j} \right) \Delta_j H_i - \left( T_k \frac{\Delta_j H_k}{H_k} \right) \Delta_k H_i = 0, \quad i, j, k \quad \text{distinct} \qquad [6]$$

which is the discrete version of the first part [1] of the Lamé system.

The Lamé coefficients allow to define the suitably normalized tangent vectors $\boldsymbol{X}_i : \mathbb{Z}^N \to \mathbb{R}^M$ by equations

$$\Delta_i \boldsymbol{x} = (T_i H_i) \boldsymbol{X}_i \qquad [7]$$

and the functions $Q_{ij} : \mathbb{Z}^N \to \mathbb{R}, i \neq j$, (the rotation coefficients) by equations

$$\Delta_i H_j = (T_i H_i) Q_{ij}, \quad i \neq j \qquad [8]$$

Then eqns [3] and [6] can be rewritten in the first-order form

$$\Delta_j \boldsymbol{X}_i = (T_j Q_{ij}) \boldsymbol{X}_j, \quad i \neq j \qquad [9]$$

$$\Delta_k Q_{ij} = (T_k Q_{ik}) Q_{kj}, \quad i, j, k \quad \text{distinct} \qquad [10]$$

The discrete Darboux system [10] implies the existence of other potentials $\rho_i$ defined by the compatible equations

$$\frac{T_j \rho_i}{\rho_i} = 1 - (T_i Q_{ji})(T_j Q_{ij}), \quad i \neq j \qquad [11]$$

The $i \leftrightarrow j$ symmetry of the RHS of eqns [11] implies the existence of yet another potential $\tau : \mathbb{Z}^N \to \mathbb{R}$,

$$\rho_i = \frac{T_i \tau}{\tau} \qquad [12]$$

which is called the $\tau$-function of the QL. In terms of the $\tau$-function, and of the functions

$$\tau_{ij} = \tau Q_{ij}, \quad i \neq j \qquad [13]$$

whose geometric interpretation will be given in a later section, the discrete Darboux equations take the following Hirota-type form:

$$(T_i T_j \tau)\tau = (T_i \tau) T_j \tau - (T_i \tau_{ji}) T_j \tau_{ij}, \quad i \neq j \qquad [14]$$

$$(T_k \tau_{ij})\tau = (T_k \tau)\tau_{ij} + (T_k \tau_{ik})\tau_{kj}, \quad i,\ j,\ k \quad \text{distinct} \qquad [15]$$

### Analytic Methods

We will show how one can construct large classes of solutions of the discrete Darboux equations and the corresponding QLs using two basic analytical methods of the soliton theory: the $\bar{\partial}$-dressing method and the algebro-geometric techniques.

**The $\bar{\partial}$-dressing method** Consider the nonlocal $\bar{\partial}$-problem

$$\bar{\partial}\chi(z) + (\hat{R}\chi)(z) = \bar{\partial}\nu(z)$$
$$\lim_{|z| \to \infty} (\chi(z) - \nu(z)) = 0 \qquad [16]$$

where $\bar{\partial} = \partial / \partial \bar{z}$, $\hat{R}$ is the integral operator

$$(\hat{R}\chi)(z) = \int_{\mathbb{C}} R(z, z')\chi(z')\, \mathrm{d}z' \wedge \mathrm{d}\bar{z}'$$

and $\nu(z)$ is a given rational function of $z$.

Let $Q_i^{\pm} \in \mathbb{C}, i = 1, \ldots, N$ be pairs of distinct points of the complex plane, which define the dependence of the kernel $R$ on the discrete variable $n \in \mathbb{Z}^N$:

$$R(z, z'; n) = \prod_{i=1}^{N} \left( \frac{z - Q_i^+}{z - Q_i^-} \right)^{n_i} \times R_0(z, z') \prod_{i=1}^{N} \left( \frac{z' - Q_i^-}{z' - Q_i^+} \right)^{n_i}$$

We consider only kernels $R_0(z, z')$ such that the nonlocal $\bar{\partial}$-problem is uniquely solvable. If $\chi(z; n)$ is the unique solution with the canonical normalization $\nu = 1$, then the function

$$\psi(z; n) = \chi(z; n) \prod_{i=1}^{N} \left( \frac{z - Q_i^-}{z - Q_i^+} \right)^{n_i}$$

satisfies the system of the Laplace equations [3] with the Lamé coefficients given by

$$H_i(n) = \lim_{z \to Q_i^+} \left( \left( \frac{z - Q_i^+}{z - Q_i^-} \right)^{n_i} \psi(z; n) \right)$$

By construction, the system of such Laplace equations is compatible, therefore the Lamé coefficients satisfy eqns [6]. To various $n$-independent measures $\mathrm{d}\mu_a$ on $\mathbb{C}$ there correspond coordinates

$$x^a(n) = \int_{\mathbb{C}} \psi(z; n) \mathrm{d}\mu_a(z)$$

of a QL $\boldsymbol{x}$, having $H_i(n)$ as the Lamé coefficients. To have real lattices, the kernel $R_0$, the points $Q_i^{\pm}$, and the measures $\mathrm{d}\mu_a$ should satisfy certain additional conditions.

One can find a similar interpretation of the normalized tangent vectors $\boldsymbol{X}_i$ and of the rotation

coefficients $Q_{ij}$. If $\chi_i(z;n)$ are the unique solutions of the nonlocal $\bar{\partial}$-problem [16] with the normalizations

$$\nu_i(z;n) = \left(\frac{Q_i^+ - Q_i^-}{z - Q_i^+}\right) \prod_{k=1,k\neq i}^{N} \left(\frac{Q_i^+ - Q_k^+}{Q_i^+ - Q_k^-}\right)^{n_k}$$

then the functions $\psi_i(z;n)$, defined by

$$\psi_i(z;n) = \prod_{k=1}^{N} \left(\frac{z - Q_k^-}{z - Q_k^+}\right)^{n_k} \chi_i(z;n)$$

satisfy the direct analog of the linear problem [9],

$$\Delta_j \psi_i(z;n) = (T_j Q_{ij}(n))\psi_j(z;n), \quad i \neq j \qquad [17]$$

where

$$Q_{ij}(n) = \lim_{z\to Q_j^+} \left( \left(\frac{z - Q_j^+}{z - Q_j^-}\right)^{n_j} \psi_i(z;n)\right)$$

Again, by construction, eqns [17] are compatible and the functions $Q_{ij}(n)$ satisfy the discrete Darboux equations [10]. The functions

$$X_i^a(n) = \int_{\mathbb{C}} \psi_i(z;n)\,\mathrm{d}\mu_a(z)$$

are coordinates of the normalized tangent vectors $\boldsymbol{X}_i$ of the QL $\boldsymbol{x}$ constructed above.

**The algebro-geometric techniques** Given a compact Riemann surface $\mathcal{R}$ of genus $g$, consider a nonspecial divisor $D = \sum_{\alpha=1}^{g} P_\alpha$. Choose $N$ pairs of points $Q_i^\pm \in \mathcal{R}$ and the normalization point $Q_\infty$. Given $n \in \mathbb{Z}^N$, there exists a unique Baker–Akhiezer function $\psi(n)$, defined as a meromorphic function on $\mathcal{R}$, with the following analytical properties: (1) as a function of $P \in \mathcal{R} \setminus \cup_{i=1}^{N} Q_i^\pm$, $\psi(n)$ may have as singularities only simple poles in the points of the divisor $D$; (2) in the points $Q_i^\pm$ function $\psi(n)$ has poles of the order $\pm n_i$; and (3) in the point $Q_\infty$ function $\psi(n)$ is normalized to 1.

When $z_i^\pm(P)$ is a local coordinate on $\mathcal{R}$ centered at $Q_i^\pm$, then condition (2) implies that the function $\psi(n)$ in a neighborhood of the point $Q_i^\pm$ is of the form

$$\psi(P;n) = \left(z_i^\pm(P)\right)^{\mp n_i} \left(\sum_{s=0}^{\infty} \xi_{s,\pm}^i(n)\left(z_i^\pm(P)\right)^s\right) \qquad [18]$$

The Baker–Akhiezer function, as a function of the discrete variable $n \in \mathbb{Z}^N$, satisfies the system of Laplace equations [3] with the Lamé coefficients $H_i(n) = \xi_{0,+}^i(n)$.

Again, by construction, the Lamé coefficients satisfy eqns [6]. To various $n$-independent measures $\mathrm{d}\mu_a$ on $\mathcal{R}$ there correspond coordinates

$$x^a(n) = \int_{\mathcal{R}} \psi(P;n)\,\mathrm{d}\mu_a(P)$$

of a QL $\boldsymbol{x}$.

We present the expression of the Baker–Akhiezer function and of the $\tau$-function of the QL in terms of the Riemann theta functions. Let us choose on $\mathcal{R}$ the canonical basis of cycles $\{a_1,\ldots,a_g,b_1,\ldots,b_g\}$ and the dual basis $\{\omega_1,\ldots,\omega_g\}$ of holomorphic differentials on $\mathcal{R}$, that is, $\oint_{a_j}\omega_k = \delta_{jk}$. Then the matrix $B$ of $b$-periods defined as $B_{jk} = \oint_{b_j}\omega_k$ is symmetric and has positively defined imaginary part. Denote by $\omega_{PQ}$ the unique differential holomorphic in $\mathcal{R}\backslash\{P,Q\}$ with poles of the first order in $P,Q$ and residues, correspondingly, 1 and –1, which is normalized by conditions $\oint_{a_j}\omega_{PQ} = 0$. The Riemann function $\theta(z;B), z \in \mathbb{C}^g$, is defined by its Fourier expansion

$$\theta(z;B) = \sum_{m\in\mathbb{Z}^g} \exp\{\pi \mathrm{i}\langle m, Bm\rangle + 2\pi\mathrm{i}\langle m, z\rangle\}$$

where $\langle\cdot,\cdot\rangle$ denotes the standard bilinear form in $\mathbb{C}^g$. Finally, the Abel map $A$ is given by $A(P) = (\int_{P_0}^{P}\omega_1,\ldots,\int_{P_0}^{P}\omega_g)$, where $P_0 \in \mathcal{R}$, and the Riemann constants vector $K$ is given by

$$K_j = \frac{1 + B_{jj}}{2} - \sum_{k\neq j}\left(\oint_{a_k}\omega_k(P)A_j(P)\omega_j\right), \quad j = 1,\ldots,g$$

The explicit form of the vacuum Baker–Akhiezer function $\psi$ can be written down with the help of the theta functions as follows:

$$\psi(n,P) = \frac{\theta\Big(A(P) + \sum_{k=1}^{N} n_k\big(A(Q_k^-) - A(Q_k^+)\big) + Z\Big)}{\theta\Big(A(Q_\infty) + \sum_{k=1}^{N} n_k\big(A(Q_k^-) - A(Q_k^+)\big) + Z\Big)} \times \frac{\theta(A(Q_\infty) + Z)}{\theta(A(P) + Z)} \exp\left(\sum_{k=1}^{N} n_k \int_{Q_\infty}^{P} \omega_{Q_k^- Q_k^+}\right)$$

where $Z = -\sum_{j=1}^{g} A(P_j) - K$.

Denote by $r_{kj}^\pm$ and $s_{kj}^\pm$ the constants in the decomposition of the abelian integrals near the point $Q_j^\pm$

$$\int_{P_0}^{P} \omega_{Q_k^- Q_k^+} \overset{P\to Q_j^\pm}{=} \mp\delta_{kj}\log z_j^\pm(P) + r_{kj}^\pm + O\Big(z_j^\pm(P)\Big)$$

$$\int_{P_0}^{P} \omega_{Q_\infty Q_k^+} \overset{P\to Q_j^\pm}{=} -\delta_{kj}\delta_{+\pm}\log z_j^\pm(P) + s_{kj}^\pm + O\Big(z_j^\pm(P)\Big)$$

Then the expression of the $\tau$-function of the QL within the subclass of algebro-geometric solutions reads

$$\tau(n) = \theta\left(\sum_{k=1}^{N} n_k\big(A\big(Q_k^-\big) - A\big(Q_k^+\big)\big) + A(Q_\infty) + Z\right) \times \prod_{k,j=1}^{N} \lambda_{kj}^{n_k n_j} \prod_{k=1}^{N} \mu_k^{n_k}$$

where

$$\lambda_{kj} = \exp\left(\frac{r_{kj}^- - r_{kj}^+}{2}\right) = \lambda_{jk}$$

$$\mu_k = \frac{1}{\lambda_{kk}} \frac{\theta(A(Q_k^+) + Z)}{\theta(A(Q_k^-) + Z)} \exp(s_{kk}^- - s_{kk}^+)$$

Finally, we remark that the geometric integrability scheme and the algebro-geometric methods work also in the finite fields setting, giving solutions of the corresponding integrable cellular automata.

### The Darboux-Type Transformations

We present the basic ideas and results of the theory of the Darboux-type transformations of the multidimensional QL.

**Line congruences and the fundamental transformation** To define the transformations we need to define first $N$-dimensional line congruences (or, simply, congruences), which are families of lines in $\mathbb{R}^M$ labeled by points of $\mathbb{Z}^N$ with the property that any two neighboring lines $\mathfrak{l}$ and $T_i\mathfrak{l}, i=1,\ldots,N$, are coplanar and therefore (eventually in the projective extension $\mathbb{P}^M$ of $\mathbb{R}^M$) intersect.

The QL $\mathcal{F}(\boldsymbol{x})$ is a fundamental transform of the QL $\boldsymbol{x}$ if the lines connecting the corresponding points of the lattices form a congruence. The superposition of a number of fundamental transformations can be compactly formulated in the vectorial fundamental transformation. The data of the vectorial fundamental transformation are: (1) the solution $\boldsymbol{Y}_i : \mathbb{Z}^N \to \mathbb{V}$, $\mathbb{V}$ being a linear space, of the linear system [9]; (2) the solution $\boldsymbol{Y}_i^* : \mathbb{Z}^N \to \mathbb{V}^*$, $\mathbb{V}^*$ being the dual of $\mathbb{V}$, of the linear system [8]. These allow to construct the linear operator-valued potential $\boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*) : \mathbb{Z}^N \to L(\mathbb{V})$, defined by the following analog of eqn [7]:

$$\Delta_i \boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*) = \boldsymbol{Y}_i \otimes (T_i \boldsymbol{Y}_i^*), \quad i = 1, \ldots, N \qquad [19]$$

Similarly, one defines $\boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*) : \mathbb{Z}^N \to L(\mathbb{V}, \mathbb{R}^M)$ and $\boldsymbol{\Omega}(\boldsymbol{Y}, H) : \mathbb{Z}^N \to \mathbb{V}$. The transforms of the lattice $\boldsymbol{x}$ and other related functions are given by

$$\mathcal{F}(\boldsymbol{x}) = \boldsymbol{x} - \boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*)\boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)^{-1}\boldsymbol{\Omega}(\boldsymbol{Y}, H)$$

$$\mathcal{F}(H_i) = H_i - \boldsymbol{Y}_i^* \boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)^{-1}\boldsymbol{\Omega}(\boldsymbol{Y}, H), \quad i = 1, \ldots, N$$

$$\mathcal{F}(\boldsymbol{X}_i) = \boldsymbol{X}_i - \boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*)\boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)^{-1}\boldsymbol{Y}_i, \quad i = 1, \ldots, N$$

$$\mathcal{F}(Q_{ij}) = Q_{ij} - \boldsymbol{Y}_j^* \boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)^{-1}\boldsymbol{Y}_i, \quad i,j = 1, \ldots, N, \ i \neq j$$

$$\mathcal{F}(\rho_i) = \rho_i\left(1 + (T_i \boldsymbol{Y}_i^*)\boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)\boldsymbol{Y}_i\right), \quad i = 1, \ldots, N$$

$$\mathcal{F}(\tau) = \tau \det \boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)$$

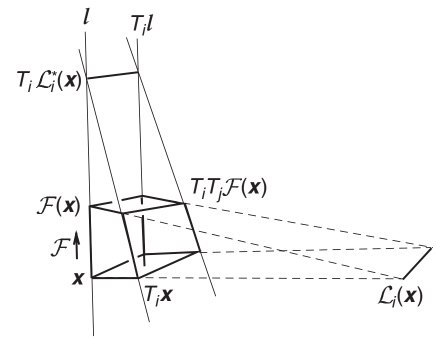

**Figure 2** The fundamental transformation as the binary transformation.

Notice that, by the coplanarity of any two neighboring lines of the congruence, also the quadrilaterals $\{\boldsymbol{x}, T_i\boldsymbol{x}, \mathcal{F}(\boldsymbol{x}), \mathcal{F}(T_i\boldsymbol{x})\}$ are planar (see Figure 2). Then the construction of the transformed lattice mimics the geometric integrability scheme. In consequence, any quadrilateral

$$\{\boldsymbol{x}, \ \mathcal{F}_1(\boldsymbol{x}), \ \mathcal{F}_2(\boldsymbol{x}), \ \mathcal{F}_1(\mathcal{F}_2(\boldsymbol{x})) = \mathcal{F}_2(\mathcal{F}_1(\boldsymbol{x}))\}$$

is planar as well. Therefore, on the discrete level, there is no difference between the lattice coordinate directions and the fundamental transformation directions. The distinction becomes visible in the limit from the QL to the conjugate net. Therefore, the vectorial description of the superposition of the fundamental transformations not only implies their permutability but also provides the explanation of the validity of the practical rule of "integrable discretization by Darboux transformations."

**The Lévy and Combescure transformations** It is easy to see that the family $\mathfrak{t}_i$ of lines passing through the points $\boldsymbol{x}$ and $T_i\boldsymbol{x}$ of a QL forms a congruence, called the $i$th tangent congruence of the lattice. When the congruence of the transformation is the $i$th tangent congruence of the lattice $\boldsymbol{x}$, then the corresponding reduction of the fundamental transformation is called the "Lévy transformation" $\mathcal{L}_i$.

It turns out that, for a generic congruence $\mathfrak{l}$, the lattice made from intersection points of the lines $\mathfrak{l}$ and $T_i^{-1}\mathfrak{l}$ is a QL, called the $i$th focal lattice of the congruence. When the fundamental transform of the lattice $\boldsymbol{x}$ is the $i$th focal lattice of the transformation congruence, then the corresponding reduction of the fundamental transformation is called the "adjoint Lévy transformation" $\mathcal{L}_i^*$.

Both Lévy transformations use only a half of the fundamental transformation data, and the corresponding reduction formulas (in the scalar case) for the lattice points read as follows:

$$\mathcal{L}_i(\boldsymbol{x}) = \boldsymbol{x} - \boldsymbol{X}_i(Y_i)^{-1}\boldsymbol{\Omega}(Y, H)$$

$$\mathcal{L}_i^*(\boldsymbol{x}) = \boldsymbol{x} - \boldsymbol{\Omega}(\boldsymbol{X}, Y^*)\,(Y_i^*)^{-1} H_i$$

Notice that the composition of the Lévy and the adjoint Lévy transformations gives (see Figure 2) the fundamental transformation, also called, for this reason, the binary transformation.

Another reduction of the fundamental transformation, important from a technical point of view, is the "Combescure transformation," in which the tangent lines of the transformed lattice $\mathcal{C}(\boldsymbol{x})$ are parallel to those of the lattice $\boldsymbol{x}$. The transformation formula reads

$$\mathcal{C}(\boldsymbol{x}) = \boldsymbol{x} - \boldsymbol{\Omega}(\boldsymbol{X}, Y^*)$$

where only the solution $Y^*$ of the adjoint linear system [8], necessary to build the transformation congruence, is needed.

**The Laplace transformations and the geometric meaning of the Hirota equation** The Laplace transform $\mathcal{L}_{ij}(\boldsymbol{x}), i \neq j$, of the QL $\boldsymbol{x}$ is the $j$th focal lattice of its $i$th tangent congruence (see Figure 3). It is uniquely determined once the lattice $\boldsymbol{x}$ is given. The transformation formulas of the lattice points and of the $\tau$-function read as follows:

$$\mathcal{L}_{ij}(\boldsymbol{x}) = \boldsymbol{x} - \frac{1}{A_{ji}} \Delta_i \boldsymbol{x} \qquad [20]$$

$$\mathcal{L}_{ij}(\tau) = \tau_{ij} = \tau Q_{ij} \qquad [21]$$

The superpositions of Laplace transformations satisfy the following identities

$$\mathcal{L}_{ij} \circ \mathcal{L}_{ji} = \mathrm{id}$$
$$\mathcal{L}_{jk} \circ \mathcal{L}_{ij} = \mathcal{L}_{ik}$$
$$\mathcal{L}_{ki} \circ \mathcal{L}_{ij} = \mathcal{L}_{kj}$$

which allow to identify them with the Schlesinger transformations of the monodromy theory.

In the simplest case $N = 2$ one obtains the so-called Laplace sequence of two-dimensional QLs

$$\boldsymbol{x}_\ell = \mathcal{L}_{12}^\ell(\boldsymbol{x}), \qquad \tau_\ell = \mathcal{L}_{12}^\ell(\tau)$$
$$\mathcal{L}_{12}^{-1} = \mathcal{L}_{21}, \quad \ell \in \mathbb{Z}$$

Equations [14] and [21] imply that the $\tau$-functions of the Laplace sequence satisfy the celebrated Hirota equation (the fully discrete Toda system)

$$\tau_\ell T_1 T_2 \tau_\ell = (T_1 \tau_\ell)(T_2 \tau_\ell) - (T_1 \tau_{\ell-1})(T_2 \tau_{\ell+1})$$

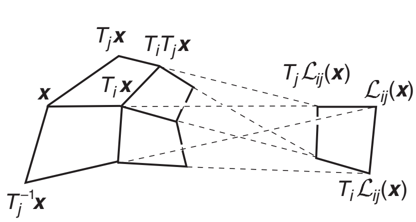

**Figure 3** The Laplace transformation $\mathcal{L}_{ij}$.

**Distinguished Integrable Reductions**

We will present here basic reductions of the multidimensional QL. The geometric criterion for their integrability is the compatibility with the geometric integrability scheme.

**The circular lattices and the Ribaucour congruences** QLs $\mathbb{Z}^N \to \mathbb{E}^M$ for which each quadrilateral is inscribed in a circle are called "circular" lattices. They are the integrable discrete analogs of submanifolds parametrized by curvature coordinates (e.g., the orthogonal coordinate systems described by the Laméequations [1]–[2]).

The integrability of circular lattices is the consequence of the fact that if the three "initial" quadrilaterals $\{\boldsymbol{x}, T_i\boldsymbol{x}, T_j\boldsymbol{x}, T_iT_j\boldsymbol{x}\}$, $\{\boldsymbol{x}, T_i\boldsymbol{x}, T_k\boldsymbol{x}, T_iT_k\boldsymbol{x}\}$, $\{\boldsymbol{x}, T_j\boldsymbol{x}, T_k\boldsymbol{x}, T_jT_k\boldsymbol{x}\}$ are circular, then also the three new quadrilaterals constructed by adding the vertex $T_iT_jT_k\boldsymbol{x}$ are circular as well (see Figure 4). In fact, all the eight vertices belong to a sphere, and, in consequence, all the vertices of any $K$-dimensional, $K = 2, \ldots, N$, elementary cell belong to a $(K-1)$-dimensional sphere.

There are various equivalent algebraic descriptions of the circular lattices:

1. the normalized tangent vectors $\boldsymbol{X}_i$ satisfy the constraint
$$\boldsymbol{X}_i \cdot T_i\boldsymbol{X}_j + \boldsymbol{X}_j \cdot T_j\boldsymbol{X}_i = 0, \quad i \neq j$$
2. the scalar function $\boldsymbol{x} \cdot \boldsymbol{x} : \mathbb{Z}^N \to \mathbb{R}$ satisfies the Laplace equations [3] of the lattice $\boldsymbol{x}$;
3. the functions $X_i^\circ = (\boldsymbol{x} + T_i\boldsymbol{x}) \cdot \boldsymbol{X}_i : \mathbb{Z}^N \to \mathbb{R}$ satisfy the same linear system [9] as the normalized tangent vectors $\boldsymbol{X}_i$; and
4. the functions $\boldsymbol{X}_i \cdot \boldsymbol{X}_i : \mathbb{Z}^N \to \mathbb{R}$ satisfy eqns [11] and thus can serve as the potentials $\rho_i$.

The Ribaucour transformation $\mathcal{R}$ is the restriction of the fundamental transformation to the class of circular lattices such that also the "side" quadrilaterals $\{\boldsymbol{x}, T_i\boldsymbol{x}, \mathcal{R}(\boldsymbol{x}), \mathcal{R}(T_i\boldsymbol{x})\}$ are circular. Again there is no geometric difference between the lattice directions and the Ribaucour transformation direction. Moreover, the quadrilaterals $\{\boldsymbol{x}, \mathcal{R}_1(\boldsymbol{x}),$

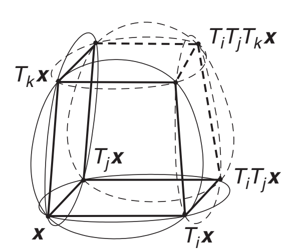

**Figure 4** The geometric integrability of circular lattices.

$\mathcal{R}_2(\boldsymbol{x}), \mathcal{R}_1(\mathcal{R}_2(\boldsymbol{x})) = \mathcal{R}_2(\mathcal{R}_1(\boldsymbol{x}))\}$ are circular as well. In consequence, the vertices of the elementary $K$-cells, $K = 2, \ldots, N$, of the circular lattice and the corresponding vertices of its Ribaucour transform are contained in a $K$-dimensional sphere. Finally, for $K = N$, one obtains a special $\mathbb{Z}^N$ family of $N$-dimensional spheres, called the Ribaucour congruence of spheres.

Algebraically, the Ribaucour transformation needs only a half of the data (necessary to build the congruence) of the fundamental transformation. The data of the vectorial Ribaucour transformation consists of the solution $\boldsymbol{Y}_i^*: \mathbb{Z}^N \to \mathbb{V}^*$, of the linear system [8]. Then, because of the circularity constraint, $\boldsymbol{Y}_i: \mathbb{Z}^N \to \mathbb{V}$ given by

$$\boldsymbol{Y}_i = (\boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*) + T_i\boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*))^{\mathrm{T}}\boldsymbol{X}_i$$

is a solution of the linear system [9], and the constraints

$$\boldsymbol{\Omega}(\boldsymbol{Y}, H) + \boldsymbol{\Omega}(X^{\circ}, \boldsymbol{Y}^*)^{\mathrm{T}} = 2\,\boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*)^{\mathrm{T}}\boldsymbol{x}$$
$$\boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*) + \boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)^{\mathrm{T}} = 2\,\boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*)^{\mathrm{T}}\boldsymbol{\Omega}(\boldsymbol{X}, \boldsymbol{Y}^*)$$

are admissible.

We remark that the above constraints have a simple geometric meaning when one considers the circular lattices in $\mathbb{E}^M$ as the stereographic projections of QLs in the Möbius sphere $S^M$; that is, as a special case of QLs subjected to quadratic constraints.

**The symmetric lattice** Given a QL $\boldsymbol{x}$ with rotation coefficients $Q_{ij}$ and potentials $\rho_i$ given by [11], then the functions $\tilde{Q}_{ij}$, defined by equation

$$\rho_j T_j \tilde{Q}_{ij} = \rho_i T_i Q_{ji}, \quad i \neq j$$

and called, because of their geometric interpretation, the backward rotation coefficients, satisfy the Darboux system [10] as well. A QL is called symmetric if its forward rotation coefficients $Q_{ij}$ are also its backward rotation coefficients. Again the constraint is compatible with the geometric integrability scheme, that is, it propagates in the construction of the lattice. One can show that a QL is symmetric if and only if its rotation coefficients satisfy the following trilinear constraint:

$$(T_iQ_{ji})(T_jQ_{kj})(T_kQ_{ik}) = (T_jQ_{ij})(T_iQ_{ki})(T_kQ_{jk})$$
$$i, j, k \quad \text{distinct}$$

To obtain the corresponding reduction of the fundamental transformation we again need only half of the data. Given a solution $\boldsymbol{Y}_i^*: \mathbb{Z}^N \to \mathbb{V}^*$, of the linear system [8], then, because of the symmetric constraint, $\boldsymbol{Y}_i: \mathbb{Z}^N \to \mathbb{V}$, defined by

$$\boldsymbol{Y}_i = \rho_i (T_i \boldsymbol{Y}^*)^{\mathrm{T}}$$

is the solution of the linear system [9]; notice that, equivalently, we could start from $\boldsymbol{Y}_i$. The constraint

$$\boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*) = \boldsymbol{\Omega}(\boldsymbol{Y}, \boldsymbol{Y}^*)^{\mathrm{T}}$$

is then admissible and gives a new symmetric lattice.

There are other multidimensional reductions of the QL like, for example, the $D$-invariant and Egorov lattices or discrete versions of immersions of spaces of constant negative curvature. We remark that the transformations and reductions discussed above have also a clear interpretation on the level of the analytic methods.

## Integrable Discrete Surfaces

In this section we present some distinguished examples of discrete integrable surfaces. Notice that, although the geometric integrability scheme is meaningless for $N = 2$, it can be applied indirectly, by considering the discrete surfaces, together with their transformations, as sublattices of multidimensional lattices.

We remark also that one can consider integrable evolutions of discrete curves, which give equations of the Ablowitz–Ladik hierarchy, and the corresponding integrable spin chains.

### Discrete Isothermic Nets

An isothermic lattice is a two-dimensional circular lattice $\boldsymbol{x}: \mathbb{Z}^2 \to \mathbb{E}^M$ with harmonic quadrilaterals; that is, given $\boldsymbol{x}, T_1\boldsymbol{x}$ and $T_2\boldsymbol{x}$, then the point $T_1T_2\boldsymbol{x}$ is the intersection of the circle (passing through $\boldsymbol{x}, T_1\boldsymbol{x}$ and $T_2\boldsymbol{x}$) and the line passing through $\boldsymbol{x}$ and the meeting point of the tangents to the circle at $T_1\boldsymbol{x}$ and $T_2\boldsymbol{x}$ (see Figure 5). Therefore, given two discrete curves intersecting in the common vertex $\boldsymbol{x}_0$, the unique isothermic lattice can be found using the above "ruler and compass" construction.

Algebraically the reduction looks as follows. Any oriented plane in $\mathbb{E}^M$ can be identified with the complex plane $\mathbb{C}$. Given any four complex points $z_1, z_2, z_3$, and $z_4$, their complex cross-ratio is defined by

$$q(z_1, z_2, z_3, z_4) = \frac{(z_1 - z_2)(z_3 - z_4)}{(z_2 - z_3)(z_4 - z_1)}$$

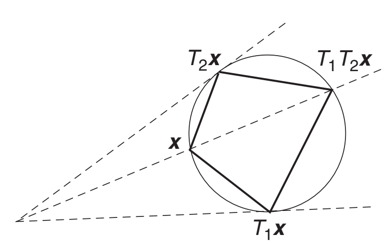

**Figure 5** Elementary quadrilaterals of the isothermic lattice.

One can show that the cross-ratio is real if and only if the four points are cocircular or collinear. In particular, a harmonic quadrilateral with vertices numbered anticlockwise has cross-ratio equal to –1. Therefore, abusing the notation (it can be formalized using Clifford algebras), the isothermic lattice is defined by the condition

$$q(\boldsymbol{x}, T_1\boldsymbol{x}, T_1T_2\boldsymbol{x}, T_2\boldsymbol{x}) = -1$$

We remark that the definition of isothermic lattices can be slightly generalized allowing for the above cross-ratio to be a ratio of two real functions of single discrete variables.

The restriction of the Ribaucour transformation to the class of isothermic lattices, named after Darboux who constructed it for isothermic surfaces, has as its data a real parameter $\lambda$ and the starting point $\mathcal{D}(\boldsymbol{x}_0)$, and can be described as follows. Given the elementary quadrilateral $\{\boldsymbol{x}, T_1\boldsymbol{x}, T_2\boldsymbol{x}, T_1T_2\boldsymbol{x}\}$ of the isothermic lattice, and given the point $\mathcal{D}(\boldsymbol{x})$, then the points $\mathcal{D}(T_1\boldsymbol{x})$ and $\mathcal{D}(T_2\boldsymbol{x})$ belong to the corresponding planes and are constructed from equations

$$q(\boldsymbol{x}, \mathcal{D}(\boldsymbol{x}), \mathcal{D}(T_1\boldsymbol{x}), T_1\boldsymbol{x}) = \lambda$$
$$q(\boldsymbol{x}, \mathcal{D}(\boldsymbol{x}), \mathcal{D}(T_2\boldsymbol{x}), T_2\boldsymbol{x}) = -\lambda$$

It turns out that the point $\mathcal{D}(T_1T_2\boldsymbol{x})$, constructed by the application of the geometric integrability scheme, is such that the quadrilateral $\{\mathcal{D}(\boldsymbol{x}), \mathcal{D}(T_1\boldsymbol{x}), \mathcal{D}(T_2\boldsymbol{x}), \mathcal{D}(T_1T_2\boldsymbol{x})\}$ is harmonic. Moreover, the construction of the Darboux transformation is compatible; that is, the new side quadrilaterals have the correct cross-ratios $\lambda$ and $-\lambda$.

There are various integrable reductions of the isothermic lattice, for example, the constant mean curvature lattice and the minimal lattice.

## Asymptotic Lattices and Their Reductions

An asymptotic lattice is a mapping $\boldsymbol{x}: \mathbb{Z}^2 \to \mathbb{R}^3$ such that any point $\boldsymbol{x}$ of the lattice is coplanar with its four nearest neighbors $T_1\boldsymbol{x}, T_2\boldsymbol{x}, T_1^{-1}\boldsymbol{x}, T_2^{-1}\boldsymbol{x}$ (see Figure 6). Such a plane is called the tangent plane of the asymptotic lattice in the point $\boldsymbol{x}$.

It can be shown that any asymptotic lattice $\boldsymbol{x}$ can be recovered from its suitably rescaled normal (to the tangent plane) field $\boldsymbol{N}: \mathbb{Z}^2 \to \mathbb{R}^3$ via the discrete analog of the Lelieuvre formulas

$$\Delta_1\boldsymbol{x} = (T_1\boldsymbol{N}) \times \boldsymbol{N}, \qquad \Delta_2\boldsymbol{x} = \boldsymbol{N} \times (T_2\boldsymbol{N}) \qquad [22]$$

By the compatibility of the Lelieuvre formulas, the normal field $\boldsymbol{N}$ satisfies the discrete Moutard equation

$$T_1T_2\boldsymbol{N} + \boldsymbol{N} = F(T_1\boldsymbol{N} + T_2\boldsymbol{N}) \qquad [23]$$

for some potential $F: \mathbb{Z}^2 \to \mathbb{R}$.

Given a scalar solution $\theta$ of the Moutard equation [23], a new solution $\mathcal{M}(\boldsymbol{N})$ of the Moutard equation, with the new potential

$$\mathcal{M}(F) = \frac{(T_1\theta)(T_2\theta)}{(T_1T_2\theta)\theta} F$$

can be found via the Moutard transformation equations

$$\mathcal{M}(T_1\boldsymbol{N}) \mp \boldsymbol{N} = \frac{\theta}{T_1\theta}(\mathcal{M}(\boldsymbol{N}) \mp T_1\boldsymbol{N}) \qquad [24]$$

$$\mathcal{M}(T_2\boldsymbol{N}) \pm \boldsymbol{N} = \frac{\theta}{T_2\theta}(\mathcal{M}(\boldsymbol{N}) \pm T_2\boldsymbol{N}) \qquad [25]$$

Now, via the Lelieuvre formulas [22], one can construct a new asymptotic lattice $\mathcal{M}(\boldsymbol{x}) = \boldsymbol{x} \pm \mathcal{M}(\boldsymbol{N}) \times \boldsymbol{N}$. The lines connecting corresponding points of the asymptotic lattices $\boldsymbol{x}$ and $\mathcal{M}(\boldsymbol{x})$ are tangent to both lattices. Such a $\mathbb{Z}^2$-family of lines in $\mathbb{R}^3$ is called Weingarten (or $W$ for short) congruence. Notice that this is not a congruence as considered earlier.

Various integrable reductions of asymptotic lattices are known in the literature: pseudospherical lattices, asymptotic Bianchi lattices and isothermally asymptotic (or Fubini–Ragazzi) lattices, and discrete (proper and improper) affine spheres.

Formally, the Moutard transformation is a reduction of the (projective version of the) fundamental transformation for the Moutard reduction of the Laplace equation. However, the geometric relation between asymptotic lattices and QLs is more subtle and the geometric scenery of this connection is the line geometry of Plücker. Straight lines in $\mathbb{R}^3 \subset \mathbb{P}^3$ are considered there as points of the so-called Plücker quadric $\mathcal{Q}_P \subset \mathbb{P}^5$. A discrete asymptotic net in $\mathbb{P}^3$, viewed as the envelope of its tangent planes, corresponds to a congruence of isotropic lines in $\mathcal{Q}_P$, whose focal lattices represent the asymptotic directions. The discrete $W$-congruences are represented by two-dimensional QLs in the Plücker quadric.

## The Koenigs Lattice

A two-dimensional QL $\boldsymbol{x}: \mathbb{Z}^2 \to \mathbb{P}^M$ is called a Koenigs lattice if, for every point $\boldsymbol{x}$ of the lattice,

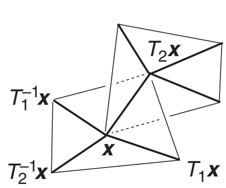

**Figure 6** Asymptotic lattices.

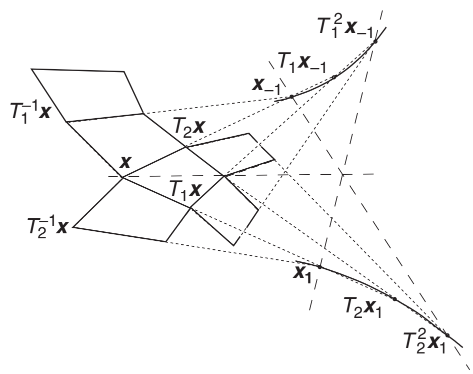

**Figure 7** The Koenigs lattice.

the six points $x_{\pm 1}, T_i x_{\pm 1}, T_i^2 x_{\pm 1}, i = 1, 2,$ of its Laplace transforms belong to a conic (see Figure 7). The nonlinear constraint in definition of the Koenigs lattice can be linearized, with the help of the Pascal "mystic hexagon" theorem, to the form that the line passing through $x$ and $T_1 T_2 x$, the line passing through $x_1$ and $T_1^2 x_{-1}$, and the line passing through $x_{-1}$ and $T_2^2 x_1$ intersect in a point.

Algebraically, the geometric Koenigs lattice condition means that the Laplace equation of the lattice in homogeneous coordinates $x : \mathbb{Z}^2 \to \mathbb{R}_*^{M+1}$ can be gauged into the form

$$T_1 T_2 x + x = T_1(Fx) + T_2(Fx) \qquad [26]$$

It turns out that, if $N$ is a solution of the Moutard equation [23], then $x = T_1 N + T_2 N$ satisfies the Koenigs lattice equation. Therefore, the algebraic theory of the discrete Koenigs lattice equation [26], its (Koenigs) transformation, and the permutability of the superpositions of such transformations is based on the corresponding theory for the Moutard equation [23].

Geometrically, the Koenigs lattices are selected from the QLs as follows. Given a two-dimensional QL $x : \mathbb{Z}^2 \to \mathbb{P}^M$ and given a congruence $\mathfrak{l}$ with lines passing through the corresponding points of the lattice. Denote by $y_i = T_i^{-1}\mathfrak{l} \cap \mathfrak{l}, i = 1, 2,$ points of the focal lattices of the congruence. For every line $\mathfrak{l}$, denote by $\imath$ the unique projective involution exchanging $y_i$ with $T_i y_i$. If, for every congruence $\mathfrak{l}$, the lattice $\mathcal{K}(x) : \mathbb{Z}^2 \to \mathbb{P}^M$, with points $\mathcal{K}(x) = \imath(x)$, is a QL, then the lattice $x$ is a Koenigs lattice. The above construction gives also the corresponding reduction of the fundamental transformation.

A distinguished reduction of the Koenigs lattice is the quadrilateral Bianchi lattice. The natural continuous limit of the corresponding equation is equivalent to the Bianchi (or hyperbolic Ernst) system describing the interaction of planar gravitational waves.

### Discrete Two-Dimensional Schrödinger Equation

In the previous sections we have discussed examples of integrable discrete geometries described by equations of hyperbolic type. Below we present some results associated with the elliptic case; it is remarkable that the QL provides a way to connect these two subjects.

Consider a solution $N : \mathbb{Z}^2 \to \mathbb{R}^3$ of the general self-adjoint five-point scheme on the star of the $\mathbb{Z}^2$ lattice

$$aT_1 N + T_1^{-1}(aN) + bT_2 N + T_2^{-1}(bN) - cN = 0 \quad [27]$$

then the lattice $x : \mathbb{Z}^2 \to \mathbb{R}^3$ obtained by the Lelieuvre type formulas

$$\begin{aligned} \Delta_1 x &= -\left(T_2^{-1} b\right) N \times T_2^{-1} N \\ \Delta_2 x &= \left(T_1^{-1} a\right) N \times T_1^{-1} N \end{aligned} \qquad [28]$$

is a QL having $N$ as normal (to the planes of elementary quadrilaterals) vector field.

The following gauge-equivalent form of eqn 27, namely

$$\frac{\Gamma}{T_1\Gamma} T_1\psi + T_1^{-1}\left(\frac{\Gamma}{T_1\Gamma}\psi\right) + \frac{\Gamma}{T_2\Gamma} T_2\psi + T_2^{-1}\left(\frac{\Gamma}{T_2\Gamma}\psi\right) - q\psi = 0 \qquad [29]$$

an integrable discretization of the Schrödinger equation

$$\frac{\partial^2 \psi}{\partial x_1^2} + \frac{\partial^2 \psi}{\partial x_2^2} - Q\psi = 0$$

is also the Lax operator associated with an integrable generalization of the Toda law to the square lattice.

The five-point scheme [27] is also a distinguished illustrative example of the sublattice theory. Indeed, it can be obtained restricting to the even sublattice $\mathbb{Z}_e^2$ the discrete Cauchy–Riemann equations

$$T_1 T_2 \phi - \phi = \mathrm{i}G(T_1\phi - T_2\phi) \qquad [30]$$

Because of the equivalence (on the discrete level!) between eqn [30] and the discrete Moutard equation [23], the five-point scheme [27] inherits integrability properties (Darboux-type transformations, superposition formulas, analytic methods of solution) from the corresponding (and simpler) integrability properties of the discrete Moutard equation.

# Integrable Systems and Recursion Operators on Symplectic and Jacobi Manifolds

**R Caseiro and J M Nunes da Costa**, Universidade de Coimbra, Coimbra, Portugal

## Introduction

Let $(M, \omega)$ be a symplectic manifold of dimension $2n$. We denote by $\sharp$ the natural isomorphism between $T^*M$ and $TM$, defined by the equation

$$i_{\sharp_\alpha}\omega = -\alpha, \quad \alpha \in T^*M \qquad [1]$$

We say that ${}^\sharp df$ is the Hamiltonian vector field defined by the Hamiltonian $f : M \to \mathbb{R}$.

Associated with the nondegenerated closed 2-form $\omega$ there is also a Poisson bracket on $C^\infty(M)$, the space of real differentiable functions on $M$, defined by

$$\{.,.\}_\omega : C^\infty(M) \times C^\infty(M) \to C^\infty(M)$$
$$(f, g) \mapsto \{f, g\}_\omega = \omega({}^\sharp df, {}^\sharp dg)$$

We say that two smooth functions $F, G : M \to \mathbb{R}$ are in involution if

$$\{F, G\}_\omega = 0 \qquad [2]$$

Suppose we have $n$ independent smooth functions in involution $H_1, \ldots, H_n$, such that the associated Hamiltonian vector fields $X_1, \ldots, X_n$ are complete on the level manifold

$$M_a = \{x \in M : H_j(x) = a_j, j = 1, \ldots, n\} \qquad [3]$$

The classical theorem of Arnol'd–Liouville states that

1. the submanifold $M_a$ is invariant with respect to each one of the Hamiltonian commuting flows generated by $H_1, \ldots, H_n$;
2. every connected component of $M_a$ is diffeomorphic to a product of a Euclidean space by a torus, $\mathbb{R}^{n-k} \times \mathbb{T}^k$;
3. there exist coordinates $f_1, \ldots, f_{n-k}, \varphi_1, \ldots, \varphi_k$ in $M_a$ such that the Hamiltonian systems in $M_a$, associated with the Hamiltonians $H_j$, have the form

$$\dot{f}_s = c^j_s \dot{\varphi}_m = \omega^j_m \quad (\omega \equiv \omega(a),\ c = \text{const.}) \qquad [4]$$

4. if $M_a$ is compact then it is diffeomorphic to $\mathbb{T}^n$ and there exists a neighborhood of $M_a$ on $M$, symplectically diffeomorphic to $\mathbb{B}^n \times \mathbb{T}^n$.

A completely integrable Hamiltonian system is a Hamiltonian vector field $X$, that admits $n$ integrals $H_1, \ldots, H_n$ satisfying the hypothesis of Arnol'd–Liouville theorem.

It may happen that a system has more than $n$ independent integrals of motion. In this case it is called superintegrable and not all the integrals are in involution. Supposing that

$$M_a = \{x \in M : H_j(x) = a_j, j = 1, \ldots, n+k\}$$

is compact and connected and that $H_1, \ldots, H_{n-k}$ commute with all the $n+k$ integrals, then $M_a$ is diffeomorphic to the torus $\mathbb{T}^{n-k}$. In particular, if the system is maximally superintegrable, that is, $k = n-1, M_a$ is diffeomorphic to $T^1 = S^1$ and all the trajectories are closed.

To prove that a system is completely integrable, we have to find a sufficient number of integrals of the system in involution. The Lax pair is an extremely powerful tool in this task, although it does not guarantee the involution of the integrals found.

A Lax pair of a vector field $X$ on a smooth manifold $M$ is a pair of operators $(L, M)$ such that

$$\dot{L} = [M, L] = ML - LM \qquad [5]$$

This equation is equivalent to

$$U^{-1}LU = L_0 \qquad [6]$$

where $U$ is the solution operator of the Cauchy problem

$$\dot{U} = MU, \quad U(0) = I \qquad [7]$$

So, the eigenvalues of $L$ are integrals of $X$. Notice that all the pairs $(L^k, M), k \in \mathbb{N}$, are Lax pairs of the system and we may conclude that the functions $\operatorname{tr} L^k, k \in \mathbb{N}$, are integrals of $X$.

The first goal of this article is to relate integrable Hamiltonian systems and recursion operators, where some of the most important properties of the latter are exhibited. Very naturally, the Poisson–Nijenhuis manifolds appear in this context and the Toda lattice is the example chosen in order to show the whole theory working in practice. Also, we see how recursion operators can help in the construction of quadratic algebras of integrals of motion and, in the last section, we present the generalization to Jacobi manifolds of the Nijenhuis structures defined for Poisson manifolds.

## Integrable Systems on Poisson–Nijenhuis Manifolds

Let $X$ be a vector field on a smooth manifold $M$. A recursion operator of $X$ is a $(1,1)$-tensor $R$ invariant of $X$:

$$\mathcal{L}_X R = 0 \qquad [8]$$

The $(1,1)$-tensors, and in particular the recursion operators, may be regarded as fiber endomorphisms of $TM$. So, given a $(1,1)$-tensor $R$, we denote by ${}^tR : T^*M \to T^*M$ the transpose of $R : TM \to TM$, that is,

$$\langle {}^tR(\alpha), X\rangle = \langle \alpha, R(X)\rangle, \quad \alpha \in T^*M,\ X \in TM \qquad [9]$$

where $\langle .,. \rangle$ denotes the canonical pairing between $T^*M$ and $TM$.

Recursion operators also generate symmetries. If $R$ is a recursion operator and $Y$ is a symmetry of $X$, that is, $[X, Y] = 0$, then $RY$ is also a symmetry of $X$. So, given a recursion operator $R$ of $X$, we may construct a sequence of symmetries of $X$, $R^kY, k \in \mathbb{N}$.

The Nijenhuis torsion of a $(1,1)$-tensor $R$ is the $(1,2)$-tensor $\mathcal{T}(R)$ defined by

$$\mathcal{T}(R)(X, Y) = [RX, RY] - R([X, RY] + [RX, Y] - R[X, Y]), \quad X, Y \in \mathfrak{X}(M) \qquad [10]$$

A Nijenhuis operator is a $(1,1)$-tensor, $R$, with vanishing Nijenhuis torsion, that is,

$$\mathcal{L}_{RX} R = R\mathcal{L}_X R \qquad [11]$$

These operators can generate sequences of closed 1-forms. If $R$ is a Nijenhuis operator and $\alpha$ is a closed 1-form such that $\mathrm{d}{}^tR(\alpha) = 0$, then $\mathrm{d}{}^tR^k(\alpha) = 0, k \in \mathbb{N}$. In the particular case of $\alpha$ being exact, that is, $\alpha = \mathrm{d}f$ and the first cohomology group being trivial, then we have a sequence of local integrals of motion $\mathrm{d}f_k = {}^tR^k(\mathrm{d}f)$.

A Nijenhuis recursion operator $R$ and a symmetry $Y$ of a vector field $X$ lead to a sequence of commuting symmetries $R^kY, k \in \mathbb{N}$,

$$[R^iY, R^jY] = 0, \quad i, j \in \mathbb{N} \qquad [12]$$

To define the integrability in terms of a $(1,1)$-tensor is of special relevance when we try to extend everything to the infinite-dimensional case.

Notice that in coordinates $(q_1, \ldots, q_n)$, the condition [8] is equivalent to

$$\dot{R} = [A, R] \qquad [13]$$

where $A$ is the $n \times n$ matrix defined by

$$A_{ij} = \left[\frac{\partial X^j}{\partial q_i}\right]$$

and $X^j = X(q_j) = \dot{q}_j$, $j = 1, \ldots, n$. So, the pair $(R, A)$ is a local Lax pair of the system and the eigenvalues of $R$ are integrals of $X$.

If a recursion operator $R$ of a vector field $X$ on a manifold $M$ has vanishing Nijenhuis torsion and $n$ doubly degenerated eigenvalues $\lambda_i$, with nowhere-vanishing differentials, $(\mathrm{d}\lambda_i)_p \neq 0$, then $X$ defines a completely integrable Hamiltonian system.

Now suppose $X$ defines a completely integrable Hamiltonian system with Hamiltonian $H$ on a symplectic manifold $(M, \omega)$. Let $(I_1, \ldots, I_n, \varphi_1, \ldots, \varphi_n)$ be the action-angle variables in a neighborhood of an invariant torus. Two cases may happen:

1. The Hamiltonian $H$ is separable in the action variable, that is,

$$H = \sum_k H_k(I_k) \qquad [14]$$

In this case, the $(1,1)$-tensor

$$R = \sum_k \lambda_k(I_k)\left(\mathrm{d}I_k \otimes \frac{\partial}{\partial I_k} + \mathrm{d}\varphi_k \otimes \frac{\partial}{\partial \varphi_k}\right) \qquad [15]$$

where $\lambda_k$ are functions with nowhere-vanishing differentials, is a recursion operator of $X$, and has vanishing Nijenhuis torsion and doubly degenerated eigenvalues.

2. The Hamiltonian has nonvanishing Hessian

$$\det\left(\frac{\partial^2 H}{\partial I_k \partial I_j}\right) \neq 0 \qquad [16]$$

In this case we may define new coordinates

$$\nu_k = \frac{\partial H}{\partial I_k}, \quad k = 1, \ldots, n \qquad [17]$$

and a new symplectic structure

$$\omega_1 = \sum_k \mathrm{d}\nu_k \wedge \mathrm{d}\varphi_k = \sum_{k,j} \frac{\partial^2 H}{\partial I_k \partial I_j} \mathrm{d}I_k \wedge \mathrm{d}\varphi_j \qquad [18]$$

The vector field $X$ is Hamiltonian with respect to $\omega_1$, with Hamiltonian

$$H = \frac{1}{2}\sum_k \nu_k^2 \qquad [19]$$

and the $(1,1)$-tensor

$$R = \sum_k \lambda_k\,(I_k)\left(\mathrm{d}\nu_k \otimes \frac{\partial}{\partial \nu_k} + \mathrm{d}\varphi_k \otimes \frac{\partial}{\partial \varphi_k}\right) \qquad [20]$$

is a recursion operator of $X$.

Nijenhuis operators also allow the construction of master symmetries from conformal ones.

A conformal symmetry of a tensor field $T$ is a vector field $Z$ such that

$$\mathcal{L}_Z T = \lambda T, \quad \text{for some constant } \lambda$$

A master symmetry of a vector field $X$ is a vector field $Y$ such that

$$[X, [X, Y]] = 0, \quad \text{but } [X, Y] \neq 0$$

Let $R$ be a recursion operator of $X_0$ and $Z_0$ be a conformal symmetry of $X_0$ and $R$ such that

$$\mathcal{L}_{Z_0} X_0 = \lambda X_0 \quad \text{and} \quad \mathcal{L}_{Z_0} R = R \qquad [21]$$

for some constants $\lambda, \mu$.

If $R$ is also a Nijenhuis operator, then defining the sequences of commuting symmetries $X_k = R^k X_0$ and of conformal symmetries $Z_k = R^k Z_0, k \in \mathbb{N}$, we have, for all $k, j \in \mathbb{N}_0$,

$$\mathcal{L}_{Z_k} R = \mu R^{k+1} \qquad [22]$$

$$[Z_k, Z_j] = \mu(j - k) Z_{j+k} \qquad [23]$$

$$[Z_k, X_j] = (\lambda + j\mu) X_{k+j} \qquad [24]$$

A bi-Hamiltonian manifold is a smooth manifold $M$ endowed with two linearly independent Poisson tensors $\Lambda_0, \Lambda_1$, compatible in the sense that their Schouten bracket vanishes, $[\Lambda_0, \Lambda_1] = 0$.

A vector field is said to be bi-Hamiltonian if it is Hamiltonian with respect to both Poisson structures. The equation that rules the flow of this vector field is said to be a bi-Hamiltonian system.

When one of the Poisson structures is obtained from the other by means of a Nijenhuis operator, we obtain a Poisson–Nijenhuis manifold. Hence, a Poisson–Nijenhuis manifold is a differentiable manifold $M$ endowed with a Poisson tensor $\Lambda$ and a $(1,1)$-tensor $R$ such that

$$R\Lambda^\sharp = \Lambda^{\sharp t} R, \quad [R\Lambda, \Lambda] = 0 \text{ and } [R\Lambda, R\Lambda] = 0$$

A classical example is the one of a bi-Hamiltonian manifold $(M, \Lambda_0, \Lambda_1)$ where $\Lambda_0$ is nondegenerated. In this case we may define the Nijenhuis operator $R = \Lambda_1^\sharp \Lambda_0^{\sharp -1}$ and the manifold $M$ is a Poisson–Nijenhuis one.

The characteristics of the Poisson–Nijenhuis manifold guarantee that all the bivectors $\Lambda_k = R^k \Lambda$ are compatible Poisson tensors and the manifold is not just bi-Hamiltonian but multi-Hamiltonian.

From what we saw, a Hamiltonian system is completely integrable if and only if it is bi-Hamiltonian

in a neighborhood of an invariant torus with the eigenvalues of the existing recursion operator providing its complete integrability. These Poisson–Nijenhuis manifolds appear quite frequently in dynamics and allow us to obtain some interesting properties easily. We finish this section with the Toda lattice. This system is a good illustration of what has been said until now.

Consider $\mathbb{R}^{2n-1}$ with coordinates $(a_1, \ldots, a_{n-1}, b_1, \ldots, b_n)$ equipped with the following compatible Poisson tensors:

$$\Lambda_0 = \frac{1}{4}\sum_{i=1}^{n-1} a_i \frac{\partial}{\partial a_i} \wedge \left(\frac{\partial}{\partial b_i} - \frac{\partial}{\partial b_{i+1}}\right) \qquad [25]$$

$$\begin{aligned}\Lambda_1 = &\sum_{i=1}^{n-1} a_i^2 \frac{\partial}{\partial b_{i+1}} \wedge \frac{\partial}{\partial b_i} - \frac{1}{4}\sum_{i=1}^{n-1} a_i \frac{\partial}{\partial a_i} \\ &\wedge \left(a_{i+1}\frac{\partial}{\partial a_{i+1}} + 2b_{i+1}\frac{\partial}{\partial b_{i+1}} - 2b_i \frac{\partial}{\partial b_i}\right)\end{aligned} \qquad [26]$$

Not only these two Poisson tensors are degenerated but also there is no Nijenhuis operator that transforms $\Lambda_0$ into $\Lambda_1$. This can be seen considering the 1-form $\sum_{i=1}^n \mathrm{d}b_i$. This 1-form belongs to the kernel of $\Lambda_0$ but not to the kernel of $\Lambda_1$. So, the bi-Hamiltonian manifold $(\mathbb{R}^{2n-1}, \Lambda_0, \Lambda_1)$ is not a Poisson–Nijenhuis one.

The Toda lattice is the bi-Hamiltonian system in $\mathbb{R}^{2n-1}$:

$$X_1 = \Lambda_0^\sharp(\mathrm{d}H_1) = \Lambda_1^\sharp(\mathrm{d}H_0) \qquad [27]$$

defined by the Hamiltonians

$$\begin{aligned} H_0 &= 2\sum_{i=1}^n b_i \\ H_1 &= 4\sum_{i=1}^{n-1} a_i^2 + 2\sum_{i=1}^n b_i^2 \end{aligned} \qquad [28]$$

that is,

$$\begin{aligned} \dot{a}_i &= a_i(b_{i+1} - b_i), \quad \text{if } 1 \le i \le n-1 \\ \dot{b}_1 &= 2a_1^2 \\ \dot{b}_i &= 2(a_i^2 - a_{i-1}^2), \quad \text{if } 2 \le i \le n-1 \\ \dot{b}_n &= -2a_{n-1}^2 \end{aligned}$$

Since we do not have a Nijenhuis operator in this setting, we are going to consider a new system in $\mathbb{R}^{2n}$ that reduces to the Toda lattice, derive a hierarchy of Hamiltonians, symmetries, Poisson tensors, conformal symmetries and the associated relations and then transport everything to $\mathbb{R}^{2n-1}$ by reduction.

Consider the Flaschka transformation

$$\begin{aligned} \pi : \mathbb{R}^{2n} &\to \mathbb{R}^{2n-1} \\ (q_1, \ldots, q_n, p_1, \ldots, p_n) &\mapsto (a_1, \ldots, a_{n-1}, b_1, \ldots, b_n) \end{aligned}$$

where

$$\begin{aligned} a_i = \frac{1}{2}\exp\left(\frac{q_i - q_{i+1}}{2}\right), &\qquad b_j = -\frac{1}{2}p_j \\ i = 1, \ldots, n-1, &\quad j = 1, \ldots, n \end{aligned} \qquad [29]$$

This application is a Poisson morphism between $(\mathbb{R}^{2n}, \widetilde{\Lambda}_0, \widetilde{\Lambda}_1)$ and $(\mathbb{R}^{2n-1}, \Lambda_0, \Lambda_1)$, where

$$\widetilde{\Lambda}_0 = \sum_{i=1}^n \frac{\partial}{\partial p_i} \wedge \frac{\partial}{\partial q_i} \qquad [30]$$

$$\begin{aligned}\widetilde{\Lambda}_1 = &\sum_{i=1}^{n-1} \mathrm{e}^{q_i - q_{i+1}} \frac{\partial}{\partial p_{i+1}} \wedge \frac{\partial}{\partial p_i} \\ &+ \sum_{i=1}^n \left(p_i \frac{\partial}{\partial q_i} \wedge \frac{\partial}{\partial p_i} + \sum_{i<j} \frac{\partial}{\partial q_j} \wedge \frac{\partial}{\partial q_i}\right)\end{aligned} \qquad [31]$$

The Poisson tensor $\widetilde{\Lambda}_0$ is nondegenerated and we may define the Nijenhuis operator $R = \widetilde{\Lambda}_1^\sharp \widetilde{\Lambda}_0^{\sharp -1}$. So, $(\mathbb{R}^{2n}, \widetilde{\Lambda}_0, \widetilde{\Lambda}_1)$ is a Poisson–Nijenhuis manifold and the bivectors of the sequence $(\widetilde{\Lambda}_k = R^k \widetilde{\Lambda}_0), k \in \mathbb{N}$, are compatible Poisson tensors.

The Toda lattice is the reduced bi-Hamiltonian system, by means of the Flaschka transformation, of the bi-Hamiltonian system

$$\widetilde{X}_1 = \widetilde{\Lambda}_0^\sharp(\mathrm{d}\widetilde{H}_1) = \widetilde{\Lambda}_1^\sharp(\mathrm{d}\widetilde{H}_0) \qquad [32]$$

where

$$\begin{aligned} \widetilde{H}_0 &= \sum_{i=1}^n p_i \\ \widetilde{H}_1 &= \sum_{i=1}^n \frac{p_i^2}{2} + \sum_{i=1}^{n-1} \mathrm{e}^{q_i - q_{i+1}} \end{aligned} \qquad [33]$$

We may define the sequence of commuting vector fields $\widetilde{X}_k = R^{n-1}\widetilde{X}_1, k \in \mathbb{N}$, and the sequence of Hamiltonians $\mathrm{d}\widetilde{H}_k = {}^t R^k(\mathrm{d}\widetilde{H}_0), k \in \mathbb{N}$, first integrals of all the vector fields $\widetilde{X}_j$ and in involution with respect to all the Poisson structures $\widetilde{\Lambda}_j$.

Moreover, considering the conformal symmetry of $\widetilde{\Lambda}_0, \widetilde{\Lambda}_1$, and $\widetilde{H}_0$ defined by

$$\widetilde{Z}_0 = \sum_{i=1}^n (n + 1 - 2i)\frac{\partial}{\partial q_i} + \sum_{i=1}^n p_i \frac{\partial}{\partial p_i} \qquad [34]$$

we have the following relations on $\mathbb{R}^{2n}$:

$$\mathcal{L}_{\widetilde{Z}_m} R = R^{m+1} \qquad [35]$$

$$[\widetilde{Z}_m, \widetilde{Z}_k] = (k-m)\widetilde{Z}_{k+m} \qquad [36]$$

$$[\widetilde{Z}_k, \widetilde{X}_{m+1}] = m\widetilde{X}_{k+m+1} \qquad [37]$$

$$\mathcal{L}_{\widetilde{Z}_k}\widetilde{\Lambda}_m = (m-k-1)\widetilde{\Lambda}_{k+m} \qquad [38]$$

$$\widetilde{Z}_k.\widetilde{H}_m = (m+n+1)\widetilde{H}_{k+m} \qquad [39]$$

Although we do not have a Nijenhuis operator on $(\mathbb{R}^{2n-1}, \Lambda_0, \Lambda_1)$, the deformation relations [35]–[39], obtained for the Poisson–Nijenhuis manifold $(\mathbb{R}^{2n}, \widetilde{\Lambda}_0, \widetilde{\Lambda}_1)$, may be reduced to the bi-Hamiltonian manifold $(\mathbb{R}^{2n-1}, \Lambda_0, \Lambda_1)$ by means of the Flaschka transformation $\pi$.

## Recursion Operators and Algebras of Integrals of Motion

A master integral of a vector field $X$ is a differentiable function $g$ such that

$$\mathcal{L}_X\mathcal{L}_X g = 0 \quad \text{and} \quad \mathcal{L}_X g \neq 0 \qquad [40]$$

So, a master integral $g$ generates an integral of motion $\mathcal{L}_X g$ of the system $X$. It is worth noticing that if $f$ and $g$ are master integrals, then not only $\mathcal{L}_X f$ and $\mathcal{L}_X g$ are integrals but also $(\mathcal{L}_X f)g - f(\mathcal{L}_X g)$ is an integral of the system. This means that several master integrals may lead to extra integrals of motion. This procedure often leads to the construction of the integrals which provide the superintegrability of the system in consideration. This is the case of, for instance, the generalized rational Calogero–Moser system or the geodesic flow on the sphere.

Recursion operators are often used to construct sequences of master symmetries of vector fields. The obvious connection between master symmetries and master integrals carries the recursion operators to this level. In many cases, the integrals of motion generated by the master integrals constructed on the basis of the existence of a recursion operator close in a quadratic algebra with respect to the Poisson structure we are considering (by quadratic algebra we mean that the brackets between the generators are polynomials of degree 2 in the generators).

Let $X$ be a vector field on a manifold $M$, $R$ a Nijenhuis operator which is also a recursion operator of $X$, and $P$ a $(1,1)$-tensor such that

$$\mathcal{L}_X P = a(R)$$

and

$$\mathcal{L}_{PX} R = b(R)$$

where $a$ and $b$ are polynomials with constant coefficients. The sequences $X_i = R^i X, Y_i = R^i(PX)$, $i \in \mathbb{N}_0, X_{-1} = Y_{-1} = 0$ satisfy

$$[X_i, X_j] = 0 \qquad [41]$$

$$[X_i, Y_j] = a(R)X_{i+j} - ib(R)X_{i+j-1} \qquad [42]$$

$$[Y_i, Y_j] = (j-i)b(R)Y_{i+j-1} \qquad [43]$$

If $(M, \Lambda)$ is a nondegenerated Poisson manifold with trivial first cohomology group, $R\Lambda$ is a bivector and $X$ and $Y$ are Hamiltonian vector fields with respect to $\Lambda$ and $R\Lambda$, that is, there exist functions $H_0, H_1, G_0$, and $G_1$ satisfying

$$X = \Lambda^\sharp(\mathrm{d}H_1) = R\Lambda^\sharp(\mathrm{d}H_0)$$
$$Y = \Lambda^\sharp(\mathrm{d}G_1) = R\Lambda^\sharp(\mathrm{d}G_0)$$

then the sequences of exact differentials

$${}^tR^i(\mathrm{d}H_1) = \mathrm{d}H_i \quad \text{and} \quad {}^tR^i(\mathrm{d}G_1) = \mathrm{d}G_i$$

may be constructed. In this case, the functions $G_j$ are master integrals of all the vector fields $X_i$ and the integrals $X_i(G_j)$ and $L^i_{k,j} = X_i(G_k)G_j - X_i(G_j)G_k$, $j, k \in \mathbb{N}_0$, close in a quadratic algebra with respect to the Poisson bracket associated with $\Lambda$.

If $M$ is not a Poisson manifold but we can find a master integral $G$ of all the vector fields $X_i$ of the sequence, then the functions $G_j = Y_j(G)$ are also master integrals of the same vector fields and the functions $X_i(G_j)$ and $L^i_{k,j} = X_i(G_k)G_j - X_i(G_j)G_k$ are integrals of $X_i$.

Now let us consider the completely integrable bi-Hamiltonian system case. In a neighborhood of an invariant torus, a completely integrable bi-Hamiltonian system may be written in the form

$$\widetilde{H}(y_1, \ldots, y_n) = y_1 + \cdots + y_n \qquad [44]$$

with

$$\Lambda_0 = \sum_{i=1}^n \frac{\partial}{\partial y_i} \wedge \frac{\partial}{\partial \phi_i}$$
$$\Lambda_1 = \sum_{i=1}^n y_i \frac{\partial}{\partial y_i} \wedge \frac{\partial}{\partial \phi_i}$$

the compatible Poisson tensors that provide the complete integrability of the bi-Hamiltonian system. In this case, we may define the recursion operator

$$R = \sum_{i=1}^n y_i \left( \frac{\partial}{\partial y_i} \otimes \mathrm{d}y_i + \frac{\partial}{\partial \phi_i} \otimes \mathrm{d}\phi_i \right)$$

for which $\Lambda_1 = R\Lambda_0$, and the bi-Hamiltonian vector field

$$X = \Lambda_0^\sharp(d\widetilde{H}) = \Lambda_1^\sharp\left[d\left(\sum_{i=1}^n \ln(y_i)\right)\right]$$

The (1, 1)-tensor

$$P = \sum_{i=1}^n \left(\phi_i \frac{\partial}{\partial \phi_i} \otimes d\phi_i + \frac{\partial}{\partial y_i} \otimes dy_i\right)$$

satisfies $\mathcal{L}_X P = \mathrm{Id}$ and $\mathcal{L}_{PX} R = 0$. So, the vector fields

$$Y_k = R^k(PX) = \sum_{i=1}^n y_i^k \phi_i \frac{\partial}{\partial \phi_i}$$

and the function $G = \sum_{i=1}^n y_i\phi_i$ help defining the functions $G_i = Y_i(G), i \in \mathbb{N}_0$.

The integrals of $X_k$

$$X_k(G_j) \quad \text{and} \quad L_{i,j}^k = X_k(G_i)G_j - G_iX_k(G_j) \qquad [45]$$

happen to close in a quadratic algebra with respect to the bracket defined by $\Lambda_0$.

## Recursion Operators on Jacobi Manifolds

In this section we extend the notion of Poisson–Nijenhuis manifold to the Jacobi setting.

Let $M$ be a smooth manifold with a bivector field $\Lambda$ and a vector field $E$. We equip the space $C^\infty(M)$ with the bracket

$$\{f, g\} = \Lambda(df, dg) + fE(g) - gE(f)$$

which is bilinear and skew-symmetric, and satisfies the Jacobi identity if and only if

$$[\Lambda, \Lambda] = -2E \wedge \Lambda \quad \text{and} \quad [E, \Lambda] = 0 \qquad [46]$$

When these conditions are satisfied, $(M, \Lambda, E)$ is called a Jacobi manifold with Jacobi bracket $\{\cdot, \cdot\}$. The pair $(C^\infty(M), \{,\})$ is a local Lie algebra in the sense of Kirillov. If the vector field $E$ identically vanishes on $M$, eqns [46] reduce to $[\Lambda, \Lambda] = 0$ and $(M, \Lambda)$ is just a Poisson manifold. But there are other examples of Jacobi manifolds that are not Poisson, for example, contact manifolds.

We denote by $(\Lambda, E)^\# : T^*M \times \mathbb{R} \to TM \times \mathbb{R}$ the vector bundle map associated with $(\Lambda, E)$, that is, for all $\alpha, \beta$ sections of $T^*M$ and $f \in C^\infty(M)$,

$$(\Lambda, E)^\#(\alpha, f) = (\Lambda^\#(\alpha) + fE, -i_E\alpha)$$

Let $\mathcal{R} : \mathfrak{X}(M) \times C^\infty(M) \to \mathfrak{X}(M) \times C^\infty(M)$ be a $C^\infty(M)$-linear map defined by

$$\mathcal{R}(X, f) = (NX + fY, i_X\gamma + gf) \qquad [47]$$

where $N$ is a tensor field of type (1, 1) on $M$, $Y \in \mathfrak{X}(M)$, $\gamma \in \Omega^1(M)$ and $g \in C^\infty(M)$. Let us denote by $\mathcal{T}(\mathcal{R})$ the Nijenhuis torsion of $\mathcal{R}$ with respect to the Lie bracket on $\mathfrak{X}(M) \times C^\infty(M)$ given by

$$[(X, f), (Z, h)] = ([X, Z], X(h) - Z(f)) \qquad [48]$$

As in the case of Poisson manifolds, if $\mathcal{R}$ has a vanishing Nijenhuis torsion, we call $\mathcal{R}$ a Nijenhuis operator.

Suppose now that $M$ is equipped with a Jacobi structure $(\Lambda_0, E_0)$ and a Nijenhuis operator $\mathcal{R}$. Then, we may define a bivector field $\Lambda_1$ and a vector field $E_1$ on $M$, by setting

$$(\Lambda_1, E_1)^\# = \mathcal{R} \circ (\Lambda_0, E_0)^\#$$

If one looks for the conditions that imply that the pair $(\Lambda_1, E_1)$ defines a new Jacobi structure on $M$ compatible with $(\Lambda_0, E_0)$, in the sense that $(\Lambda_0 + \Lambda_1, E_0 + E_1)$ is again a Jacobi structure, one finds that $\Lambda_1$ is skew-symmetric if and only if $\mathcal{R} \circ (\Lambda_0, E_0)^\# = (\Lambda_0, E_0)^\# \circ {}^t\mathcal{R}$. When $\Lambda_1$ is skew-symmetric, $(\Lambda_1, E_1)$ defines a Jacobi structure on $M$ if and only if, for all $(\alpha, f), (\beta, h) \in \Omega^1(M) \times C^\infty(M)$,

$$\mathcal{T}(\mathcal{R})\Big((\Lambda_0, E_0)^\#(\alpha, f), (\Lambda_0, E_0)^\#(\beta, h)\Big) = \mathcal{R} \circ (\Lambda_0, E_0)^\#(\mathcal{C}((\Lambda_0, E_0), \mathcal{R})((\alpha, f), (\beta, h)))$$

where $\mathcal{C}((\Lambda_0, E_0), \mathcal{R})$ is the Magri concomitant of $(\Lambda_0, E_0)$ and $\mathcal{R}$. In the case where $(\Lambda_1, E_1)$ is a Jacobi structure, it is compatible with $(\Lambda_0, E_0)$ if and only if, for all $(\alpha, f), (\beta, h) \in \Omega^1(M) \times C^\infty(M)$,

$$(\Lambda_0, E_0)^\#(\mathcal{C}((\Lambda_0, E_0), \mathcal{R})((\alpha, f), (\beta, h))) = 0$$

A Jacobi–Nijenhuis manifold $(M, (\Lambda_0, E_0), \mathcal{R})$ is a Jacobi manifold $(M, \Lambda_0, E_0)$ with a Nijenhuis operator $\mathcal{R}$ such that: (1) $\mathcal{R} \circ (\Lambda_0, E_0)^\# = (\Lambda_0, E_0)^\# \circ {}^t\mathcal{R}$ and (2) the map $(\Lambda_0, E_0)^\# \circ \mathcal{C}((\Lambda_0, E_0), \mathcal{R})$ identically vanishes. $\mathcal{R}$ is called the recursion operator of $(M, (\Lambda_0, E_0), \mathcal{R})$.

A recursion operator on a Jacobi–Nijenhuis manifold displays a hierarchy of Jacobi–Nijenhuis structures on the manifold. In fact, if $((\Lambda_0, E_0), \mathcal{R})$ is a Jacobi–Nijenhuis structure on $M$, there exists a hierarchy $((\Lambda_k, E_k), k \in \mathbb{N})$ of Jacobi structures on $M$, which are pairwise compatible. For all $k \in \mathbb{N}$, $(\Lambda_k, E_k)$ is the Jacobi structure associated with the vector bundle map $(\Lambda_k, E_k)^\#$ given by $(\Lambda_k, E_k)^\# = \mathcal{R}^k \circ (\Lambda_0, E_0)^\#$. Moreover, for all $k, l \in \mathbb{N}$, the pair $((\Lambda_k, E_k), \mathcal{R}^l)$ defines a Jacobi–Nijenhuis structure on $M$.

# Integrable Systems and the Inverse Scattering Method

**A S Fokas**, University of Cambridge, Cambridge, UK

## Introduction

A British experimentalist, J S Russell, first observed a soliton in 1834 while riding on horseback beside a narrow barge channel. He challenged the theoreticians of the day "to predict the discovery after it happened, that is to give an *a priori* demonstration *a posterori*." This work created a controversy which, in fact, lasted almost 50 years, and which involved such distinguished scientists as Stokes and Airy. It was resolved by Korteweg and deVries in 1895, who derived the KdV equation as an approximation to water waves,

$$\frac{\partial q}{\partial t} + 6q\frac{\partial q}{\partial x} + \frac{\partial^3 q}{\partial x^3} = 0 \qquad [1]$$

This equation is a nonlinear partial differential equation (PDE) of the evolution type, where $t$ and $x$ are related to time and space respectively, and $q(x,t)$ is related to the height of the wave above the mean water level. Korteweg and de Vries were able to show that equation [1] supports a particular solution that exhibits the behavior described by Russell. This solution, which was later called 1-soliton solution, is given by

$$q_1(x - p^2 t) = \frac{p^2/2}{\cosh^2((1/2)p(x - p^2 t) + c)} \qquad [2]$$

where $p, c$ are constants. The location of this soliton at time $t$, that is, its maximum position, is given by $p^2 - 2c/p$, its velocity is given by $p^2$, and its amplitude by $p^2/2$. Thus, faster solitons are higher and narrower. It should be noted that $q_1$ is a traveling-wave solution, that is, $q_1$ depends only on the variable $X = x - p^2 t$, thus in this case the PDE [1] reduces (after integration) to the second-order ordinary differential equation (ODE)

$$-p^2 q_1(X) + 3q_1^2(X) + \frac{d^2 q_1}{dX^2}(X) = 0$$

Under the assumption that $q$ and $dq/dX$ tend to zero as $|X| \to \infty$, this ODE yields the 1-soliton solution [2].

The problem of finding a solution describing the interaction of two 1-soliton solutions is much more difficult and was not addressed by Korteweg and deVries. This question was studied by M Kruskal and N Zabusky in 1965. Studying numerically the interaction of two solutions of the form [2] (i.e., two solutions corresponding to two different $p_1$ and $p_2$), Kruskal and Zabusky discovered the defining property of solitons: after interaction, these waves regained exactly the shapes they had before. This posed a new challenge to mathematicians, namely to explain analytically the interaction properties of such coherent waves. In order to resolve this challenge one needs to develop a larger class of solutions than the 1-soliton solution. We note that eqn [1] is nonlinear and no effective method to solve such nonlinear equations existed at that time.

Gardner *et al.* (1967) not only derived an explicit solution describing the interaction of an arbitrary number of solitons, but also discovered what was to

evolve into a new method of mathematical physics. The 2-soliton solution is given by

$$q_2(x,t) = \frac{2\left(p_1^2 e^{\eta_1} + p_2^2 e^{\eta_2}\right) + 4e^{\eta_1+\eta_2}(p_1-p_2)^2 + 2A_{12}\left(p_2^2 e^{2\eta_1+\eta_2} + p_1^2 e^{\eta_1+2\eta_2}\right)}{\left(1+e^{\eta_1}+e^{\eta_2}+A_{12}e^{\eta_1+\eta_2}\right)^2} \qquad [3]$$

where

$$\eta_j = p_j x - p_j^3 t + \eta_j^0, j=1,2, \qquad A_{12} = \frac{(p_1-p_2)^2}{(p_1+p_2)^2}$$

and $p_j, \eta_j^0$ are constants. A snapshot of this solution with $p_1 = 1, p_2 = 2$ is given in **Figure 1**. After some time the taller soliton will overtake the shorter one and the only effect of the interaction will be a "phase shift," that is, a change in the position the two solitons would have reached without interaction.

Regarding the general method introduced in Gardner *et al.* (1967), we note that if eqn [1] is formulated on the infinite line, then the most interesting problem is the solution of the initial-value problem: given initial data $q(x,0) = q_0(x)$ which decay as $|x| \to \infty$, find $q(x,t)$. If $q_0$ is small and $qq_x$ can be neglected, then eqn [1] becomes linear and $q(x,t)$ can be found using the Fourier transform,

$$q(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{ikx+ik^3 t}\hat{q}_0(k)\,dk \qquad [4a]$$

where

$$\hat{q}_0(k) = \int_{-\infty}^{\infty} e^{-ikx} q_0(x)\,dx \qquad [4b]$$

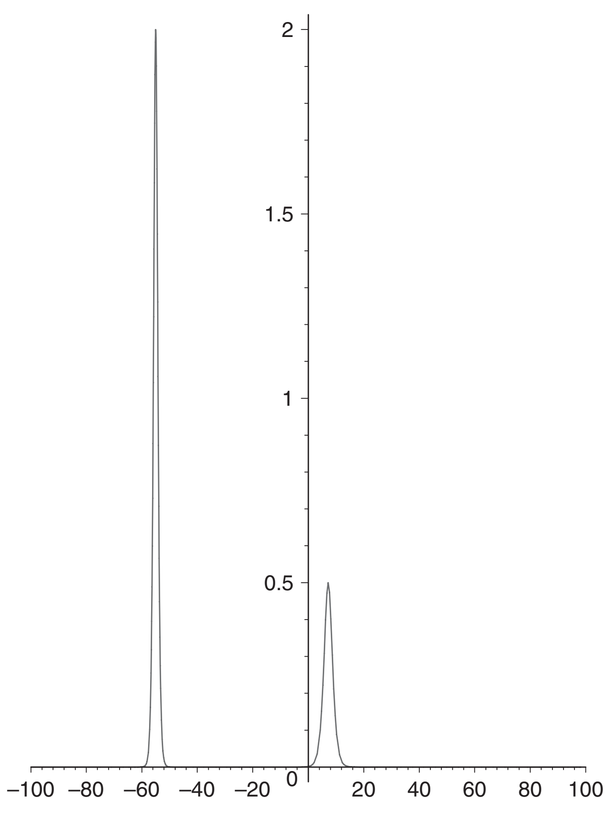

**Figure 1** A snapshot of the 2-soliton solution of the KdV equation.

The remarkable discovery of Gardner *et al.* (1967) is that for eqn [1] there exists a "nonlinear analog" of the Fourier transform capable of solving the initial-value problem even if $q_0$ is not small. Although this nonlinear Fourier transform cannot in general be written in closed form, $q(x,t)$ can be expressed through the solution of a linear integral equation, or more precisely through the solution of a linear $2 \times 2$ matrix Riemann–Hilbert (RH) problem (see the section "A nonlinear Fourier transform"). This linear integral equation is uniquely specified in terms of $q_0(x)$. For particular initial data, $q(x,t)$ can be written explicitly. For example, if $q_0(x) = q_1(x)$, where $q_1(x)$ is obtained by evaluating eqn [2] at $t=0$, then $q(x,t) = q_1(x - p^2 t)$. Similarly, if $q_0(x) = q_2(x,0)$, where $q_2(x,0)$ is obtained by evaluating eqn [3] at $t=0$, then $q(x,t) = q_2(x,t)$.

The most important question, both physically and mathematically, is the description of the long-time behavior of the solution of the initial-value problem mentioned above. If the nonlinear term of eqn [1] can be neglected, one finds a linear dispersive equation. In this case different waves travel with different wave speeds, these waves cancel each other out and the solution decays to zero as $t \to \infty$. Indeed, using the stationary-phase method to compute the large $t$ behavior of the integral appearing in eqn [4a], it can be shown that $q(x,t)$ decays like $0(1/\sqrt{t})$ as $t \to \infty$, $x/t = 0(1)$. The situation with the KdV equation is more interesting: dispersion is balanced by nonlinearity and $q(x,t)$ has a "nontrivial" asymptotic behavior as $t \to \infty$. Indeed, using a nonlinear analog of the steepest descent method discovered by Deift and Zhou (1993) to analyze the RH problem mentioned earlier, it can be shown that $q(x,t)$ asymptotes to $q_N(x,t)$, where $q_N(x,t)$ is the exact $N$-soliton solution. This underlines the physical and mathematical significance of solitons: they are the coherent structures emerging from any initial data as $t \to \infty$. This implies that if a nonlinear phenomenon is modeled by the KdV equation on the infinite line, then one can immediately predict the structure of the solution as $t \to \infty$, $x/t = 0(1)$: it will consist of $N$ ordered single solitons, where the highest soliton occurs to the right; the number $N$ and the parameters $p_j$ and $\eta_j^0$ depend on the particular initial data $q_0(x)$. It should

be noted that this result can be obtained only using the machinery of the theory of integrability, and until now cannot be obtained using standard PDE techniques.

So far we have concentrated on the KdV equation. However, there exist numerous other equations which exhibit similar behavior. Such equations are called "integrable" and the method of solving their initial-value problem is called the "inverse-scattering" or "inverse-spectral" method.

The following section presents a brief historical review of some of the important developments of soliton theory. Next, typical solitons, lumps, and dromions are given. The inverse-spectral method is discussed in the penultimate section. Finally, the extension of this method to boundary-value problems is briefly discussed.

## Important Analytical Developments in Soliton Theory

Lax (1968) introduced the so-called Lax pair formulation of the KdV. In an example, he showed that eqn [1] can be written as the compatibility condition of the following pair of linear eigenvalue equations for the eigenfunction $\psi(x,t,k)$:

$$\psi_{xx} + (q + k^2)\psi = 0 \qquad [5a]$$

$$\psi_t + (2q - 4k^2)\psi_x - (q_x + \nu)\psi = 0, \quad k \in \mathbb{C} \qquad [5b]$$

where $\nu$ is an arbitrary constant. The nonlinear Fourier transform mentioned earlier can be obtained by performing the spectral analysis of eqn [5a]. The time evolution of the associated nonlinear Fourier data, which are now called spectral data, is linear and can be determined using eqn [5b]. Following Lax's formulation, Zakharov and Shabat (1972) solved the nonlinear Schrödinger (NLS) equation

$$\mathrm{i}q_t + q_{xx} - 2\lambda|q|^2 q = 0, \quad \lambda = \pm 1 \qquad [6]$$

which has ubiquitous physical applications including nonlinear optics. Soon thereafter the sine-Gordon equation

$$q_{xx} - q_{tt} = \sin q \qquad [7]$$

and the modified KdV equation

$$q_t + 6q^2 q_x + q_{xxx} = 0 \qquad [8]$$

were solved. Since then, numerous nonlinear equations have been solved. Thus, the mathematical technique introduced by Gardner *et al.* (1967) for the solution of a particular physical equation gave rise to a new method in mathematical physics, the so-called inverse-scattering (spectral) method. Among the most important equations solved by this method are a particular two-dimensional reduction of Einstein's equation and the self-dual Yang–Mills equations.

The next important development in the analysis of integrable equations was the study of the KdV with space-periodic initial data. This occurred in the mid-1970s in the USA and in the USSR. This method involves algebraic-geometric techniques; in particular there exists a periodic analog of the $N$-soliton solution which can be expressed in terms of a certain Riemann-theta function of genus $N$.

In the mid-1970s, it was also realized that there exist integrable ODEs. For example, a stationary reduction of some of the equations introduced in connection with the space-periodic problem mentioned above led to the integration of some classical tops. Furthermore, the similarity reduction of some of the integrable PDEs led to the classical Painlevé equations. For example, letting $q = t^{-1/3}u(\xi)$, $\xi = xt^{-1/3}$ in the modified KdV equation [8], and integrating we find

$$\frac{\mathrm{d}^2}{\mathrm{d}\xi^2} + 2u^3 - \frac{1}{3}\xi u + \alpha = 0 \qquad [9]$$

where $\alpha$ is a constant. This is Painlevé II, that is, the second equation in the list of six classical ODEs introduced by Painlevé and is his school around 1900. These equations are nonlinear analogs of the linear special functions such as Airy, Bessel, etc. The connection between integrable PDEs and ODEs of the Painlevé type was established by Ablowitz and Segur (1977). Their work marked a new era in the theory of these equations. Indeed, soon thereafter Flaschka and Newell (1980) introduced an extension of the inverse-spectral method, the so-called isomonodromy method, capable of integrating these equations. The most remarkable achievement of this new development is the construction of nonlinear analogs of the classical connection formulas that exist for the linear special functions. These formulas, although rather complicated, are as explicit as the corresponding linear ones (Fokas *et al.* 2005).

It was mentioned earlier that the inverse-spectral method gives rise to a matrix RH problem. An RH problem involves the determination of a function analytic in given sectors of the complex plane, from the knowledge of the jumps of this function across the boundaries of these sectors. The algebraic-geometric method for solving the space-periodic initial-value problem can be interpreted as formulating an RH problem which can be analyzed using functions defined on a Riemann surface. Also, it was noted by Fokas and Ablowitz (1983a) and later rigorously established by Fokas and Zhou (1992) that the isomonodromy method also gives rise to a novel RH problem. This

implies the following interesting unification: Self-similar, decaying, and periodic initial-value problems for integrable evolution equations in one space variable lead to the study of the same mathematical object, namely to the RH problem.

Every integrable nonlinear evolution equation in one spatial dimension has several integrable versions in two spatial dimensions. Two such integrable physical generalizations of the Korteweg–deVries equation are the so-called Kadomtsev–Petviashvili I (KPI) and II (KPII) equations. In the context of water waves, they arise in the weakly nonlinear, weakly dispersive, weakly two-dimensional limit, and in the case of KPI when the surface tension is dominant. The NLS equation also has two physical integrable versions known as the Davey–Stewartson I (DSI), and II (DSII) equations. They can be derived from the classical water-wave problem in the shallow-water limit and govern the time evolution of the free surface envelope in the weakly nonlinear, weakly two-dimensional, nearly monochromatic limit. The KP and DS equations have several other physical applications.

A method for solving the Cauchy problem for decaying initial data for integrable evolution equations in two spatial dimensions emerged in the early 1980s. This method is sometimes referred to as the $\bar{\partial}$ ($d$-bar) method. We recall that the inverse-spectral method for solving nonlinear evolution equations on the line is based on a matrix RH problem. This problem expresses the fact that there exist solutions of the associated $x$-part of the Lax pair which are sectionally analytic. Analyticity survives in some multidimensional problems: it was shown formally by Fokas and Ablowitz (1983b) that KPI gives rise to a nonlocal RH problem. However, for other multidimensional problems, such as the KPII, the underlying eigenfunctions are nowhere analytic and the RH problem must be replaced by the $\bar{\partial}$ problem. Actually, a $\bar{\partial}$ problem had already appeared in the work of Beals and Coifman (1982) where the RH problem appearing in the analysis of one-dimensional systems was considered as a special case of a $\bar{\partial}$ problem. Soon thereafter, it was shown in Ablowitz *et al.* (1983) that KPII required the essential use of the $\bar{\partial}$ problem. The situation for the DS equations is analogous to that of the KP equations.

Multidimensional integral PDEs can support localized solutions. Actually there exist two types of localized coherent structures associated with integrable evolution equations in two spatial variables: the "lumps" and the "dromions." The spectral meaning, and therefore the genericity of these solutions was established by Fokas and Ablowitz (1983b) and Fokas and Santini (1990).

The analysis of integrable singular integro-differential equations and of integrable discrete equations, although conceptually similar to the analysis reviewed above, has certain novel features.

The fact that integrable nonlinear equations appear in a wide range of physical applications is not an accident but a consequence of the fact that these equations express a certain physical coherence which is natural, at least asymptotically, to a variety of nonlinear phenomena. Indeed, Calogero (1991) has emphasized that large classes of nonlinear evolution PDEs, characterized by a dispersive linear part and a largely arbitrary nonlinear part, after rescaling yield asymptotically equations (for the amplitude modulation) having a universal character. These "universal" equations are, therefore, likely to appear in many physical applications. Many integrable equations are precisely these "universal" models.

## Solitons, Lumps, and Dromions

Solitons, lumps, and dromions, are important not because they are exact solutions, but because they characterize the long-time behavior of integrable evolution equations in one and two space dimensions. The question of solving the initial-value problem of a given integrable PDE, and then extracting the long-time behavior of the solution is quite complicated. It involves spectral analysis, the formulation of either an RH problem or of a $\bar{\partial}$ problem, and rigorous asymptotic techniques. On the other hand, having established the importance of solitons, lumps, and dromions, it is natural to develop methods for obtaining these particular solutions directly, avoiding the difficult approaches of spectral theory. There exist several such direct methods, including the so-called Bäcklund transformations, the dressing method of Zakharov–Shabat, the direct linearizing method of Fokas–Ablowitz, and the bilinear approach of Hirota.

### Solitons

Using the bilinear approach, multisoliton solutions for a large class of integrable nonlinear PDEs in one space dimension are given in Hietarinta (2002). Here we only note that the 1-soliton solution of the NLS [6], of the sine-Gordon [7], and of the modified KdV equation [8] are given, respectively, by

$$q(x,t) = \frac{p_R \mathrm{e}^{\mathrm{i}(p_I x + (p_R^2 - p_I^2)t + \eta)}}{\cosh[p_R(x - 2p_I t) + \eta]} \quad [10]$$

$$q(px + qt) = 4 \arctan[\mathrm{e}^{px+qt+\eta}], \quad p^2 = 1 + q^2 \quad [11]$$

$$q(x - p^2 t) = \frac{\pm p}{\cosh[px - p^2 t + \eta]} \qquad [12]$$

where $p_R$, $p_I$, $\eta$, $p$, $q$ are real constants.

### Lumps

The KPI equation is

$$\partial_x[q_t + 6qq_x + q_{xxx}] = 3q_{yy} \qquad [13]$$

The 1-lump solution of this equation is given by

$$\begin{aligned} q(x,y,t) &= 2\partial_x^2 \ln\left[|L(x,y,t)|^2 + \frac{1}{4\lambda_I^2}\right], \\ L &= x - 2\lambda y + 12\lambda^2 t + a \\ \lambda &= \lambda_R + \mathrm{i}\lambda_I, \quad \lambda_I > 0 \end{aligned} \qquad [14]$$

where $\lambda$ and $a$ are complex constants.

The focusing DSII equation is

$$\mathrm{i}q_t + q_{zz} + q_{\bar{z}\bar{z}} - 2q\left(\partial_{\bar{z}}^{-1}|q|_z^2 + \partial_z^{-1}|q|_{\bar{z}}^2\right) = 0 \qquad [15]$$

where $z = x + \mathrm{i}y$, and the operator $\partial_{\bar{z}}^{-1}$ is defined by

$$\left(\partial_{\bar{z}}^{-1} f\right)(z,\bar{z}) = \frac{1}{2\mathrm{i}\pi}\int_{\mathbb{R}^2} \frac{f(\zeta,\bar{\zeta})}{\zeta - z}\,\mathrm{d}\zeta \wedge \mathrm{d}\bar{\zeta}$$

The 1-lump solution of this equation is given by

$$q(z,\bar{z},t) = \frac{\beta \mathrm{e}^{\mathrm{i}(p^2+\bar{p}^2)t + pz - \bar{p}\bar{z}}}{|z + \alpha + 2\mathrm{i}pt|^2 + |\beta|^2} \qquad [16]$$

where $\alpha, \beta, p$ are complex constants. A typical 1-lump solution is depicted in Figure 2.

### Dromions

The DSI equation is

$$\begin{aligned} \mathrm{i}q_t + \left(\partial_x^2 + \partial_y^2\right)q + qu &= 0 \\ u_{xy} &= 2\left(\partial_x^2 + \partial_y^2\right)|q|^2 \end{aligned} \qquad [17]$$

The 1-dromion solution of this equation is given by

$$\begin{aligned} q(x,y,t) &= \frac{\rho \mathrm{e}^{X - \bar{Y}}}{\alpha \mathrm{e}^{X+\bar{X}} + \beta \mathrm{e}^{-Y-\bar{Y}} + \gamma \mathrm{e}^{X+\bar{X}-Y-\bar{Y}} + \delta} \\ X &= px + \mathrm{i}p^2 t, \quad Y = qy + \mathrm{i}q^2 t \\ |\rho|^2 &= 4p_R q_R(\alpha\beta - \gamma\delta) \end{aligned} \qquad [18]$$

where $p, q$ are complex constants and $\alpha, \beta, \gamma, \delta$ are positive constants.

## A Nonlinear Fourier Transform

The solution of the initial-value problem of an integrable nonlinear evolution equation on the infinite line is based on the spectral analysis of the $x$-part of the Lax pair. Thus, for the KdV equation one must analyze eqn [5a]. This equation is the famous time-independent Schrödinger equation. We now give a physical interpretation of the relevant spectral analysis. Let KdV describe the propagation of a water wave and suppose that this wave is frozen at a given instant of time. By bombarding this water wave with quantum particles, one can reconstruct its shape from knowledge of how these particles scatter. In other words, the scattering data provide an alternative description of the wave at fixed time.

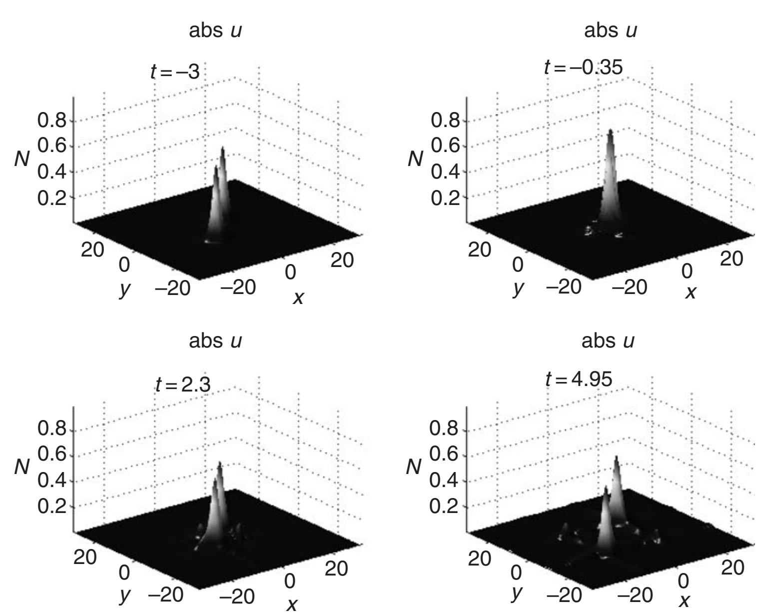

**Figure 2** A typical 1-lump solution.

The mathematical expression of this description takes the form of a linear integral equation found by Faddeev (the so-called Gel'fand–Levitan–Marchenko equation) or equivalently the form of a $2 \times 2$ matrix RH problem uniquely specified by the scattering data. This alternative description of the shape of the wave will be useful if the evolution of the scattering data is simple. This is indeed the case, namely using eqn [5b], it can be shown that the scattering data evolve linearly. Thus, this highly nontrivial change of variables from the physical to scattering space provides a linearization of the KdV equation.

In what follows we will describe some of the relevant mathematical formulas. We first "assume" that there exists a real solution $q(x, t)$ of the initial-value problem which has sufficient smoothness and which decays for all $t$ as $|x| \to \infty$. We then discuss how this assumption can be eliminated.

As it was mentioned earlier most of the analysis of the inverse-scattering transform is carried out on the $x$-part of the Lax pair, that is, on eqn [5a]. Hence, we first concentrate on eqn [5a] and for convenience of notation we suppress the time dependence.

### The Direct Problem

As $|x| \to \infty, q \to 0$, thus there exist solutions of eqn [5a] which tend to $\exp[\pm ikx]$ as $|x| \to \infty$. Let $\psi(k, x)$ and $\hat{\psi}(k, x)$ denote solutions of eqn [5a] with the following asymptotic property:

$$\psi \to e^{ikx}, \quad \hat{\psi} \to e^{-ikx}, \quad \text{as } x \to \infty, \quad k \in \mathbb{R} \qquad [19]$$

Under the transformation $k \to -k$, eqn [5a] remains invariant and the boundary condition for $\psi$ is mapped to the boundary condition for $\hat{\psi}$. Hence

$$\hat{\psi}(k, x) = \psi(-k, x) \qquad [20]$$

We denote by $\phi(k, x)$ the solution of eqn [5a] which tends to $\exp[-ikx]$ as $x \to -\infty$,

$$\phi \to e^{-ikx}, \quad \text{as } x \to -\infty, \quad k \in \mathbb{R} \qquad [21]$$

It is more convenient to work with eigenfunctions (i.e., solutions of [5a]) normalized to unity as $x \to \infty$, thus we introduce $M(k, x)$ and $N(k, x)$ as follows:

$$M = \phi e^{ikx}, \qquad N = \psi e^{-ikx} \qquad [22]$$

The functions $M$ and $N$ can be expressed in terms of $q$ through the solution of linear Volterra integral equations. Indeed, $M$ satisfies

$$\begin{gathered} M_{xx} - 2ikM_x = -qM, \quad k \in \mathbb{R} \\ M \to 1, \quad x \to -\infty \end{gathered} \qquad [23]$$

The homogeneous version of [23] has solutions 1 and $e^{2ikx}$. Thus,

$$M = c_1 + c_2 e^{2ikx} + M_p \qquad [24]$$

where $c_1, c_2$ are constants and $M_p$ is given by

$$M_p = u_1(x) + u_2(x) e^{2ikx} \qquad [25]$$

The functions $u_1, u_2$ satisfy

$$u_1' + e^{2ikx} u_2' = 0, \qquad 2ike^{2ikx} u_2' = -qM$$

Thus,

$$\begin{aligned} u_1(x) &= \frac{1}{2ik} \int_{-\infty}^{x} d\xi q(\xi) M(k, \xi), \\ u_2(x) &= -\frac{1}{2ik} \int_{-\infty}^{x} d\xi e^{-2ik\xi} q(\xi) M(k, \xi) \end{aligned} \qquad [26]$$

Substituting [25] and [26] into [24] and using the boundary condition [23], we find

$$\begin{aligned} M(k, x) & \\ = 1 + \frac{i}{2k} & \int_{-\infty}^{x} d\xi (-1 + e^{2ik(x-\xi)}) q(\xi) M(k, \xi) \end{aligned} \qquad [27]$$

Similarly, one may establish that $N$ satisfied

$$\begin{aligned} N(k, x) & \\ = 1 + \frac{i}{2k} & \int_{x}^{\infty} d\xi (-1 + e^{-2ik(x-\xi)}) q(\xi) N(k, \xi) \end{aligned} \qquad [28]$$

The kernel of eqn [27], as a function of $k$, is bounded and analytic for $\operatorname{Im} k > 0$. Thus, if $q \in L_1, M(k, x)$ as a function of $k$ is holomorphic for $\operatorname{Im} k > 0$. Similarly, $N(k, x)$ as a function of $k$ is holomorphic for $\operatorname{Im} k > 0$.

Thus, we have found particular solutions of eqn [5a] which are holomorphic for $\operatorname{Im} k > 0$. Furthermore, these solutions are simply related for $k$ real. Indeed, the linear independence of solutions of the second-order ODE [5a] implies

$$\phi(k, x) = a(k)\hat{\psi}(k, x) + b(k)\psi(k, x), \quad k \in \mathbb{R}$$

Using [20] and replacing $\phi$ and $\psi$ in terms of $M$ and $N$, we find

$$\begin{gathered} \frac{M(k, x)}{a(k)} = N(-k, x) + \rho(k) e^{2ikx} N(k, x) \\ \rho(k) = \frac{b(k)}{a(k)}, \quad k \in \mathbb{R} \end{gathered} \qquad [29]$$

The functions $a(k)$ and $b(k)$ are given by

$$a(k) = 1 - \frac{\mathrm{i}}{2k}\int_{-\infty}^{\infty} \mathrm{d}\xi q(\xi) M(k,\xi), \quad k \in \mathbb{R}$$
$$b(k) = \frac{\mathrm{i}}{2k}\int_{-\infty}^{\infty} \mathrm{d}\xi q(\xi) M(k,\xi)\mathrm{e}^{-2\mathrm{i}k\xi}, \quad k \in \mathbb{R} \qquad [30]$$

Indeed as $x \to \infty, N \to 1$, thus, eqn [29] implies

$$M \to a(k) + b(k)\mathrm{e}^{2\mathrm{i}kx} \text{ as } x \to \infty \qquad [31]$$

On the other hand, eqn [27] implies that

$$M \to 1 + \frac{\mathrm{i}}{2k}\int_{-\infty}^{\infty} \mathrm{d}\xi(-1 + \mathrm{e}^{2\mathrm{i}k(x-\xi)}q(\xi)M(k,\xi)) \quad x \to \infty \qquad [32]$$

Comparing eqns [31] and [32], we find eqns [30].

The expression for $a(k)$ implies that this function is also holomorphic for $\mathrm{Im}\, k > 0$.

In summary, in the "direct problem," we have found particular solutions of eqn [5a] which are sectionally holomorphic:

$$\begin{pmatrix} M(k,x) \\ N(k,x) \end{pmatrix} \text{ and } \begin{pmatrix} M(-k,x) \\ N(-k,x) \end{pmatrix}$$

are holomorphic for $\mathrm{Im}\, k > 0$ and $\mathrm{Im}\, k < 0$, respectively. These solutions, which are characterized in terms of $q$ by eqns [27] and [28], are simply related by eqn [29].

### The Inverse Problem

Equation [28] expresses $N$ in terms of $q$. Is it possible to find an alternative expression for $N$ in terms of some appropriate "spectral data"? The answer is positive and is a direct consequence of the fact that eqn [29] defines the "jump condition" of an RH problem. Indeed, it can be shown that $a(k)$ may have simple zeros $k_1, \ldots, k_n$ in the positive imaginary axis of the $k$-complex plane. Hence, in general, $M/a$ can be expressed in the form

$$\frac{M(k,x)}{a(k)} = \mathcal{M}(k,x) + \sum_{j=1}^{n} \frac{A_j(x)}{k - \mathrm{i}p_j}, \quad p_j > 0$$

where $\mathcal{M}(k,x)$ as a function of $k$ is holomorphic for $\mathrm{Im}\, k > 0$. It can also be shown that $A_j(x) = C_j \exp[-2p_j, x]N(k_j, x)$. Hence eqn [29] becomes

$$\mathcal{M}(k,x) - N(-k,x) = \sum_{j=1}^{n} \frac{C_j \mathrm{e}^{-2p_j x} N(\mathrm{i}p_j, x)}{k - \mathrm{i}p_j} + \rho(k)\mathrm{e}^{2\mathrm{i}kx}N(k,x), \quad k \in \mathbb{R}$$

Taking the $(-)$ projection of this equation, and using the fact that both $\mathcal{M}$ and $N$ tend to 1 as $k \to \infty$, we find

$$N(k,x) - \frac{1}{2\mathrm{i}\pi}\int_{-\infty}^{\infty} \frac{\mathrm{d}l \rho(l)\mathrm{e}^{2\mathrm{i}lx}N(l,x)}{l + k + \mathrm{i}0} = 1 - \sum_{j=1}^{n} \frac{C_j \mathrm{e}^{-2p_j x}}{k + \mathrm{i}p_j} N(\mathrm{i}p_j, x) \qquad [33]$$

In summary, this equation expressed $N(k,x)$ in terms of the scattering data $(\rho(k), \{C_j, p_j\}_1^n)$.

Since both eqns [28] and [33] are associated with the same $q$, these equations can be used to obtain the following expression for $q$:

$$q = -2\frac{\partial}{\partial x}\left[\frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{d}l \rho(l)\mathrm{e}^{2\mathrm{i}lx}N(l,x) - \mathrm{i}\sum_{j=1}^{n} C_j e^{-2p_j x} N(\mathrm{i}p_j, x)\right] \qquad [34]$$

Indeed, eqn [28] implies

$$\lim_{k\to\infty} N(k,x) = 1 - \frac{\mathrm{i}}{2k}\int_{x}^{\infty} \mathrm{d}\xi q(\xi)$$

Comparing this expression with the large-$k$ behavior of eqn [33], we find [34].

### Time Dependence of the Scattering Data

We now use eqn [5b] to compute the time dependence of the scattering data by evaluating eqn [5b] as $x \to -\infty$ we find $\nu = 4\mathrm{i}k^3$. Then, evaluating it as $x \to \infty$ and using

$$\phi \sim a\mathrm{e}^{-\mathrm{i}kx} + b\mathrm{e}^{\mathrm{i}kx}, \quad x \to +\infty$$

we find

$$a_t = 0, \qquad b_t = 8\mathrm{i}k^3 b$$

Hence,

$$a(t,k) = a(0,k), \qquad \rho(t,k) = \rho(0,k)\mathrm{e}^{8\mathrm{i}k^3 t} \qquad [35]$$

Thus,

$$p_j(t) = p_j(0), \qquad C_j(t) = C_j(0)\mathrm{e}^{8p_j^3 t} \qquad [36]$$

The above formal results motivate the following definitions (for simplicity, we assume that $a(k)$ has no zeros). Given a decaying real function

$q_0(x)$, $x \in \mathbb{R}$, define $M_0(k,x)$ as the solution of the linear Volterra integral equation

$$M_0(k,x) = 1 + \frac{\mathrm{i}}{2k}\int_{-\infty}^{x} \mathrm{d}\xi\left(-1 + \mathrm{e}^{2\mathrm{i}k(x-\xi)}q(\xi)M_0(k,\xi)\right)$$
$$\operatorname{Im} k \geq 0$$

Given $M_0(k,x)$, define $a_0(k)$ and $b_0(k)$ by

$$M_0(k,x) \to a_0(k) + b_0(k)\mathrm{e}^{2\mathrm{i}kx}, \quad x \to \infty, \quad k \in \mathbb{R}$$

Given $a_0$ and $b_0$, define $N(k,x,t)$ by the solution of the linear integral equation

$$N(k,x,t) - \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{d}l \frac{b_0(l)}{a_0(l)} \mathrm{e}^{8\mathrm{i}l^3 t + 2\mathrm{i}lx} \frac{N(l,x,t)}{l + k + \mathrm{i}0} = 1$$

A theorem of Gohberg and Krein implies that this equation has a unique global solution. Given $a_0, b_0, N$, define $q(x,t)$ by

$$q(x,t) = -\frac{1}{\pi}\frac{\partial}{\partial x}\int_{-\infty}^{\infty} \mathrm{d}k \frac{b_0(k)}{a_0(k)} \mathrm{e}^{8\mathrm{i}k^3 t + 2\mathrm{i}kx} N(k,x,t)$$

Then it can be shown that $q(x,t)$ satisfies the KdV equation and $q(x,0) = q_0(x)$.

## A Unification

After the emergence of a method for solving the initial-value problem for nonlinear integrable evolution equations in one and two space variables, the most outstanding open problem in the analysis of these equations became the solution of initial boundary-value problems. A general approach for solving such problems for evolution equations in one space dimension was provided by Fokas (1997). This approach has already been used for the study of nonlinear integrable evolution PDEs on the half-line (Fokas 2002, 2005), on the interval, and in a time-dependent domain. An important advantage of this new method is that it yields the formulation of a matrix RH problem (or a $\bar{\partial}$ problem in the case of a convex time-dependent domain), which although has more complicated jump matrices than the analogous problem on the infinite line, it still has an explicit exponential $(x,t)$ dependence. This fact allows one to describe effectively the asymptotic properties of the solution, using the powerful Deift–Zhou method (Deift and Zhou 1993). For example, the long-time asymptotics of boundary-value problems on the half line are discussed in Fokas and Its (1996).

It is remarkable that the above results have motivated the discovery of a new method for solving boundary-value problems, not only for linear evolution PDEs, but also for linear elliptic PDEs in two dimensions. This includes the Laplace, the biharmonic and the Helmholtz equations in a convex polygon (Dassios and Fokas 2005). In a most recent development, this method has also been applied to certain classes of linear PDEs with variable coefficients. This highly unexpected development unifies and extends several classical branches of mathematics. In particular, it unifies the classical transform methods for simple linear PDEs as well as the method of images, the treatment of linear PDEs via certain ingenious techniques such as the Wiener–Hopf technique, the formulation of Ehrenpreis type integral representations, and the solution of integrable nonlinear PDEs via the inverse-scattering transform. Furthermore, it extends these results to arbitrary domains and to certain classes of PDEs with variable coefficients.

Regarding linear equations we note the following:

Almost as soon as linear two-dimensional PDEs made their appearance, d'Alembert and Euler discovered a general approach for constructing large classes of their solutions. This approach involved separating variables and superimposing solutions of the resulting ODEs. The method of separation of variables naturally led to the solution of PDEs by a transform pair. The prototypical such pair is the direct and the inverse Fourier transforms; variations of this fundamental transform include the Laplace, Mellin, sine, cosine transforms, and their discrete analogs.

The proper transform for a given boundary-value problem is specified by the PDE, by the domain, and by the given boundary conditions. For some simple boundary-value problems, there exists an algorithmic procedure for deriving the associated transform. This procedure involves constructing the Green's function of a single eigenvalue equation, and integrating this Green's function in the $k$-complex plane, where $k$ denotes the eigenvalue.

The transform method has been enormously successful for solving a great variety of initial- and boundary-value problems. However, for sufficiently complicated problems the classical transform method fails. For example, there does not exist a proper analog of the sine transform for solving a third-order evolution equation on the half-line. Similarly, there do not exist proper transforms for solving boundary-value problems for elliptic equations even of second order and in simple domains. The failure of the transform method led to the development of several ingenious but *ad hoc* techniques, which include: conformal mappings for the Laplace and the biharmonic equations; the Jones method and the formulation of the Wiener–Hopf factorization problem; the use of some integral representation, such as that of Sommerfeld; the

formulation of a difference equation, such as the Malyuzhinet's equation. The use of these techniques has led to the solution of several classical problems in acoustics, diffraction, electromagnetism, fluid mechanics, etc. The Wiener–Hopf technique played a central role in the solution of many of these problems.

A crucial role in the new method is played by the global equation satisfied by the boundary values of $q$ and of its derivatives. For evolution equations and for elliptic equations with simple boundary conditions, this involves the solution of a system of algebraic equations, while for elliptic equations with arbitrary boundary conditions, it involves the solution of an RH problem. For simple polygons, this RH problem is formulated on the infinite line, thus it is equivalent to a Wiener–Hopf problem. This explains the central role played by the Wiener–Hopf technique in many earlier works.

For linear PDEs, the explicit $x_1, x_2$ dependence of $q(x_1, x_2)$ is consistent with the Ehrenpreis formulation of the solution. Thus, this method provides the concrete implementation as well as the generalization to concave domains of this fundamental principle. For nonlinear equations, it provides the extension of the Ehrenpreis principle to integrable nonlinear PDEs.

## Random Matrix Models

A random matrix model is a probability space $(\Omega, \mathcal{P}, \mathcal{F})$ where the sample space $\Omega$ is a set of matrices. There are three classic finite $N$ random matrix models (see, e.g., Mehta (1991)):

1. Gaussian orthogonal ensemble ($\beta = 1$):
   (a) $\Omega = N \times N$ real symmetric matrices;
   (b) $\mathcal{P} =$ "unique" measure that is invariant under orthogonal transformations and the matrix elements are i.i.d. random variables; explicitly, the density is

$$c_N \exp\left(-\mathrm{tr}(A^2)\right) \mathrm{d}A \qquad [1]$$

   where $c_N$ is a normalization constant and $\mathrm{d}A = \prod_i \mathrm{d}A_{ii} \prod_{i<j} \mathrm{d}A_{ij}$, the product Lebesgue measure on the independent matrix elements.
2. Gaussian unitary ensemble ($\beta = 2$):
   (a) $\Omega = N \times N$ Hermitian matrices;
   (b) $\mathcal{P} =$ "unique" measure that is invariant under unitary transformations and the (independent) real and imaginary matrix elements are i.i.d. random variables; and
3. Gaussian symplectic ensemble ($\beta = 4$) (see Mehta (1991) for a definition).

Generally speaking, the interest lies in the $N \to \infty$ limit of these models. Here we concentrate on one aspect of this limit. In all three models the eigenvalues, which are random variables, are real and with probability 1 they are distinct. If $\lambda_{\max}(A)$ denotes the largest eigenvalue of the random matrix $A$, then for each of the three Gaussian ensembles we introduce the corresponding distribution function

$$F_{N,\beta}(t) := \mathrm{P}_\beta(\lambda_{\max} < t), \quad \beta = 1, 2, 4$$

The basic limit laws (see Tracy and Widom (1996) and references therein) state that

$$F_\beta(s) := \lim_{N\to\infty} F_{N,\beta}\left(2\sigma\sqrt{N} + \frac{\sigma s}{N^{1/6}}\right), \quad \beta = 1, 2, 4 \qquad [2]$$

exist and are given explicitly by

$$\begin{aligned} F_2(s) &= \det\left(I - K_{\mathrm{Airy}}\right) \\ &= \exp\left(-\int_s^\infty (x - s) q^2(x)\, \mathrm{d}x\right) \end{aligned}$$

where

$$K_{\mathrm{Airy}} \doteq \frac{\mathrm{Ai}(x)\mathrm{Ai}'(y) - \mathrm{Ai}'(x)\mathrm{Ai}(y)}{x - y}$$
$$\text{acting on } L^2(s, \infty) (\text{Airy kernel})$$

and $q$ is the unique solution to the Painlevé II equation

$$q'' = sq + 2q^3$$

satisfying the condition

$$q(s) \sim \mathrm{Ai}(s) \quad \text{as } s \to \infty$$

$\sigma$ in eqn [2] is the standard deviation of the Gaussian distribution on the off-diagonal matrix elements. For the normalization we have chosen $\sigma = 1/\sqrt{2}$; however, for subsequent comparisons, the normalization $\sigma = \sqrt{N}$ is perhaps more natural.

The orthogonal and symplectic distribution functions are

$$F_1(s) = \exp\left(-\frac{1}{2}\int_s^\infty q(x)\, \mathrm{d}x\right)(F_2(s))^{1/2}$$
$$F_4(s/\sqrt{2}) = \cosh\left(\frac{1}{2}\int_s^\infty q(x)\, \mathrm{d}x\right)(F_2(s))^{1/2}$$

Graphs of the densities $\mathrm{d}F_\beta/\mathrm{d}s$ are in the adjacent figure and some statistics of $F_\beta$ can be found in **Figure 1**.

The Airy kernel is an example of an integrable integral operator and a general theory is developed in Tracy and Widom (1994). A vertex operator approach to these distributions (and many other closely related distribution functions in random matrix theory) was initiated by Adler, Shiota, and van Moerbeke (see the review article var Moerbeke (2001) for further developments of this latter approach).

Historically, the discovery of the connection between Painlevé functions ($P_{\mathrm{III}}$ in this case) and Toeplitz/Fredholm determinants appears in work of Wu *et al.* (1976) on the spin–spin correlation functions of the two-dimensional Ising model. Painlevé functions first appear in random matrix theory in

| $\beta$ | $\mu_\beta$ | $\sigma_\beta$ | $S_\beta$ | $K_\beta$ |
|---|---|---|---|---|
| 1 | –1.20653 | 1.2680 | 0.293 | 0.165 |
| 2 | –1.77109 | 0.9018 | 0.224 | 0.093 |
| 4 | –2.30688 | 0.7195 | 0.166 | 0.050 |

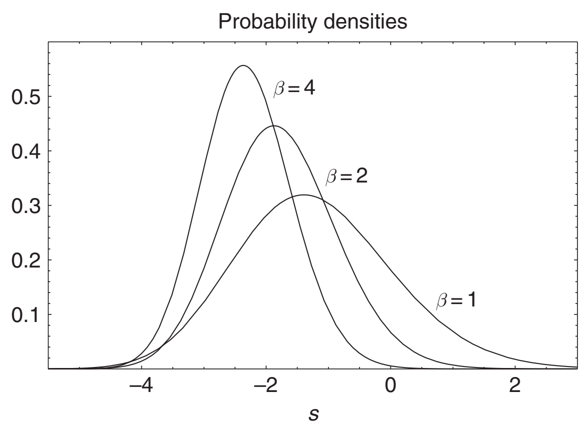

**Figure 1** The mean ($\mu_\beta$), standard deviation ($\sigma_\beta$), skewness ($S_\beta$), and kurtosis ($K_\beta$) of $F_\beta$.

Jimbo *et al.* (1980) where they prove that the Fredholm determinant of the sine kernel is expressible in terms of $P_V$. Gaudin (using Mehta's then newly invented method of orthogonal polynomials (Porter 1965)) was the first to discover the connection between random matrix theory and Fredholm determinants.

### Universality Theorems

A natural question is to ask whether the above limit laws depend upon the underlying Gaussian assumption on the probability measure. To investigate this for unitarily invariant measures ($\beta = 2$), one replaces in [1]

$$\exp\left(-\mathrm{tr}(A^2)\right) \rightarrow \exp(-\mathrm{tr}(V(A)))$$

Bleher and Its (1999) choose

$$V(A) = gA^4 - A^2, \quad g > 0$$

and subsequently a large class of potentials $V$ was analyzed by Deift *et al.* (1999). These analyses require proving new Plancherel–Rotach type formulas for nonclassical orthogonal polynomials. The proofs use Riemann–Hilbert methods. It was shown that the generic behavior is GUE; hence, the limit law for the largest eigenvalue is $F_2$. However, by finely tuning the potential new universality classes will emerge at the edge of the spectrum. For $\beta = 1, 4$ a universality theorem was proved by Stojanovic (2000) for the quartic potential.

In the case of noninvariant measures, Soshnikov (1999) proved that for real symmetric Wigner matrices (complex Hermitian Wigner matrices), the limiting distribution of the largest eigenvalue is $F_1$ (respectively, $F_2$). (A symmetric Wigner matrix is a random matrix whose entries on and above the main diagonal are independent and identically distributed random variables with distribution function $F$. Soshnikov assumes that $F$ is even and all moments are finite.) The significance of this result is that non-Gaussian Wigner measures lie outside the "integrable class" (e.g., there are no Fredholm determinant representations for the distribution functions) yet the limit laws are the same as in the integrable cases.

## Appearance of $F_\beta$ in Limit Theorems

In this section we briefly survey the appearances of the limit laws $F_\beta$ in widely differing areas.

### Combinatorics

A major breakthrough occurred with the work of Baik, Deift, and Johansson (see Baik *et al.* (2000) and references therein) when they proved that the limiting distribution of the length of the longest increasing subsequence in a random permutation is $F_2$. Precisely, if $\ell_N(\sigma)$ is the length of the longest increasing subsequence in the permutation $\sigma \in S_N$, then

$$P\left(\frac{\ell_N - 2\sqrt{N}}{N^{1/6}} < s\right) \rightarrow F_2(s)$$

as $N \rightarrow \infty$. Here the probability measure on the permutation group $S_N$ is the uniform measure. Further discussion of this result can be found in Johansson (2000b).

Baik and Rains (2001) showed by restricting the set of permutations (and these restrictions have natural symmetry interpretations) that $F_1$ and $F_4$ also appear. Even the distributions $F_1^2$ and $F_2^2$ (Tracy and Widom 1999) arise. By the Robinson–Schensted–Knuth correspondence, the Baik–Deift–Johansson result is equivalent to the limiting distribution on the number of boxes in the first row of random standard Young tableaux. (The measure is the push-forward of the uniform measure on $S_N$.) These same authors conjectured that the limiting distributions of the number of boxes in the second, third, etc., rows were the same as the limiting distributions of the next-largest, next-next-largest, etc., eigenvalues in GUE. Since these eigenvalue distributions were also found in Tracy and Widom (1996), they were able to compare the then unpublished numerical work of Odlyzko and Rains (2000) with the predicted results of random matrix theory. Subsequently, Baik *et al.* (2000) proved the conjecture for the second row. The full conjecture was proved by Okounkov (2000) using topological methods and by,

among others, Johansson (2001) using analytical methods. For an interpretation of the Baik–Deift–Johansson result in terms of the card game patience sorting, see the very readable review paper by Aldous and Diaconis (1999).

### Growth Processes

Growth processes have an extensive history both in the probability literature and the physics literature (see, e.g., Meakin (1998) and references therein), but it was only recently that Johansson (2002b) proved that the fluctuations about the limiting shape in a certain growth model ("corner growth model") are $F_2$. Johansson further pointed out that certain symmetry constraints (inspired from the Baik and Rains (2001) work) lead to $F_1$ fluctuations (*see* Growth Processes in Random Matrix Theory).

Subsequently, Baik and Rains (2000) and Gravner *et al.* (2002) have shown the same distribution functions appearing in closely related lattice growth models. Prähofer and Spohn (2000) reinterpreted the work of Baik *et al.* in terms of the physicists' polynuclear growth (PNG) model thereby clarifying the role of the symmetry parameter $\beta$. For example, $\beta=2$ describes growth from a single droplet, whereas $\beta=1$ describes growth from a flat substrate. They also related the distribution functions $F_\beta$ to fluctuations of the height function in the KPZ equation (Kardar *et al.* 1986, Meakin 1998). (The connection with the KPZ equation is heuristic.) Thus, one expects on physical grounds that the fluctuations of any growth process falling into the $1+1$KPZ universality class will be described by the distribution functions $F_\beta$ or one of the generalizations by Baik and Rains (2000). Such a physical conjecture can be tested experimentally. Earlier Myllys *et al.* established experimentally that a slow, flameless burning process in a random medium (paper!) is in the $1+1$KPZ universality class. This sequence of events is a rare instance in which new results in mathematics inspire new experiments in physics.

In the context of the PNG model, Prähofer and Spohn have given a process interpretation, the Airy process, of $F_2$.

There is an extension of the growth model in Gravner *et al.* (2002) to growth in a random environment. In Gravner *et al.* (2002) the following model of interface growth in two dimensions is considered by introducing a height function on the sites of a one-dimensional integer lattice with the following update rule: the height above the site $x$ increases to the height above $x-1$, if the latter height is larger; otherwise, the height above $x$ increases by 1 with probability $p_x$. It is assumed that the $p_x$ are chosen independently at random with a common distribution function $F$, and that the initial state is such that the origin is far above the other sites. In the pure regime, Gravner–Tracy–Widom identify an asymptotic shape and prove that the fluctuations about that shape, normalized by the square root of the time, are asymptotically normal. This contrasts with the quenched version: conditioned on the environment and normalized by the cube root of time, the fluctuations almost surely approach the distribution function $F_2$. We mention that these same authors find, under some conditions on $F$ at the right edge, a composite regime where now the interface fluctuations are governed by the extremal statistics of $p_x$ in the annealed case while the fluctuations are asymptotically normal in the quenched case.

### Random Tilings

The Aztec diamond of order $n$ is a tiling by dominoes of the lattice squares $[m,m+1]\times[\ell,\ell+1], m,n\in\mathbb{Z}$, that lie inside the region $\{(x,y):|x|+|y|\le n+1\}$. A domino is a closed $1\times 2$ or $2\times 1$ rectangle in $\mathbb{R}^2$ with corners in $\mathbb{Z}^2$. A typical tiling is shown in **Figure 2**. One observes that near the center the tiling appears random, called the temperate zone, whereas near the edges the tiling is frozen, called the polar zones. As $n\to\infty$ the boundary between the temperate zone and the polar zones (appropriately scaled) converges to a circle ("arctic circle theorem"). Johansson (2002a) proved that the fluctuations about this limiting circle are $F_2$.

### Statistics

Johnstone (2001) considers the largest principal component of the covariance matrix $X^tX$ where $X$ is an $n\times p$ data matrix all of whose entries are independent standard Gaussian variables and proves that for appropriate centering and scaling, the limiting distribution equals $F_1$ in the limit $n,p\to\infty$ with $n/p\to\gamma\in\mathbb{R}^+$. Soshnikov has removed the Gaussian assumption but requires that $n-p=\mathrm{O}(p^{1/3})$. Thus, we can anticipate applications of the distributions $F_\beta$ (and particularly $F_1$) to the statistical analysis of large data sets.

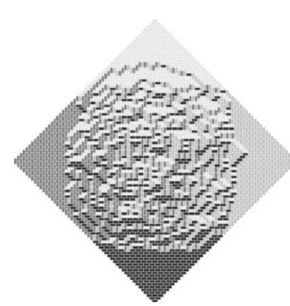

**Figure 2** Random tilings.

### Queuing Theory

Glynn and Whitt (1991) consider a series of $n$ single-server queues each with unlimited waiting space with a first-in and first-out service. Service times are i.i.d. with mean one and variance $\sigma^2$ with distribution $V$. The quantity of interest is $D(k,n)$, the departure time of customer $k$ (the last customer to be served) from the last queue $n$. For a fixed number of customers, $k$, they prove that

$$\frac{D(k,n)-n}{\sigma\sqrt{n}}$$

converges in distribution to a certain functional $\hat{D}_k$ of $k$-dimensional Brownian motion. They show that $\hat{D}_k$ is independent of the service time distribution $V$. It was shown in, for example, Gravner *et al.* (2002) that $\hat{D}_k$ is equal in distribution to the largest eigenvalue of a $k\times k$ GUE random matrix. This fascinating connection has been greatly clarified in recent work of O'Connell and Yor (2002).

From Johansson (2002), it follows for $V$ Poisson that

$$P\left(\frac{D(\lfloor xn\rfloor,n)-c_1 n}{c_2 n^{1/3}}<s\right)\to F_2(s)$$

as $n\to\infty$ for some explicitly known constants $c_1$ and $c_2$ (depending upon $x$).

### Superconductors

Vavilov *et al.* (2001) have conjectured (based upon certain physical assumptions supported by numerical work) that the fluctuation of the excitation gap in a metal grain or quantum dot induced by the proximity to a superconductor is described by $F_1$ for zero magnetic field and by $F_2$ for nonzero magnetic field. They conclude their paper with the remark:

> The universality of our prediction should offer ample opportunities for experimental observation.

# Integrable Systems: Overview

**Francesco Calogero**, University of Rome, Rome, Italy and Institute Nazionale di Fisica Nucleare, Rome, Italy

## Introduction

This section introduces some elementary notions and sets the (mathematically low brow) tone of this presentation.

A *dynamical system* is characterized by an evolution equation the general structure of which reads

$$Q_t = F \qquad [1]$$

Here $Q \equiv Q(x,t)$ is the dependent variable, and it might be a scalar, a vector, a matrix, you name it. The focus of interest is on its evolution as function of the (real, scalar) "time" variable $t$. The *a priori* unknown quantity $Q$ might moreover depend on another independent "space" variable (scalar or vector) $x$, $Q \equiv Q(x,t)$. The appended variable $t$ in the left-hand side of the above equation denotes partial differentiation, and this notation will be used throughout, although when $t$ is the only independent variable differentiation with respect to it might be instead denoted by a superimposed dot:

$$Q_t \equiv \frac{\partial Q(x,t)}{\partial t},\ Q_x \equiv \frac{\partial Q(x,t)}{\partial x},\ \dot{Q} \equiv \frac{dQ(t)}{dt}$$

The quantity in the right-hand side of the evolution equation (1), which has of course the same (scalar, vector, matrix) character as $Q$, is an *assigned* function of $t$, $x$ and $Q$, $F \equiv (x,t,Q)$ (more generally, its dependence on $Q$ might be functional, see below). A typical example of the dynamical systems we shall consider is the $N$-body problem characterized by the Newtonian equations of motion

$$\ddot{q}_n = -\omega^2 q_n + 2g^2 \sum_{m=1,\, m\neq n}^{N} (q_n - q_m)^{-3},\ n = 1, 2, \ldots N \qquad [2]$$

where the dependent variable is the $N$-vector $\vec{q} \equiv (q_1, \ldots q_N)$, the components of which are the "particle coordinates" $q_n \equiv q_n(t)$. Note however that these equations of motion are of *second-order* in time (contrary to (1)); but they can of course be reformulated as *first-order* ODEs indeed their Hamiltonian version, derived in the standard manner from the Hamiltonian

$$H = \frac{1}{2}\sum_{n=1}^{N}(p_n^2 + \omega^2 q_n^2) + \frac{g^2}{2}\sum_{m,n=1;m\neq n}^{N}(q_n - q_m)^{-2} \qquad [3a]$$

reads

$$\dot{q}_n = p_n \qquad [3b]$$

$$\dot{p}_n = -\omega^2 q_n + 2g^2 \sum_{m=1,\, m\neq n}^{N} (q_n - q_m)^{-3},\ n = 1, 2, \ldots N \qquad [3c]$$

Other typical examples are the ("Korteweg-de Vries", "Burgers", "Nonlinear Schrödinger", "sine Gordon") PDEs satisfied by the scalar dependent variable $q \equiv q(x,t)$,

$$q_t = -q_{xxx} + 2q_x q = \left(-q_{xx} + q^2\right)_x \qquad [4]$$

$$q_t = -q_{xx} + 2q_x q = \left(-q_x + q^2\right)_x \qquad [5]$$

$$q_t = i\left[q_{xx} + s|q|^2 q\right],\ s = \pm \qquad [6]$$

$$q_t - q_x = s,\, s_t + s_x = \sin q \qquad [7]$$

as well as the integrodifferential ("Benjamin–Ono") equation

$$q_t = P\int_{-\infty}^{\infty} dy \frac{q_{yy}(y)}{x-y} + q_x q \qquad [8]$$

and the ("Kadomtsev–Petviashvili") PDE satisfied by the scalar dependent variable $q \equiv q(x, y, t)$,

$$q_{tx} = (-q_{xxx} + q_x q)_x + s q_{yy},\ s = \pm \qquad [9]$$

This last equation should of course be reformulated as an integrodifferential equation to fit with (1).

These are all examples of *integrable systems* (see below). In this presentation we restrict attention to dynamical systems of these general types, without considering evolutions in which the space variable, and/or the time variable, and/or the dependent variable, only take discrete values, forsaking thereby the discussion of discrete evolution equations, cellular automata and functional equations, see other entries of this Encyclopedia. We shall consider mainly the "initial-value problem" in which the solution is assigned at the initial time, say at $t = 0$,

$$Q(x, 0) = Q_0(x)$$

and the subsequent evolution of the dependent variable, namely the values taken by $Q(x, t)$ for $t > 0$, is the focus of attention. Note however that, except when there is no dependence at all on the space variable $x$ (see for instance (2)), the functional class to which $Q(x, t)$ belongs as regards its $x$-dependence should be specified (and the assigned initial-value $Q_0(x)$ should of course belong to this functional class). A typical class of functions are those vanishing (adequately fast) at (spatial) infinity; another typical class are those characterized by periodicity properties as functions of $x$; and still another class are those restricted to a finite spatial domain (for instance, the positive $x$-axis, $x > 0$, or a finite interval, $a \le x \le b$), in which cases the initial-value problem must be supplemented by assigning boundary conditions. These latter class of problems, called initial/boundary-value problems, are generally more difficult; even the identification of which boundary conditions are adequate to identify uniquely the solution may be a nontrivial task. In the following we will always focus on the simpler class of problems characterized by solutions defined in the entire space region and vanishing (sufficiently fast) asymptotically (far away).

Thus, in the spirit of the initial-value problem, a dynamical system is generally characterized by assigning its evolution equation, the functional class to which its solutions are required to belong, and possibly in addition some (additional) restriction on the set of initial data.

Let us finally mention that, aside from considering the initial-value problem, the study of dynamical systems may focus on the identification of special (classes of) solutions, for instance those obtained by using symmetry properties of the evolution equation under consideration (yielding, say, "similarity solutions"), and, in the integrable case, "solitonic" and "multisolitonic" solutions (see below).

## Integrable dynamical systems

The solution of a dynamical system, however simple the equation that defines its time evolution, see (1), may be extremely complicated, indeed its time-dependence might feature one or more of the characteristics of *deterministic chaos*, such as a *sensitive dependence* on the initial data. But there are "exceptional" dynamical systems, the behavior of which is instead, in some sense, *simple*. Such systems are termed – in the least technical sense of the word – "integrable".

This characterization can be made precise for Hamiltonian systems with a finite number $N$ of degrees of freedom, the equations of motion of which read

$$\dot{q}_n = \frac{\partial H(\vec{p}, \vec{q})}{\partial p_n}, \dot{p}_n = -\frac{\partial H(\vec{p}, \vec{q})}{\partial q_n}, n = 1, \ldots N$$

Such a system is *integrable* if there exist, in addition to the Hamiltonian $H(\vec{p}, \vec{q}) \equiv H^{(1)}(\vec{p}, \vec{q})$ itself, $N - 1$ other (nontrivial and functionally independent) constants of motion $H^{(m)}(\vec{p}, \vec{q})$ *in involution*, namely such that their Poisson brackets vanish:

$$\left\{H^{(n)}, H^{(m)}\right\} \equiv \sum_{\ell=1}^{N}\left[\frac{\partial H^{(n)}(\vec{p}, \vec{q})}{\partial q_\ell}\frac{\partial H^{(m)}(\vec{p}, \vec{q})}{\partial p_\ell} - \frac{\partial H^{(m)}(\vec{p}, \vec{q})}{\partial q_\ell}\frac{\partial H^{(n)}(\vec{p}, \vec{q})}{\partial p_\ell}\right] = 0, \quad n, m = 1, \ldots, N$$

Let us however emphasize the crucial role of the words "there exist", as used just above. For definiteness let us require that the constants of motion $H^{(n)}(\vec{p}, \vec{q})$ be *analytic functions* of their $2N$ arguments, and *not excessively multivalued*: they might feature some branch points, but not so many to vanify their effectiveness in constraining the time evolution of the dynamical variables $q_n(t), p_n(t)$ sufficiently to avoid their behavior from being too complicated. On the other hand it is of course not necessary that these functions $H^{(n)}(\vec{p}, \vec{q})$ be *explicitly* known.

When these conditions hold it is in principle possible ("Liouville theorem") to identify a

*canonical transformation* from the canonical coordinates and momenta $q_n$ and $p_n$ to *action-angle variables* $\theta_n$ and $I_n$ such that

$$I_n = H^{(n)}(\vec{p}, \vec{q}) \qquad [10]$$

Then these action variables evolve trivially,

$$I_n(t) = I_n(0), \theta_n(t) = \theta_n(0) + I_n(0)t, n = 1, \ldots N$$

Note that, once these new canonical variables are identified, the solution of the initial-value problem for the original Hamiltonian problem is provided directly by the expressions of the action-angle variables $\theta_n$ and $I_n$ in terms of the original variables $q_n$ and $p_n$, as well as the expressions of the latter in terms of the former. The second step of this procedure requires inverting the expressions (10), and the corresponding expressions of the angle variables $\theta_n$ in terms of the original variables $q_n$ and $p_n$; a necessary condition in order that this step allow to identify uniquely, at least in principle, the original canonical variables $q_n$ and $p_n$ in terms of the action-angle variables $I_n$ and $\theta_n$ – hence imply a *simple* time-evolution of these original variables – is the requirement, as mentioned above, that the expressions of the constants of the motion $H^{(n)}(\vec{p}, \vec{q})$ in terms of their arguments $q_n$ and $p_n$ not be excessively multivalued.

The statements outlined above can be rigorously formulated for finite-dimensional Hamiltonian systems, and they can be heuristically extended to all analogous dynamical systems with a finite number of degrees of freedom, even if they are not Hamiltonian.

A system with $N$ degrees of freedom might possess more than $N$ constants of motion. Such a system that possesses $2N - 1$ (nontrivial and functionally independent) constants of motion (the maximal number, to avoid the evolution being frozen) is called *superintegrable*, and its evolution is in some sense analogous to that of a system with a single degree of freedom, in particular *all* its *confined* and *nonsingular* motions are then *completely periodic*,

$$q_n(t + T) = q_n(t), p_n(t + T) = p_n(t), n = 1, \ldots, N$$

The period $T$ depends generally on the initial data. If it does not, at least for an open set of such data having full dimensionality in phase space, the system is called *isochronous*: *all* its motions in that phase space region are then *completely periodic with the same period*.

A dynamical system might be integrable in a region of its "natural" phase space, and nonintegrable in another region. Sometimes such systems are referred to as *partially integrable*. There even are systems which are *isochronous* (hence *superintegrable*) in a region of their phase space, and behave instead *chaotically* in another region. These regions are generally separated by boundaries where the evolution of the system runs into singularities, and the constants of motion associated with the integrable behavior become *excessively multivalued* in the regions where the behavior is *chaotic*. (*see* Isochronous Systems).

Dynamical systems featuring an additional space variable $x$ (see Section 1) can be interpreted as *infinite-dimensional* dynamical systems (by considering the variable $x$ as a continuous label for the dependent variable $Q$). Accordingly, a necessary condition in order that such systems be considered *integrable* is the requirement that they possess an *infinite* number of constants of the motion. But – even for such systems that allow a Hamiltonian formulation – this condition cannot be considered sufficient (due to the inherent ambiguities in the counting of infinities), and in fact a completely cogent, universally accepted definition of *integrability* for infinite-dimensional dynamical systems is still lacking (various definitions can of course be given in special contexts). It is nevertheless rather well understood by practitioners what is meant by such a term at least for *integrable* equations such as those indicated at the end of the previous section, which generally give rise to the *solitonic* phenomenology – as explained below.

The study of integrable systems has an illustrious history, to which many eminent mathematicians and mathematical physicists contributed after the Newtonian revolution: Euler, Jacobi, Poincaré, Painlevé, Kowalewskaya, Kolmogorov, Moser ... Below we report – most tersely – on the bloom that this topic has witnessed over the last 3–4 decades, without being generally able, due to space constraints, to attribute the appropriate credit to the many colleagues, most of them still living, who contributed to this endeavor. For more detailed treatments of the topics outlined below, of related developments not mentioned here, and of such credits, the interested reader is referred to the bibliography given below, including the additional references traceable from there.

### Integrable many-body problems

An important class of integrable dynamical systems is provided by $N$-body problems characterized by Hamiltonians such as

$$H(\vec{p}, \vec{q}) = \frac{1}{2}\sum_{n=1}^{N} p_n^2 + V(\vec{q}) \qquad [11]$$

with a potential energy $V(\vec{q})$ that includes "external" and "two-body" forces,

$$V(\vec{q}) = \sum_{n=1}^{N} V^{(1)}(q_n) + \frac{1}{2}\sum_{m,n=1;m\neq n}^{N} V^{(2)}(q_n - q_m),$$
$$V^{(2)}(-q) = V^{(2)}(q) \qquad [12]$$

The corresponding Hamiltonian and Newtonian equations of motion read

$$\dot{q}_n = p_n, \dot{p}_n = -\frac{\partial V^{(1)}(q_n)}{\partial q_n} - \sum_{m=1, m\neq n}^{N} \frac{\partial V^{(2)}(q_n - q_m)}{\partial q_n},$$

$$\ddot{q}_n = -\frac{\partial V^{(1)}(q_n)}{\partial q_n} - \sum_{m=1, m\neq n}^{N} \frac{\partial V^{(2)}(q_n - q_m)}{\partial = q_n} \quad [13]$$

**The Lax pair and the constants of motion** Suppose that two $N \otimes N$ matrices $L \equiv L(\vec{p}, \vec{q})$ and $M \equiv M(\vec{p}, \vec{q})$ could be found such that the matrix "Lax equation"

$$\dot{L} = [L, M] \quad [14]$$

be equivalent to the Hamiltonian equations of motion (13). Here and throughout the notation $[A, B]$ denotes the commutator:

$$[A, B] \equiv A\,B - B\,A$$

Because this matrix equation clearly entails that the $N$ traces

$$T_n = \text{trace}\,[L^n], n = 1, \ldots, N$$

are constants of the motion,

$$\dot{T}_n = 0, n = 1, \ldots, N$$

the possibility to write the Hamiltonian equations (13) in the Lax form (14) yields as a bonus $N$ constants of the motion, namely it entails that the Hamiltonian system under consideration is *integrable*. (One must moreover show that these constants of motion are *in involution*; this is usually the case).

Hence a route to identify *integrable* $N$-body problems is via the search of Lax pairs $L$, $M$ of matrices such that (14) correspond to (13), with an appropriate assignment of the potential energy (12). For $N > 2$ this is a nontrivial task, because (13) is a system of $2N$ ODEs in $2N$ unknowns, while the matrix Lax equation (14) amounts to a system of $N^2$ ODEs.

**Functional equations and the identification of integrable many-body problems** A convenient *ansatz* to identify a *Lax pair* suitable for the purpose outlined above reads as follows:

$$L_{nm} = p_n \text{ for } n = m, L_{nm} = \alpha(q_n - q_m) \text{ for } m \neq n,$$

$$M_{nm} = \sum_{\ell=1, \ell\neq n}^{N} \beta(q_n - q_\ell) \text{ for } n = m,$$

$$M_{nm} = \gamma(q_n - q_m), \text{ for } m \neq n$$

where $\alpha(q), \beta(q)$ and $\gamma(q)$ are 3 functions to be determined. It is then easily seen that these functions may be assigned so that the corresponding Lax equation (14) be equivalent to the Hamiltonian equations (13) with

$$V^{(1)}(q) = 0 \quad [15a]$$

$$V^{(2)}(q) = \alpha(q)\alpha(-q) \quad [15b]$$

provided the function $\alpha(x)$ satisfies the *functional equation*

$$\frac{\alpha(x)\alpha'(y) - \alpha(y)\alpha'(x)}{\alpha(x+y)} = \beta(x) - \beta(y), \beta(x) = \beta(-x)$$

The general solution of this functional equation yields via [15b] the two-body potential

$$V^{(2)}(q) = g^2\, a^2 \wp(a\,q|\omega, \omega') \quad [16]$$

where $g$ and $a$ are two arbitrary constants and $\wp(x|\omega, \omega')$ is the Weierstrass elliptic function (with semiperiods $\omega$ and $\omega'$, as well arbitrary). One concludes therefore that the $N$-body problem characterized by the Hamiltonian (11) with (12), (15a) and (16) is *integrable*.

This Hamiltonian system has played, since the mid-seventies, a seminal role in the developments of finite-dimensional integrable systems that occurred over the last few decades. However, since the Weierstrass function is doubly-periodic, from a "physical" point of view this $N$–body problem is rather unrealistic, or perhaps rather suited for the study of crystalline configurations, including their statistical mechanics. But there are two special cases, obtained by assigning an infinite value to one or both of the semiperiods of the Weierstrass function in (16), that qualify $V^{(2)}(q)$ as a physical two-body potential:

$$V^{(2)}(q) = \frac{g^2\, a^2}{\sinh^2(a\,q)} \quad [17a]$$

$$V^{(2)}(q) = \frac{g^2}{q^2} \quad [17b]$$

(Of course the second of these two-body potentials, (17b), is merely the special case of the first, (17b), corresponding to $a = 0$). These Hamiltonian models are then naturally interpretable as one-dimensional many-body problems with repulsive two-body forces singular at zero separation and vanishing at large distances. Actually the fact that these systems are *integrable* is far from remarkable, since it is generally true that any many-body problem characterized by repulsive forces vanishing at large distances (hence causing *unconfined* motions) is *integrable*: indeed in such models the particles eventually separate and move freely, so that their trajectories cannot display the extreme complication

characterizing a *chaotic* (i.e., *nonintegrable*) behavior. But these models are in fact *superintegrable* and they (as well as various *integrable* extensions of them) feature many (physically and mathematically) interesting properties. For instance the asymptotic behavior of their trajectories,

$$q_n(t) = p_n^{(\pm)}t + q_n^{(\pm)} + o(1), p_n(t) = p_n^{(\pm)} + o(1) \quad \text{as } t \to \pm\infty, n = 1, \ldots, N \tag{18}$$

is characterized by the simple rules

$$p_n^{(+)} = p_{N+1-n}^{(-)}, n = 1, \ldots, N,$$
$$q_n^{(+)} = q_n^{(-)} + \sum_{m=1, m\neq n}^{N} \Delta\left(p_m^{(-)} - p_n^{(-)}; g, a\right) \quad n = 1, \ldots, N \tag{19}$$

with

$$\Delta(p; g, a) = \text{sign}(p)\frac{\log\left[1 + (ga/p)^2\right]}{2a}$$

The formula (19) indicates that the shift $q_n^{(+)} - q_n^{(-)}$ among the asymptotic positions of the particles (see (18)) is merely a sum of *two-body* shifts $\Delta$ (which incidentally vanish altogether if $a = 0$, namely in the (17b) case), and it only depends on the velocities $p_n^{(-)}$ of the particles in the remote past (*not* on the corresponding asymptotic positions $q_n^{(-)}$, in spite of their relevance in determining the order in which the different particles approach each other through the motion).

A generalization of the above model in the (17b) case – nontrivial inasmuch as it yields *confined* motions – is characterized by the additional presence in the potential (12) of the one-body potential

$$V^{(1)}(q) = \tfrac{1}{2}\,\omega^2 q^2 \tag{20}$$

yielding the Hamiltonian (3a). This model is *integrable*, indeed *superintegrable*, indeed *isochronous*, all its (real) solutions being *completely periodic* with period

$$T = \frac{2\pi}{\omega} \tag{21}$$

A neat way to understand this result is by noting that, if $\tilde{q}(t)$ is a (possibly *complex*) solution of the model discussed above (in this subsection, with the two-body potential (17b) and no one-body potential, see (15a)), then

$$q_n(t) = \exp(-i\omega t)\tilde{q}_n(\tau), \tau = \frac{\exp(2\,i\omega t) - 1}{2\,i\omega}$$

provides a (possibly *real*) solution of the Newtonian equations of motion (2), namely of the same model but with the additional one-body potential (20). Remarkably this model was solved firstly in the quantal case (at the beginning of the seventies), and only a few years later in the classical case considered here (by J. Moser, who, for the $\omega = 0$ case, introduced the special version of the Lax matrix appropriate for this case).

Another class of many-body problems, introduced in the mid-sixties by M. Toda, played a seminal role in the study of *integrable* dynamical systems, indeed the first application (independently by H. Flaschka and S. Manakov) of the Lax approach to *integrable* many-body problems occurred in that context. This model is often referred to as the Toda lattice, because its (two-body) interaction (of exponential type) is only assumed to act among "nearest neighbors".

A particularly interesting, and just as integrable, generalization of this class of Hamiltonian many-body problems features an extra parameter, say $c$, which might be considered to play the role of "speed of light". These models reduce to those considered above for $c = \infty$, and for finite $c$ they are invariant under the Poincaré group of coordinate transformations (while of course the many-body problems described above are invariant under the Galilei group). They are sometimes termed RS models, to recognize those who first introduced them (S. Ruijsenaars and H. Schneider) as well as the possibility to interpret them in some sense as "relativistic" generalizations of the "nonrelativistic" models described above.

**Reduction of the solution to algebraic operations** The solution of the models described above can actually be reduced to purely algebraic operations. For instance for the model characterized by the Newtonian equations of motion (2) such a solution of the initial-value problem is provided by the following prescription: the particle coordinates $q_n(t)$ coincide with the $N$ eigenvalues of the $N \otimes N$ matrix:

$$\tilde{Q}_{nm}(t) = q_n(0)\cos(\omega t) + \dot{q}_n(0)\frac{\sin(\omega t)}{\omega} \text{ for } n = m,$$
$$\tilde{Q}_{nm}(t) = \frac{ig\ \sin(\omega t)}{\omega[q_n(0) - q_m(0)]} \text{ for } n \neq m$$

**Many-body problems related to the motion of the zeros of linear PDEs** Another convenient approach to manufacture and investigate *integrable* many-body problems is by identifying the motion of the particles with that of the zeros of (polynomial)

solutions of linear (hence solvable) evolution PDEs. Assume for instance that the monic polynomial

$$\psi(z,t) = x^N + \sum_{m=1}^{N} c_m(t) x^{N-m} = \prod_{n=1}^{N} [z - z_n(t)] \qquad [22]$$

satisfies the (compatible) linear PDE

$$\begin{aligned}&\left[A_0 + A_1 z + A_2 z^2 + A_3 z^3\right]\psi_{zz}\\ &\quad + \left[B_0 + B_1 z - 2(N-1)A_3 z^2\right]\psi_z\\ &\quad + C\psi_{tt} + [E - (N-1)D_2 z]\psi_t\\ &\quad + \left[D_0 + D_1 z + D_2 z^2\right]\psi_{zt}\\ &\quad - [N(N-1)(A_2 - A_3 z) + NB_1]\psi = 0 \qquad [23]\end{aligned}$$

where the letters $A_0, A_1, A_2, A_3, B_0, B_1, C, D_0, D_1, D_2, E$ denote 11 arbitrary constants. Then the zeros $z_n(t)$ evolve according to the system of ODEs

$$\begin{aligned}C\ddot{z}_n + E\dot{z}_n &= B_0 + B_1 z_n - 2(N-1)A_3 z_n^2\\ &\quad + \sum_{m=1,\, m\neq n}^{N} (z_n - z_m)^{-1}\\ &\quad \times [2C\dot{z}_n\dot{z}_m - (\dot{z}_n + \dot{z}_m)(D_0 + D_1 z_n)\\ &\quad - D_2 z_n(\dot{z}_n z_m + \dot{z}_m z_n)\\ &\quad + 2\left(A_0 + A_1 z_n + A_2 z_n^2 + A_3 z_n^3\right)] \qquad [24]\end{aligned}$$

interpretable as the Newtonian equations of motion of an $N$-body problem with one- and two-body (velocity-dependent) forces. This problem is *integrable*, indeed its solution can be reduced to the algebraic problem of finding the zeros of the polynomial $\psi(z,t)$, see (22), whose time evolution can be ascertained by solving the linear PDE (23), itself a purely algebraic problem as it amounts to solving the system of (constant coefficients, linear) ODEs implied via (22) by this PDE (23) for the $N$ coefficients $c_m(t)$.

This class of many-body problems is rather rich, thanks to the arbitrariness of the 11 constants it features. Several subcases, characterized by special choices of these constants, are suitable to display a gamut of different phenomenological behaviors: confined and nonconfined motions, periodic and nonperiodic evolutions, limit cycles, Hamiltonian cases, . . . .

**Solvable many-body problems in the plane** The many-body problems considered above were all essentially *one-dimensional*. But via a simple trick it is possible to obtain from some of them *many-body problems in the plane* (which should of course be *rotation-invariant* to be certified as such). Consider for instance the special case of the above model, (24), with $C=1$ and with $A_0 = A_1 = A_3 = B_0 = D_0 = D_2 = 0$ so that its equations of motion,

$$\begin{aligned}\ddot{z}_n + E\dot{z}_n &= B_1 z_n + \sum_{m=1,\, m\neq n}^{N} (z_n - z_m)^{-1}\\ &\quad \times \left[2\dot{z}_n\dot{z}_m - D_1(\dot{z}_n + \dot{z}_m)z_n + 2A_2 z_n^2\right] \qquad [25]\end{aligned}$$

are invariant under rescaling of the dependent variables ($z_n \Longrightarrow c z_n$). Let us then assume to work in the *complex* rather than the *real*, and let us set

$$E = \gamma + i\omega,\ A_2 = \alpha + i\tilde{\alpha},\ B_1 = \beta + i\tilde{\beta},\\ D_1 = \delta + i\tilde{\delta}$$

where the Greek letter indicate now *real* constants, and let us moreover relate the $N$ complex coordinates $z_n$ to $N$ two-vectors $\vec{r}_n$ in the horizontal plane via the self-evident positions

$$z_n = x_n + iy_n, \vec{r}_n = (x_n, y_n, 0); \hat{k} = (0,0,1) \qquad [26]$$

It is then easily seen that the *integrable* equations of motion (25) become the following *rotation-invariant* Newtonian equations of motion identifying a (no less *integrable*) $N$-body problem *in the plane*:

$$\begin{aligned}&\ddot{\vec{r}}_n + \left(\gamma + \omega\hat{k}\wedge\right)\dot{\vec{r}}_n\\ &\quad = \left(\beta + \tilde{\beta}\hat{k}\wedge\right)\vec{r}_n + \sum_{m=1,\, m\neq n}^{N} r_{nm}^{-2}\\ &\quad \Big[2\left\{\dot{\vec{r}}_n\left(\dot{\vec{r}}_m\cdot\vec{r}_{nm}\right) + \dot{\vec{r}}_m\left(\dot{\vec{r}}_n\cdot\vec{r}_{nm}\right) - \vec{r}_{nm}\left(\dot{\vec{r}}_n\cdot\dot{\vec{r}}_m\right)\right\}\\ &\quad - \left(\delta + \tilde{\delta}\hat{k}\wedge\right)\Big\{\left(\dot{\vec{r}}_n + \dot{\vec{r}}_m\right)\left[r_n^2 - (\vec{r}_n\cdot\vec{r}_m)\right]\\ &\quad - \vec{r}_n\left[\vec{r}_m\cdot\left(\dot{\vec{r}}_n + \dot{\vec{r}}_m\right)\right] + \vec{r}_m\left[\vec{r}_n\cdot\left(\dot{\vec{r}}_n + \dot{\vec{r}}_m\right)\right]\Big\}\\ &\quad + 2\left(\alpha + \tilde{\alpha}\hat{k}\wedge\right)\left\{\vec{r}_n\left[r_n^2 - 2(\vec{r}_n\cdot\vec{r}_m)\right] + \vec{r}_m r_n^2\right\}\Big] \qquad [27]\end{aligned}$$

Here and below we use the short-hand notation $\vec{r}_{nm} = \vec{r}_n - \vec{r}_m$ entailing $r_{nm}^2 = r_n^2 + r_m^2 - 2\vec{r}_n\cdot\vec{r}_m$, the symbol $\wedge$ denotes the three-dimensional vector product so that $\hat{k}\wedge\vec{r}_n = (-y_n, x_n, 0)$ (see (26)), and the rest of the notation is self-evident. Note that these *rotation-invariant* Newtonian equations of motion are also *translation-invariant* if $\beta = \tilde{\beta} = \delta = \tilde{\delta} = \alpha = \tilde{\alpha} = 0$.

**The "goldfish" model** The attribute of "goldfish" has been attributed to the special case of the above model with *all* "coupling constants" vanishing, thanks to the neatness of its equations of motion, which in their *complex* version read

$$\ddot{z}_n = 2\sum_{m=1,\, m\neq n}^{N} \frac{\dot{z}_n\dot{z}_m}{z_n - z_m}, n = 1, \ldots, N$$

and in their *real* ("physical") version as Newtonian equations of motion of an $N$-body problem in the horizontal plane read

$$\ddot{\vec{r}}_n = 2 \sum_{m=1, m\neq n}^{N} \frac{\dot{\vec{r}}_n\left(\dot{\vec{r}}_m \cdot \vec{r}_{nm}\right) + \dot{\vec{r}}_m\left(\dot{\vec{r}}_n \cdot \vec{r}_{nm}\right) - \vec{r}_{nm}\left(\dot{\vec{r}}_n \cdot \dot{\vec{r}}_m\right)}{r_{nm}^2}$$
$$n = 1, \ldots, N$$

(This name has also been attributed to some extensions of this model, see the entry *Isochronous Systems* in this Encyclopedia). This model is invariant under time rescaling ($t \Rightarrow ct$), in its physical version it is *translation-* and *rotation-invariant*, it only features *two-body* forces and in spite of their *velocity-dependence* it is *Hamiltonian* (it is in fact a simple instance of the RS models mentioned above). The solution of its initial-value problem (in its *complex* version) is given by a remarkably neat rule: the $N$ coordinates $z_n(t)$ are the $N$ roots of the following algebraic equations in $z$:

$$\sum_{n=1}^{N} \frac{\dot{z}_n(0)}{z - z_n(0)} = \frac{1}{t} \quad [28]$$

The phenomenology of its *generic* solution is also remarkable, corresponding to the "game of musical chairs": in the remote past all particles but one are *almost* at rest in $N-1$ positions ("sitting in $N-1$ chairs") and one particle comes in from infinity, moving initially as a free particle; as it approaches, all the particles begin to move around ("dancing"); in the remote future one particle goes away (moving eventually with the same speed as the incoming particle), and all the others settle down in the same $N-1$ positions ("of the $N-1$ chairs"), but with the possibility that the outgoing particle be different from the incoming one, and that the other particles have reshuffled their "seating".

Another remarkable version (also *translation-* and *rotation-invariant*, as well as *Hamiltonian*) of the $N$-body model in the plane (27) obtains if all the "coupling constants" vanish except $\omega$. Then *all* its *nonsingular* solutions – which are given by the same prescription indicated just above, except for the replacement of $\frac{1}{t}$ with $\frac{i\omega}{\exp(i\omega t)-1}$ in the right-hand side of (28) – are *completely periodic* with periods which are an integer multiple – no larger than a number depending on $N$, generally (much) smaller than $N!$ – of $T$ (see (21)), the domains of phase space that give rise to solutions with different periodicity being separated from each other by boundaries characterized by lower-dimensional sets of initial data yielding trajectories that run into *singularities* corresponding to *particle collisions* (note that when two or more particles collide their individuality gets lost, and their velocities diverge).

**Integrable many-body problems in spaces with arbitrary dimensions** *Integrable*, or even *solvable*, many-body problems in spaces with more than two dimensions – with *rotation-invariant* equations of motion of Newtonian type – can be manufactured by starting from an appropriate *integrable*, or *solvable*, second-order *matrix* evolution equation, and by then parametrizing the evolving matrix in terms of multidimensional vectors so as to transform the matrix evolution equation into a *covariant* – hence *rotation-invariant* – system of evolution equations for these vectors, interpretable as Newtonian equations of motion of a many-body problem in multidimensional space.

For instance the matrix equation

$$\dot{M} = AM + MA + M^3$$

is *integrable*. Here $M \equiv M(t)$ is a square matrix of arbitrary order and $A$ is an *arbitrary* constant matrix. By parametrizing appropriately these two matrices one concludes that either one of the following two Newtonian systems of ODEs is *integrable*:

$$\ddot{\vec{r}}_{nm} = \sum_{\nu=1}^{N} \alpha_{n\nu}\vec{r}_{\nu m} + \sum_{\mu=1}^{M}\sum_{\nu=1}^{N} \vec{r}_{n\mu}\left(\vec{r}_{\nu\mu}\cdot\vec{r}_{\nu m}\right)$$
$$n = 1, \ldots, N, m = 1, \ldots, M,$$
$$\ddot{\vec{r}}_{nm} = \sum_{\nu=1}^{N} \alpha_{n\nu}\vec{r}_{\nu m} + \sum_{\mu=1}^{M}\sum_{\nu=1}^{N} \vec{r}_{\nu\mu}\left(\vec{r}_{\nu\mu}\cdot\vec{r}_{nm}\right)$$
$$n = 1, \ldots, N, m = 1, \ldots, M.$$

Here $N$ and $M$ are *arbitrary* positive integers, the $NM$ constants $\alpha_{nm}$ are also *arbitrary*, the $NM$ "particle coordinates" $\vec{r}_{nm} \equiv \vec{r}_{nm}(t)$ are $S$-vectors, with $S$ an *arbitrary* positive integer, and the dots sandwiched among these $S$-vectors denote the standard scalar product in $S$-dimensional space.

Let us emphasize the physical relevance of this class of many-body problems, characterized by *linear* and *cubic* forces. This is reinforced by the fact that these models are *Hamiltonian*.

**Nonlinear harmonic oscillators** Two classes of *integrable* systems obtain from the classes written above by first setting to zero all the constants $\alpha_{nm}$ and by then performing the change of variables

$$\vec{w}_{nm}(t) = \exp(i\omega t)\vec{r}_{nm}(\tau), \tau = \frac{\exp(i\omega t) - 1}{i\omega} \quad [29]$$

with $\omega > 0$. The corresponding Newtonian equations of motion read

$$\ddot{\vec{w}}_{nm} - 3i\omega\dot{\vec{w}}_{nm} - 2\vec{w}_{nm} = \sum_{\mu=1}^{M}\sum_{\nu=1}^{N}\vec{w}_{n\mu}(\vec{w}_{\nu\mu}\cdot\vec{w}_{\nu m})$$

$$n = 1, \ldots, N, m = 1, \ldots, M,$$

$$\ddot{\vec{w}}_{nm} - 3i\omega\dot{\vec{w}}_{nm} - 2\vec{w}_{nm} = \sum_{\mu=1}^{M}\sum_{\nu=1}^{N}\vec{w}_{\nu\mu}(\vec{w}_{\nu\mu}\cdot\vec{w}_{nm})$$

$$n = 1, \ldots, N, m = 1, \ldots, M$$

These equations of motion cause the $N\,M$ evolving $S$-vectors $\vec{w}_{nm} \equiv \vec{w}_{nm}(t)$ to be *complex* (see the second term in their left-hand sides), but a *real* system (with double the number of dependent variables) can be easily obtained by setting

$$\vec{w}_{nm} = \vec{u}_{nm} + i\vec{v}_{nm}$$

Remarkably (but clearly suggested by (29)), *all* the *nonsingular* solutions of each of these two many-body problems are *completely periodic*, with a period which is an integer multiple of the period $T$, see (21). This justifies the title given to this subsection. It also shows that these are *isochronous systems* (*see* Isochronous Systems).

## Integrable nonlinear PDEs

As indicated in Section 1 another class of integrable systems are nonlinear evolution PDEs. In this section we outline (some of) their properties, focussing mainly on the Korteweg-de Vries PDE (4), the solution of which by C. S. Gardner, J. M. Greene, M. D. Kruskal and R. M. Miura in the mid-sixties was the opening shot of a major scientific development which is still blooming. Other important early steps of this development were, in the late sixties, the introduction by P. D. Lax of what is now called the Lax pair technique, and at the beginning of the seventies the solution by V. E. Zakharov and A. B. Shabat of the Nonlinear Schrödinger equation (6) – an evolution PDE of great applicative importance. Subsequently many researchers developed various techniques to identify, classify and investigate *integrable* nonlinear PDEs, a continuing activity for an overall appraisal of which the interested reader is referred to the bibliography reported below.

Here we outline one of the approaches to obtaining these results; other approaches are tersely mentioned below.

### Identification and investigation of integrable PDEs via the inverse spectral transform technique

The class of *linear dispersive* evolution PDEs reads

$$u_t(x,t) = -i\omega\left(-i\frac{\partial}{\partial x}\right)u(x,t), -\infty < x < \infty \quad [30]$$

where the "dispersion function" $\omega(z)$ is, say, a (*real*) polynomial (which must be *odd* to guarantee that this PDE be *real*). The solution of this PDE is achieved via the introduction of the Fourier transform $\hat{u}(k,t)$,

$$u(x,t) = (2\pi)^{-1}\int_{-\infty}^{\infty} dk \exp(i\,kx)\,\hat{u}(k,t) \quad [31a]$$

$$\hat{u}(k,t) = \int_{-\infty}^{\infty} dx \exp(-i\,kx)u(x,t) \quad [31b]$$

whose evolution corresponding to (30) is then given by the simple linear ODE

$$\hat{u}_t(k,t) = -i\omega(k)\hat{u}(k,t), -\infty < k < \infty \quad [32a]$$

which can be immediately integrated:

$$\hat{u}(k,t) = \hat{u}(k,0)\exp[-i\omega(k)t] \quad [32b]$$

Thus the solution of the initial-value problem of (30) is achieved via three steps: (i) at the initial time one obtains the initial value of the Fourier transform, $\hat{u}(k,0)$, from the initial datum $u(x,0)$ (via (31b)); (ii) one then obtains $\hat{u}(k,t)$ (via (32b)); (iii) one finally obtains $u(x,t)$ (via (31a)). From these formulas the main features of the resulting phenomenology are easily evinced (even when the above integrals cannot be explicitly performed).

A class of *integrable nonlinear* evolution PDEs reads

$$u_t(x,t) = \alpha(\mathbf{R})u_x(x,t) \quad [33]$$

where the assigned function $\alpha(z)$ is again, say, a (*real*) polynomial, while $\mathbf{R}$ is now the integrodifferential "recursion operator" defined by the following formula that specifies its action on a generic function $f(x,t)$ (vanishing asymptotically so as to allow all integrations to converge):

$$\mathbf{R}\,f(x,t) = f_{xx}(x,t) - 4u(x,t)f(x,t) + 2u_x(x,t)\int_x^{\infty} dy\,f(y,t) \quad [34]$$

Note that the presence of the time variable $t$ plays no relevant role (it is merely parametric). A remarkable property of this operator – which depends on $u(x,t)$ – is that any power of it acting

on $u_x(x,t)$ yields a nonlinear combination of $u(x,t)$ and its $x$-derivatives – without any left-over integration, in fact yielding a result which is itself an exact $x$-derivative, ready for exact integration in case of a further application of **R**, see the last term in the right-hand side of (34). For instance

$$\mathbf{R}u_x = u_{xxx} - 6u_x u = \left(u_{xx} - 3u^2\right)_x,$$
$$\mathbf{R}^2 u_x = u_{xxxxx} - 10u_{xxx}u - 20u_{xx}u_x + 30u_x u^2 = \left(u_{xxxx} - 10u_{xx}u - 5u_x^2 + 10u^3\right)_x$$

and so on. Hence the simplest nonlinear evolution equation contained in the class (33) is the Korteweg-de Vries (KdV) equation

$$u_t + u_{xxx} = 6u_x u \qquad [35]$$

(corresponding to $\alpha(z) = -z$; and note the identity with (4), via the trivial rescaling $q(x,t) = 3\,u(x,t)$). Note that, if one neglects all nonlinear contributions, the class (33) reduces to (30) with

$$\omega(z) = -z\alpha\left(-z^2\right)$$

The solution of this class of *nonlinear* PDEs, (33), is given by a somewhat analogous procedure to that described above for the class of *linear* dispersive PDEs (30).

Firstly, one introduces the *spectral transform*, a nonlinear generalization of the Fourier transform which indeed reduces to it if nonlinear effects are altogether neglected. That relevant for the class of PDEs (33) is based on the spectral problem associated with the linear Schrödinger operator

$$\mathbf{L} = -\left(\frac{\partial}{\partial x}\right)^2 + u(x,t), -\infty < x < \infty \qquad [36]$$

Via it, the spectral transform

$$S[u(x,t)] = \{R(k,t), -\infty < k < \infty; p_n, \rho_n(t), n = 1, \ldots, N\} \qquad [37]$$

is introduced. Here the function $R(k,t)$ is the "reflection coefficient" associated to the eigenvalue $k^2$ of the *continuous* spectrum of **L**, while the nonnegative number $N$ gives the number of *discrete* eigenvalues of **L**, and the positive quantities $p_n$ and $\rho_n(t)$ are associated to these discrete eigenvalues, specifically $-p_n^2$ are the "binding energies", and $\rho_n(t)$ the "normalization coefficients", associated to the "bound states" possessed by the "potential" $u(x,t)$. (All this terminology comes from the interpretation of the above spectral problem in quantum-mechanical terms). And it can be shown not only that there is a one-to-one correspondence among a function $u(x,t)$ and its spectral transform $S[u(x,\,t)]$, but moreover that both the *direct spectral problem* to compute $S[u(x,t)]$ from $u(x,t)$ (arbitrarily assigned within an appropriate class), and the *inverse spectral problem* to compute $u(x,t)$ from $S[u(x,\,t)]$ (arbitrarily assigned within an appropriate class), only entail solving *linear* equations (an ODE in the former case, a Fredholm integral equation in the latter case).

Note that, in the above definition of the spectral transform, the time variable $t$ plays merely a parametric role. But the usefulness of this spectral transform to solve the PDE (33) resides in the fact that, if $u(x,\,t)$ evolves in time according to this PDE, the corresponding evolution of the spectral transform is quite simple: the number $N$ and the positive numbers $p_n$ are time-independent (as already implied by our notation), while the time evolution of the reflection coefficient $R(k,t)$ and of the normalization coefficients $\rho_n(t)$ is given by the simple *linear* ODEs

$$R_t(k,t) = 2ik\alpha\left(-4k^2\right)R(k,t), -\infty < k < \infty \qquad [38a]$$

$$\dot{\rho}_n(t) = -2p_n\alpha(4p_n^2)\rho_n(t), n = 1, \ldots, N \qquad [38b]$$

which can be readily integrated:

$$R(k,t) = R(k,0)\exp\left[2ik\alpha\left(-4k^2\right)t\right] \qquad [39a]$$

$$\rho_n(t) = \rho_n(0)\exp\left[-2p_n\alpha(4p_n^2)t\right] \qquad [39b]$$

Hence the solution of the initial-value problem for the class of nonlinear PDEs (33) can now be achieved via the following three steps: (i) at the initial time, via the solution of the *direct spectral problem*, the spectral transform $S[u(x,0)]$ (see (37)) is obtained (from $u(x,0)$, arbitrarily assigned within an appropriate class); (ii) the spectral transform at time $t$ is then obtained via (39); (iii) by solving the *inverse spectral problem*, $u(x,t)$ is obtained from $S[u(x,t)]$ (see (37)).

The analogy of this procedure to that outlined above for the class of linear dispersive PDEs (30) is clear, and the fact that in this manner the solution of the initial-value problem for the nonlinear PDEs (33) can be achieved via a sequence of steps involving only the solution of *linear* problems is an indication of the *integrable* character of this class of *nonlinear* evolution PDEs. And it allows to gain thereby a lot of insight on the behavior of these solutions, and also to construct classes of explicit solutions of these equations, as we now indicate.

### Solitons

The *integrable* nonlinear PDE (33) possesses the *single-soliton* solution

$$u(x,t) = \frac{-2p^2}{\cosh^2\{p[x-\xi(t)]\}} \qquad [40a]$$

$$\xi(t) = (2p)^{-1}\log\left[\frac{\rho(t)}{2p}\right] = \xi(0) + vt,$$
$$v = -\alpha(4p^2) \qquad [40b]$$

to which corresponds the simple *spectral transform*

$$S[u(x,t)] = \{R(k,t) = 0; p_1 = p,$$
$$\rho_1(t) = \rho(t) = \rho(0)\exp[-2p\alpha(4p^2)t]; N = 1\} \qquad [41]$$

This solution, (40), describes a localized wave of constant shape moving with the constant speed $v$: the "soliton". It is characterized by two (*real*) parameters, $\xi(0)$ and $p$. The first identifies the initial location of the *soliton*; its arbitrariness corresponds to the translation invariant character of (33). The second, $p$, the spectral significance of which is clear from (41), determines the shape of the *soliton* (both its "height" $2p^2$ and its "width" $\frac{1}{p}$) as well as its speed $v$ (see (40b)); note that the shape is identical for all the nonlinear evolution PDEs of the class (33), while the speed depends on the function $\alpha(z)$, see (40b), namely it depends on which specific equation of the class (33) one is considering. For instance for the KdV equation (35), corresponding to $\alpha(z) = -z$, the speed of the soliton is

$$v = 4p^2 \qquad [42]$$

thus *all* solitons of the KdV equation move from left to right, and taller and thinner solitons move faster than less tall and more fat ones.

More generally, every PDE of the class (33) possesses the $N$-soliton solution

$$u(x,t) = -2\left(\frac{\partial}{\partial x}\right)^2 \log\det[\mathbf{I} + \mathbf{C}(x,t)] \qquad [43a]$$

Here $\mathbf{I}$ is the $N \otimes N$ unit matrix and $\mathbf{C}(t)$ is the $N \otimes N$ matrix

$$C_{mn}(x,t) = [\rho_m(t)\rho_n(t)]^{1/2}\frac{\exp[-(p_m+p_n)x]}{p_m+p_n} \qquad [43b]$$

where the time-evolution of the $\rho_n(t)$'s is given by (39b). Indeed the spectral transform of this solution is given by (37) with $R(k,t) = 0$ and $\rho_n(t)$ given by (39b). To discuss the multisolitonic phenomenology, let us focus on the KdV equation, so that the speed of each soliton is given by the simple formula (42) and let us order the $N$ positive numbers $p_n$ in increasing order,

$$p_1 < p_2 < \cdots < p_N$$

so that the corresponding soliton velocities, $v_n = 4p_n^2$, are as well ordered in increasing order:

$$v_1 < v_2 < \cdots < v_N$$

The $N$-soliton solution (43) is not so transparent, especially if $N$ is large, but it becomes quite simple in the remote past and future:

$$u(x,t) \approx \sum_{n=1}^{N} \frac{-2p_n^2}{\cosh^2\{p_n[x-\xi_n(t)]\}},$$
$$\xi_n(t) = \xi_n^{(\pm)} + v_n t,\ t \to \pm\infty$$

with the $2N$ (*real*) constants $\xi_n^{(\pm)}$ related to one another (see below). It is thus seen that, both in the remote past and future, the $N$-soliton solution (43) splits into the sum of $N$ separated solitons. In the remote past the solitons are ranged, from left to right, in order of decreasing amplitude, and they move to the right with speeds ordered in decreasing magnitude; then the taller and faster solitons gradually catch up and eventually "overtake" the fatter and slower ones (the quotation marks underscore the fact that whenever two, or possibly more, solitons get together, their individuality is in fact lost: for a while the solution might have just one peak, or instead the "overtaking" of two solitons may rather appear as an "exchange of identity", with the taller soliton becoming fatter and the fatter becoming taller as they get close together until they separate again because the one in front, having become taller, speeds up while the one behind, having become fatter, slows down). The final outcome is of course that the order of the solitons gets altogether reversed, with the taller and faster heading the escape to the right. The most remarkable aspect of this phenomenology is that precisely the same solitons that existed in the remote past are found in the remote future, the only effect of their "interaction" having been to shift the position of the *n-th* soliton, relative to what it would have been if it had been moving in isolation, by the amount

$$\Delta_n = \xi_n^{(+)} - \xi_n^{(-)}$$

These $N$ shifts are moreover determined (while either the $N$ quantities $\xi_n^{(-)}$ or the $N$ quantities $\xi_n^{(+)}$ can be arbitrarily assigned), being given by the simple rule

$$\Delta_n = \sum_{m=1}^{n-1} \Delta(p_n, p_m) - \sum_{m=n+1}^{N} \Delta(p_n, p_m) \qquad [44a]$$

$$\Delta(p_n, p_m) = \frac{1}{p_n}\log\left(\frac{p_n + p_m}{|p_n - p_m|}\right) \qquad [44b]$$

Of course in (44a) a sum vanishes if its lower limit exceeds its upper limit.

This formula (44), has a simple phenomenological significance. From the two-soliton case ($N = 2$) it is seen that in a *two-body* encounter the taller and faster soliton gets *advanced* by the amount $\Delta(p_2, p_1)$, while the slower and fatter one gets *delayed* by the amount $\Delta(p_1, p_2)$. Hence the overall shift (44) experienced by the $n$-th soliton in the $N$-soliton case is the sum of the $n - 1$ positive shifts derived from its "overtaking" $n - 1$ slower solitons and the $N - n$ negative shifts derived from its being "overtaken" by $N - n$ faster solitons. This outcome is obvious when each two-soliton encounter occurs *separately*, but is quite nontrivial in the general case when, at some intermediate time, several solitons might all encounter simultaneously.

This soliton phenomenology strongly suggest ascribing to each soliton an individuality, even though in configuration space it only shows up as a separate entity in the remote past and future. The separated identity of each soliton is instead quite clear in the spectral transform context, since each of them corresponds to a (time-independent) discrete eigenvalue of the spectral problem. Indeed in the spectral context this identity is clear also for the generic solution of the class of integrable nonlinear PDEs (33) which, in contrast to the purely solitonic solution (43), is *not* characterized by a vanishing reflection coefficient $R(k, t)$. And indeed, even in configuration space, the soliton phenomenology described above is still featured by a *generic* solution (each of which is characterized, via its spectral transform (37), by the number $N$ of its solitons), up to the additional presence of a "background" component of this solution (corresponding to the nonvanishing reflection coefficient $R(k, t)$), which however behaves in a manner analogous to the solution of the linear, dispersive part of the PDE under consideration, becoming eventually locally small due to its dispersive character.

**Kinks, breathers, boomerons and trappons, dromions** The solitonic phenomenology described above for the class of integrable PDEs (33), and in particular for the KdV equation (35), is more or less common to all *integrable* nonlinear evolution PDEs – of which many other classes exist besides (33). But there also are some significant differences, some of which we now review tersely.

For certain *integrable* PDEs the typical shape of the soliton is not localized, but it rather has the form of a "kink". Some *integrable* PDEs also feature additional kinds of localized "solitons" which, in isolation, move overall with constant speed as ordinary solitons, but feature in addition a time-dependent amplitude modulation and are therefore called "breathers". For *integrable* matrix nonlinear evolution PDEs – or, equivalently, for *integrable* systems of coupled PDEs – the new phenomenology may emerge of solitons that, even in isolation, move with a variable speed, the change of which over time is correlated with the variable interplay of the amplitudes of the different components of the solution: typically such solitons come in from one side in the remote past and boomerang back to that side in the remote future ("boomerons"), or they may be trapped to oscillate around some fixed position ("trappons"); and there are *integrable* evolution equations in which both these types of solitons are simultaneously present in a generic solution. All these phenomenologies refer to the simpler class of *integrable* evolution PDEs in $1 + 1$ (one space and one time) variables, with asymptotically vanishing boundary conditions (at large space distances; or perhaps asymptotically constant, as in the case of kinks). There also exist *integrable* evolution PDEs in $2 + 1$ dimensions (such as the KP equation (9)) the generic solution of which may feature localized soliton-like components, although in this case appropriate boundary conditions play a crucial role (for this reason such solitons have been called "dromions", hinting at their being to some extent driven by the boundary conditions, as objects moving in a stadium).

While there are quite many (classes of) integrable PDEs in $1 + 1$ dimensions, there are only a few in $2 + 1$ dimensions, and there is a widespread belief that no integrable PDEs exist in $D + 1$ dimensions with $D > 2$. But already in the early days of soliton theory it was pointed out that there do exist quite many (classes of) integrable PDEs in $1 + D$ dimensions (namely, one space and $D$ time variables) and that it is quite possible via a different formulation of the initial-value problem to interpret such equations as (no less *integrable*) PDEs in $D + 1$ dimensions ($D$ space and one time variables); and *integrable* PDEs in $D + 1$ dimensions have also been identified and investigated in the context of (the simpler class of) *C-integrable* PDEs (see below).

### Other properties of integrable PDEs

For the *linear* evolution equations (30) the main message implied by their solvability via the Fourier transform is, that the time-evolution is much simpler in Fourier space (see (32)) than in configuration

space. This has a profound impact on the understanding of all phenomena describable by such equations, to the extent of determining the kind of experimental tools better suited to understand the underlining physics (for instance, the use of monochromatic beams of light, the use of high-energy particle accelerators, and so on). The same kind of message is as well relevant for the class of *integrable* nonlinear PDEs solvable via the spectral transform technique – even more so inasmuch as the time-evolution is in this case so much simpler in the spectral space (being actually *linear* there, see (38) and (39)) than in configuration space (where the evolution is *nonlinear*, see (33)). It is indeed the basis for the possession by the class of *integrable* nonlinear PDEs (33) of several other remarkable properties as outlined tersely in the following subsections.

**Bäcklund transformations** A Bäcklund transformation is a formula relating two functions, say $u^{(0)}(x,t)$ and $u^{(1)}(x,t)$, so that, if one of them satisfies a (generally nonlinear) PDE, the other one satisfies the same PDE. In the context of the class (33) of *integrable* PDEs, such a (class of) Bäcklund transformations is provided by the formula

$$g(\mathbf{\Lambda})\left[u^{(0)}(x,t)-u^{(1)}(x,t)\right]+h(\mathbf{\Lambda})\mathbf{\Gamma}\ 1=0 \qquad [45]$$

where $g(z)$ and $h(z)$ are two (*a priori* arbitrary) entire functions (say, two polynomials), while $\mathbf{\Lambda}$ and $\mathbf{\Gamma}$ are two integrodifferential operators the effect of which on a function $f(x,t)$ (such that all relevant integrations are convergent) reads

$$\begin{aligned}\mathbf{\Gamma}f(x,t)=&\left[u_x^{(0)}(x,t)+u_x^{(1)}(x,t)\right]f(x,t)\\&+\left[u^{(0)}(x,t)-u^{(1)}(x,t)\right]\\&\times\int_x^\infty dy\left[u^{(0)}(y,t)-u^{(1)}(y,t)\right]f(y,t)\end{aligned} \qquad [46a]$$

$$\begin{aligned}\mathbf{\Lambda}f(x,t)=&f_{xx}(x,t)-2\left[u^{(0)}(x,t)+u^{(1)}(x,t)\right]f(x,t)\\&+\mathbf{\Gamma}\int_x^\infty dyf(y,t)\end{aligned} \qquad [46b]$$

Note that here the variable $t$ plays no relevant role (its presence is merely parametric), and that $\mathbf{\Gamma}$ and $\mathbf{\Lambda}$ depend (in a symmetrical way) on $u^{(0)}(x,t)$ and $u^{(1)}(x,t)$, whose presence causes the Bäcklund transformation (45) to be *nonlinear* in these functions. Also important is the observation that, for $u^{(0)}(x,t)=u^{(1)}(x,t)=u(x,t)$, the operator $\mathbf{\Lambda}$ becomes the recursion operator $\mathbf{R}$, see (34).

The reason why the formulas (45) constitute a class of Bäcklund transformations is because – as a property of the spectral transform based on the linear Schrödinger operator $\mathbf{L}$, see (36) – if two "potentials" $u^{(0)}(x,t)$ and $u^{(1)}(x,t)$ are related by (45), the corresponding "reflection coefficients" $R^{(0)}(k,t)$ and $R^{(1)}(k,t)$ are related *algebraically*, as follows:

$$\begin{aligned}&g(-4k^2)\left[R^{(0)}(k,t)-R^{(1)}(k,t)\right]\\&\quad+2ikh(-4k^2)\left[R^{(0)}(k,t)+R^{(1)}(k,t)\right]=0\end{aligned} \qquad [47a]$$

entailing

$$R^{(1)}(k,t)=R^{(0)}(k,t)\frac{g(-4k^2)+2ikh(-4k^2)}{g(-4k^2)-2ikh(-4k^2)} \qquad [47b]$$

Clearly this formula entails that, if $R^{(0)}(k,t)$ satisfies (38a), so does $R^{(1)}(k,t)$. Hence, as the fact that $R^{(0)}(k,t)$ satisfies (38a) is a consequence of the fact that $u^{(0)}(x,t)$ satisfies (33), likewise the fact that $R^{(1)}(k,t)$ satisfies (38a) provides the basis for concluding that $u^{(1)}(x,t)$ also satisfies (33).

The simpler version of the Bäcklund transformation (45) obtains by setting $g(z)=-2ph(z)$ with $p$ an arbitrary constant, hence it reads

$$\begin{aligned}&w_x^{(0)}(x,t)+w_x^{(1)}(x,t)\\&\quad=2p\left[w^{(0)}(x,t)-w^{(1)}(x,t)\right]\\&\qquad-\frac{1}{2}\left[w^{(0)}(x,t)-w^{(1)}(x,t)\right]^2\end{aligned} \qquad [48]$$

Here and below we use for convenience the functions $w^{(j)}(x,t)$ related to $u^{(j)}(x,t)$ as follows:

$$\begin{aligned}&w^{(j)}(x,t)=\int_x^\infty dy\,u^{(j)}(y,t),\\&w_x^{(j)}(x,t)=-u^{(j)}(x,t)\end{aligned} \qquad [49]$$

A convenient application of Bäcklund transformations is to yield new solutions of (33) from known solutions; for instance from the trivial solution $u^{(0)}(x,t)=w^{(0)}(x,t)=0$ the single-soliton solution (40) can be readily obtained via (48) and (49) (of course an appropriate time-dependence must be attributed to the $x$-independent "integration constant" that obtains from the integration of (48), which is an ODE in the independent variable $x$).

Another important property of Bäcklund transformations is their *commutativity*. Consider two sets of two polynomials, $g^{(m)}(z)$ and $h^{(m)}(z), m=1,2$, and the two Bäcklund transformations (45) they generate, say BT1 and BT2. Take as starting point some function $u^{(0)}(x)$ and associate to it two functions,

$u^{(1)}(x)$ respectively $u^{(2)}(x)$, obtained from $u^{(0)}(x)$ via these two Bäcklund transformations, BT1 respectively BT2. Then obtain a new function, say $u^{(12)}(x)$, from $u^{(1)}(x)$ via BT2; and likewise obtain $u^{(21)}(x)$ from $u^{(2)}(x)$ via BT1. The property of commutativity entails that, provided an appropriate choice is made of integration constants (see (45)),

$$u^{(12)}(x) = u^{(21)}(x) \qquad [50]$$

This property is highly nontrivial when viewed, as we just did, in configuration space; it is instead rather obvious in the spectral space, indeed the corresponding property for the "reflection coefficients" reads (in self-evident notation, see (47b))

$$R^{(12)}(k) = R^{(21)}(k) = R^{(0)}(k)\, B^{(1)}(k)\, B^{(2)}(k) \qquad [51a]$$

$$B^{(m)}(k) = \frac{g^{(m)}(-4\,k^2) + 2ikh^{(m)}(-4\,k^2)}{g^{(m)}(-4\,k^2) - 2ikh^{(m)}(-4\,k^2)}, \quad m = 1, 2 \qquad [51b]$$

hence it corresponds simply to the commutativity of the ordinary product.

**Nonlinear superposition principle** Another remarkable property of the class of evolution equations (33) is a straightforward consequence of the commutativity property, (50), of Bäcklund transformations. It reads (hereafter with a slight abuse of language we refer to "solutions" $w^{(j)}$ even though the actual solutions are the functions $u^{(j)}$ related to the $w^{(j)}$ by (49))

$$w^{(12)} = w^{(21)} = w^{(0)} - \frac{2(p_1+p_2)\left(w^{(1)} - w^{(2)}\right)}{2(p_1-p_2) + w^{(1)} - w^{(2)}} \qquad [52]$$

where $w^{(0)} \equiv w^{(0)}(x,t)$ is an arbitrary solution of (33), $w^{(1)} \equiv w^{(1)}(x,t)$ respectively $w^{(2)} \equiv w^{(2)}(x,t)$ are likewise the solutions of the same PDE related to $w^{(0)}$ by the Bäcklund transformation (48) with $p = p_1$ respectively $p = p_2$, and $w^{(12)}(x,t) = w^{(21)}(x,t)$ is another solution of the same PDE. Note that this formula, for which the title of this subsection seems appropriate, provides a completely explicit, rational expression of a new solution of (33) in terms of three other solutions of the same equation: an arbitrary solution $w^{(0)}$, and the two solutions $w^{(1)}$ and $w^{(2)}$ related to it by a simple Bäcklund transformation, see (48).

**Soliton ladder** A simple application of the preceding formula is to start from the trivial solution

$$w^{(0)} = 0 \qquad [53]$$

so that (see (48))

$$w^{(j)}(x,t) = -2p_j\left[1 - \tan\left\{p_j\left[x - x_0^{(j)} + \alpha(4p^2)t\right]\right\}\right], \quad j = 1, 2 \qquad [54a]$$

where, in order that this function be real, either

$$\mathrm{Im}\left[x_0^{(j)}\right] = 0 \qquad [54b]$$

or

$$\mathrm{Im}\left[x_0^{(j)}\right] = \frac{\pi}{2p_j} \qquad [54c]$$

Via (49), the expression (54a) with (54b) yields, for each value of $j$, a version of the *single-soliton* solution (40). Insertion of (53) and (54a) in (52) yields, via (49), the *two-soliton* solution of (33), provided $0 < p_1 < p_2$ and $x_0^{(1)}$ satisfies (54b) while $x_0^{(2)}$ satisfies (54c) (otherwise the solution produced by (52) is complex or singular).

Having thus obtained the *two-soliton* solution, one can apply the nonlinear superposition formula (52) to get the three-soliton solutions, by inserting in place of $w^{(0)}$ the *single-soliton* expression (54a) (with parameter, say, $p_1$) and in place of $w^{(1)}$ and $w^{(2)}$ the *two-soliton* expression (with parameters $p_1$ and $p_2$ respectively $p_1$ and $p_3$); and the process can be continued, as suggested by the title of this subsection. In this manner the multisolitonic solution can be constructed by a sequence of purely algebraic operations: and simple rules can be given, detailing the restrictions on the soliton parameter $p_n$ and the reality properties of the constants $x_0^{(n)}$ ((54b) or (54c)) to insure that the solution so arrived at be real and nonsingular, and thus coincide with (43).

**Conservation laws** As mentioned above, *integrable* evolution PDEs are interpretable as *infinite-dimensional* dynamical systems. It is therefore natural that they possess an *infinite* number of conserved quantities. For instance every PDE of the class [33] possesses the following infinite sequence of conserved quantities:

$$C_n = \frac{(-1)^n}{2n+1}\int_{-\infty}^{\infty} dx\, \mathbf{R}^n[xu_x(x,t) + 2u(x,t)], \quad n = 0, 1, 2, \ldots, \qquad [55a]$$

where $\mathbf{R}$ is the recursion operator (34). An alternative definition for this sequence is

$$C_n = \frac{(-1)^n}{2n+1}\int_{-\infty}^{\infty} dx \tilde{\mathbf{R}}^n u(x,t), \quad n = 0, 1, 2, \ldots, \qquad [55b]$$

where the integrodifferential operator $\tilde{\mathbf{R}}$ is in some sense the adjoint of $\mathbf{R}$, being defined by the formula

$$\tilde{\mathbf{R}}f(x,t) = f_{xx}(x,t) - 4u(x,t)f(x,t) + 2\int_x^\infty dy\, u(y,t)f_y(y,t) \qquad [55c]$$

that specifies its action on a generic function $f(x,t)$ (such that the integration converge). The first 3 of these conserved quantities read as follows:

$$C_0 = \int_{-\infty}^{\infty} dx\, u(x,t),$$

$$C_1 = \int_{-\infty}^{\infty} dx\, u^2(x,t),$$

$$C_2 = \int_{-\infty}^{\infty} dx\, \left[2\,u^3(x,t) + u_x^2(x,t)\right]$$

These constants of the motion (55) are functionally independent and, in the context of a Hamiltonian formulation characterized by the Poisson bracket

$$\{A,B\} = \int_{-\infty}^{\infty} dx\, \frac{\delta A}{\delta u(x)} \frac{\partial}{\partial x} \frac{\delta B}{\delta u(x)}$$

(where $A$ and $B$ are functionals of $u(x)$ and $\delta/\delta u(x)$ denotes the functional derivative), they are *in involution*,

$$\{C_n, C_m\} = 0$$

Note that, in this context, the KdV PDE (35) coincides with the Hamiltonian equation

$$u_t(x,t) = \{u(x,t), H\} = \left(\frac{\partial}{\partial x}\right) \frac{\delta H}{\delta u(x,t)}$$

with

$$H = \frac{1}{2}C_2 = \frac{1}{2}\int_{-\infty}^{\infty} dx\, \left[2\,u^3(x,t) + u_x^2(x,t)\right]$$

Several alternative sequences of constants of motion also exist. For instance another infinite sequence is provided by the two equivalent formulas

$$c_n = (-1)^n \int_{-\infty}^{\infty} dx\, \hat{\mathbf{R}}^{2n} \cdot 1 \qquad [56a]$$

$$c_n = (-1)^n \int_{-\infty}^{\infty} dx\, \mathbf{\Lambda}_0^n\, u(x,t) \qquad [56b]$$

with the integrodifferential operators $\hat{\mathbf{R}}$ and $\mathbf{\Lambda}_0$ defined by the formulas

$$\hat{\mathbf{R}}f(x,t) = f_x(x,t) - \int_{-\infty}^{x} dy\, u(y,t)\, f(y,t),$$

$$\mathbf{\Lambda}_0 f(x,t) = f_{xx}(x,t) - 2\,u(x,t)\, f(x,t) + u_x(x,t)\int_x^\infty dy\, f(y,t) + u(x,t)\int_x^\infty dy\, u(y,t)\int_y^\infty dz\, f(z,t)$$

Note that the integrodifferential operator $\mathbf{\Lambda}_0$ is just $\mathbf{\Lambda}$, see (46), with $u^{(0)}(x,t)=0$ and $u^{(1)}(x,t)=u(x,t)$.

The constants $c_n$ are also all independent of each other, but there is a relationship between the constants of the two sequences, (55) and (56),

$$\sum_{n=0} c_n\, z^{2n+1} = \sin\left[\sum_{n=0} C_n\, z^{2n+1}\right]$$

which is to be understood by expanding the right-hand side in powers of $z$ and then equating the coefficients of equal powers of $z$:

$$c_0 = C_0,$$
$$c_1 = C_1 - \tfrac{1}{6}C_0^3,$$
$$c_2 = C2 - \tfrac{1}{2}C_0^2 C_1 + \tfrac{1}{120}C_0^5$$

and so on.

Of course all these conservation laws are applicable to the class of solutions of (33) defined for all (*real*) values of $x$ and vanishing asymptotically (as $x \to \pm\infty$). But they can also be reformulated as *local* "continuity equations". And – rather remarkably – all these results hold as well for the explicitly time-dependent class of PDEs that obtains if one allows the polynomial $\alpha(z)$ in the right-hand side of (33) to feature an *arbitrary* time-dependence, say

$$\alpha(z,t) = \sum_{m=0}^{M} \alpha_m(t) z^m \qquad [57]$$

Finally let us note that there is an additional conserved quantity for this (generalized) class of PDEs,

$$C = \int_{-\infty}^{\infty} dx\left[xu(x,t) + \int_0^t dt'\alpha(\tilde{\mathbf{R}},t')u(x,t)\right]$$

with $\tilde{\mathbf{R}}$ defined by (55c). This implies that, for the generic solution of this (generalized) class of PDEs the *center of mass*

$$X(t) = \frac{\int_{-\infty}^{\infty} dx\, x\, u(x,t)}{\int_{-\infty}^{\infty} dx\, u(x,t)}$$

moves according to the formula

$$X(t) = X_0 + \sum_{m=0}^{M} (-1)^{m+1} (2\,m+1) \left(\frac{C_m}{C_0}\right) \times \int_0^t dt' \alpha_m(t'), X_0 = \frac{C}{C_0}$$

Hence for all the *autonomous* evolution PDEs of the class (33) (with $\alpha(z,t) = \alpha(z), \alpha_m(t) = \alpha_m$, see (57)) the center of mass of the *generic* solution moves uniformly,

$$X(t) = X_0 + Vt$$

with the (constant) speed

$$V = \sum_{m=0}^{M} (-1)^{m+1} (2\,m+1) \left(\frac{C_m}{C_0}\right) \alpha_m$$

#### Other techniques to identify, classify and investigate integrable PDEs

The spectral transform approach on which we focussed above is just one of the various techniques used to identify and investigate *integrable* nonlinear evolution PDEs. (Incidentally; because the less standard aspect of this approach is the *inverse* transformation to reconstruct, in the framework of the spectral problem, the "potential" $u(x)$ from its spectral transform, this approach is often called the Inverse Spectral, or Scattering, Transform method – abbreviated as IST). In this subsection we tersely mention some other approaches, referring to the literature indicated below for more adequate treatments.

An approach starts from a trivially integrable PDE – say, linear and autonomous, see for instance (30) – and performs a nonlinear change of dependent, and possibly as well of independent, variables. The PDE thus obtained is generally *integrable*, indeed the term *C-integrable* is used to denote such equations (to distinguish them from the *S-integrable* equations solvable via IST: the letter C refers to the Change of variables, the letter S to the Spectral, or Scattering, transform). A simple instance of *C-integrable* equations is the Burgers equation (5), which is linearized via the change of dependent variable

$$\tilde{q}(x,t) = q(x,t) \exp\left[-\int_{-\infty}^{x} dy q(y,t)\right]$$

$$q(x,t) = \frac{\tilde{q}(x,t)}{1 - \int_{-\infty}^{x} dy\, \tilde{q}(y,t)}$$

entailing the linear PDE

$$\tilde{q}_t + \tilde{q}_{xx} = 0$$

A second example is the "Liouville equation"

$$u_{xt} = \exp(u) \qquad [58a]$$

or equivalently, in "light-cone coordinates" ($\xi = x + t$, $\tau = -x + t$)

$$u_{\tau\tau} - u_{\xi\xi} = \exp(u) \qquad [58b]$$

the general solution of which reads

$$u(x,t) = f(x) - g(t) - 2\log\left\{a \int_{x_0}^{x} dx' \exp[f(x')] + (2a)^{-1} \int_{t_0}^{t} dt' \exp[-g(t')]\right\}$$

with $f(x)$ and $g(t)$ arbitrary functions and $x_0, t_0$, $a$ arbitrary constants. And a third example is the Eckhaus equation

$$q_t = i\left\{q_{xx} + \left[2\left(|q|^2\right)_x + |q|^4\right] q\right\} \qquad [59]$$

which is linearized by the transformation

$$\hat{q}(x,t) = q(x,t) \exp\left[\int_{-\infty}^{x} dy |q(y,t)|^2\right]$$

$$q(x,t) = \frac{\hat{q}(x,t)}{\sqrt{1 + 2\int_{-\infty}^{x} dy |\hat{q}(y,t)|^2}}$$

entailing the linear PDE

$$\hat{q}_t = i\hat{q}_{xx}$$

Thanks to the simplicity of the technique to solve them, *C-integrable* PDEs provide a convenient tool to investigate the phenomenology associated with *nonlinear* PDEs. For instance the Burgers equation (5), which possesses kink-like solitons, is a simple nonlinear generalization of the heat equation; and the "relativistic invariance" of the Liouville equation, see (58b), makes it a convenient "toy model" in the context of relativistic field theory. The Eckhaus equation, (59), provides an interesting theoretical tool because of its similarity with the phenomenologically important NLS equation (6), as well as the fact that, thanks to its *C-integrability*, the structure of its solutions – which feature a remarkable solitonic zoology, including the possibility of "anelastic" solitonic reactions – can be studied in considerable detail, entailing an understanding of why such anelastic reactions are unlikely to be featured by solutions obtained in the context of the initial-value problem.

*C-integrable* PDEs are generally as well *S-integrable*, being generally associable with a spectral problem that can be explicitly solved; the converse, instead, is not generally true. Hence *C-integrability* represents a higher level of integrability than *S-integrability*; a ranking that is quite useful in spite of its lack of strict cogency caused by the possibility to consider also the transformation from a function to its spectral transform as a change of (dependent) variable.

The Lax approach, described in some detail above in the context of finite-dimensional integrable dynamical systems, was in fact originally invented in the context of integrable PDEs. For instance the KdV equation (35) corresponds to the (operator) Lax equation (to be compared with the matrix Lax equation (14))

$$\mathbf{L}_t = [\mathbf{L}, \mathbf{M}]$$

where now the Schrödinger operator $\mathbf{L}$ is defined by (36) (so that $\mathbf{L}_t = u_t(x,t)$) and the operator $\mathbf{M}$ is defined as follows:

$$\mathbf{M} = -4\left(\frac{\partial}{\partial x}\right)^3 + 6u(x,t)\frac{\partial}{\partial x} + 3u_x(x,t)$$

Closely connected with this approach is the AKNS method (due to M. J. Ablowitz, D. J. Kaup, A. C. Newell and H. Segur), based on the observation that the KdV equation (35) coincides with the integrability condition

$$\psi_{xxt} = \psi_{txx} \qquad [60]$$

for the following pair of linear PDEs (the first of which is just the eigenvalue equation for the Schrödinger operator $\mathbf{L}$, see (36)) satisfied by the function $\psi(x,k,t)$ :

$$\psi_{xx} = \left[u(x,t) - k^2\right]\psi \qquad [61a]$$

$$\psi_t = \left[-u_x(x,t) + 4ik^3\right]\psi + 2\left[u(x,t) + 2k^2\right]\psi_x \qquad [61b]$$

and, more generally, that every equation of the class (33) coincides with the integrability condition (60) for the eigenvalue equation (61a) and the equation

$$\psi_t = a(x,k,t)\,\psi + b(x,k,t)\,\psi_x \qquad [61c]$$

with an appropriate choice of the two functions $a(x,k,t)$ and $b(x,k,t)$. Indeed this *ansatz*, (61c), with $a(x,k,t)$ and $b(x,k,t)$ low-order polynomials in $k$, provides a quite straightforward technique to identify the simpler equations of the class (33); ditto for the extension of this approach based on more general eigenvalue problems than (61a).

Another powerful approach suitable to identify and investigate *integrable* PDEs is the so-called "dressing method" (introduced by V. E. Zakharov and A. B. Shabat and pursued by many others), in which one starts again (as in the approach leading to *C-integrable* equations) from an easily solvable evolution equation and then performs transformations (less elementary than just a change of variables) that modify ("dress") the original equation, obtaining thereby new (nontrivial and interesting) evolution equations, the *integrability* of which hinges on the control one has on the (dressing) transformation relating (both ways) the solutions of the new equations with those of the original equation. Of course many specific techniques are accommodated within this (admittedly vague) description; we must confine our remarks here to noting the crucial role that the Riemann-Hilbert problem generally plays in this context (indeed the Riemann-Hilbert problem also lies at the core of the solvability of the inverse spectral problem, although techniques not explicitly relying on it are also available).

*Algorithmic* approaches, particularly suitable to manufacture multisolitonic solutions and to identify nonlinear PDEs that are *integrable* inasmuch as they feature such solutions, were developed already at the beginning of the 70's. The pioneer of this approach was R. Hirota; less than a decade later a more sophisticated and general development – the so-called "tau-function" method – was invented by M. Sato and his pupils/collaborators.

Finally let us mention that many remarkable connections exist among *integrable* PDEs and *integrable* finite-dimensional dynamical systems such as those discussed above; for instance the time-evolution (taking generally place in the complex plane) of the poles of *rational* solutions of certain *integrable* PDEs obey the equations of motion of *integrable* dynamical systems interpretable as many-body problems.

### Why are certain nonlinear PDEs both integrable and widely applicable?

Several integrable PDEs play a key role in various applicative contexts, justifying the question figuring as title of this subsection. A metamathematical but enlightening, and heuristically quite useful, reply to this question reads as follows.

Consider as starting point a *large* class of nonlinear PDEs, and associate to it via some kind of asymptotic limit procedure a *single* nonlinear

PDE – to which it is then justified to attribute a certain *universal* character. If this procedure corresponds to a *physically* (or, more generally, *applicatively*) significant limit, it stands to reason that this universal PDE play a role in *several* applicative contexts (because the original class of PDEs, being *large*, certainly contains *several* equations of applicative relevance). And if the limit procedure is in some sense *asymptotically exact*, and it therefore *preserves* the property of *integrability*, it is also likely that this universal PDE be *integrable*, because for this it is sufficient that the original, *large* class of PDEs contain just one *integrable* PDE.

For instance most phenomena characterized by a dominant dispersive plane wave in a weakly nonlinear context can be shown, via an asymptotically exact multiscale expansion, to be modeled by the Nonlinear Schroedinger equation (6), the solution of which provides then the evolution, in appropriately rescaled "slow" and "coarse-grained" time and space variables, of the amplitude modulation of the dominant dispersive wave. This explains why this nonlinear PDE plays a key role in so many, disparate applicative contexts, and it also implies, in the light of the above argument, its integrability.

The reasoning outlined above is quite robust, and it allows to infer that, if instead the universal limit equation is *not* integrable, then the large class of PDEs from which it originates cannot contain *any* integrable equation, providing thereby the point of departure to obtain (quite useful) *necessary conditions for integrability*. Indeed these conditions are adequate to distinguish among different levels of integrability, for instance among *C-integrability* and *S-integrability*; with the Eckhaus equation (59) playing in this context a somewhat analogous role for *C-integrable* PDEs to that played by the Nonlinear Schrödinger equation (6) for *S-integrable* PDEs.

## Outlook

Many more important developments than could be covered in this overview have occurred in the last few decades; for these we refer to the books listed below (and there are many more), and to the literature cited there.

Let us end this entry by emphasizing that both the study of *integrable systems*, and its application to phenomenologically interesting situation – including technological innovations, for instance in nonlinear optics and telecommunications – are still in the forefront of current research; although perhaps the "heroic era" of this field of study is over.

# Interacting Particle Systems and Hydrodynamic Equations

**C Landim**, IMPA, Rio de Janeiro, Brazil
and UMR 6085, Université de Rouen, France

## Introduction

We present the theory of hydrodynamic behavior of interacting particle systems in the context of exclusion processes, in which no more than one particle per site is allowed.

Denote by $\mathbb{T}_N = \mathbb{Z}/N\mathbb{Z}$ the discrete torus with $N$ points and let $\mathbb{T}_N^d = (\mathbb{T}_N)^d$. The state space $\mathcal{E}_N = \{0,1\}^{\mathbb{T}_N^d}$ consists of all configurations obtained by distributing particles on the discrete torus $\mathbb{T}_N^d$ respecting the exclusion rule which prevents more than one particle per site. The configurations are denoted by the Greek letter $\eta$ so that $\eta(x)$ is equal to 0 or 1 if site $x \in \mathbb{T}_N^d$ is vacant or occupied for the configuration $\eta$.

Denote by $\{\tau_x : x \in \mathbb{Z}^d\}$ the group of translations in $\mathcal{E}_N$: $(\tau_x\eta)(z) = \eta(x+z)$ for each $x$, $z$ in $\mathbb{Z}^d$. Here and below summations are performed modulo $N$. A function $f : \{0,1\}^{\mathbb{Z}^d} \to \mathbb{R}$ with finite support is called a cylinder function.

Fix a family of non-negative cylinder functions $c_j$, $1 \le j \le d$. Let $c_{x,x+e_j}(\eta) = c_j(\tau_x\eta)$ and consider the Markov process $\{\eta_t : t \ge 0\}$ on $\mathcal{E}_N$ with generator $L_N$ given by

$$(L_N f)(\eta) = \sum_{j=1}^{d} \sum_{x \in \mathbb{T}_N^d} c_{x,x+e_j}(\eta)[f(\sigma^{x,x+e_j}\eta) - f(\eta)] \qquad [1]$$

Here, $\{e_1, \ldots, e_d\}$ stands for the canonical basis of $\mathbb{R}^d$ and $\sigma^{x,y}\eta$ for the configuration obtained from $\eta$ by exchanging the occupation variables $\eta(x)$ and $\eta(y)$:

$$(\sigma^{x,y}\eta)(z) = \begin{cases} \eta(z) & \text{if } z \ne x, y \\ \eta(y) & \text{if } z = x \\ \eta(x) & \text{if } z = y \end{cases} \qquad [2]$$

In this dynamics at each bond $\{x, x+e_j\}$ the occupation variables $\eta(x), \eta(x+e_j)$ are exchanged at rate $c_{x,x+e_j}(\eta)$. This happens simultaneously and independently at each bond.

Notice that the total number of particles is conserved by the dynamics since only exchanges are allowed. Denote by $\Sigma_{N,K}(0 \le K \le |\mathbb{T}_N^d|)$ the hyperplane of all configurations $\eta$ of $\mathcal{E}_N$ with $K$ particles. Assume that the rates $c_j$ are nondegenerate for $\eta_t$ to be an irreducible Markov process on each $\Sigma_{N,K}$.

For $0 \le \alpha \le 1$, denote by $\nu_\alpha^N$ the Bernoulli product measure of parameter $\alpha$ on $\mathcal{E}_N$. Under $\nu_\alpha^N$, the variables $\{\eta(x), x \in \mathbb{T}_N^d\}$ are independent, with marginals given by

$$\nu_\alpha^N\{\eta(x) = 1\} = \alpha = 1 - \nu_\alpha^N\{\eta(x) = 0\}$$

Assume that the measures $\nu_\alpha^N, 0 \le \alpha \le 1$ are stationary for the Markov process $\eta_t$. An elementary computation shows that this is the case if each function $c_j$ does not depend on $\eta(0)$, $\eta(e_j)$, in which case the process is in fact reversible with respect to $\nu_\alpha^N$.

Let $\mathcal{M}_+(\mathbb{T}^d)$ be the space of finite positive measures on the torus $\mathbb{T}^d$ endowed with the weak topology. For each configuration $\eta$, let $\pi^N = \pi^N(\eta, \mathrm{d}u)$ be the positive measure on $\mathbb{T}^d$ obtained by assigning mass $N^{-d}$ to each particle:

$$\pi^N := N^{-d} \sum_{x \in \mathbb{T}_N^d} \eta(x)\delta_{x/N}(\mathrm{d}u) \qquad [3]$$

where $\delta_u$ stands for the Dirac measure on $u$. The measure $\pi^N$ is called the empirical measure associated to the configuration $\eta$. The integral of a continuous function $G : \mathbb{T}^d \to \mathbb{R}$ with respect to $\pi^N$ is denoted by

$$\langle \pi^N, G \rangle = N^{-d} \sum_{x \in \mathbb{T}_N^d} G(x/N)\eta(x)$$

Fix a density profile $\rho_0 : \mathbb{T}^d \to [0,1]$. A sequence of probability measures $\mu^N$ on $\mathcal{E}_N$ is said to be associated to $\rho_0$ if $\pi^N$ converges in probability to $\rho_0(u)\mathrm{d}u$ under $\mu^N$:

$$\lim_{N\to\infty} \mu^N \left\{ \left| \langle \pi^N, G \rangle - \int_{\mathbb{T}^d} G(u)\rho_0(u)\, \mathrm{d}u \right| > \delta \right\} = 0$$

for all continuous functions $G: \mathbb{T}^d \to \mathbb{R}$ and all $\delta > 0$. For a continuous profile $\rho_0$ consider, for instance, the product measure $\nu^N_{\rho_0(\cdot)}$ on $\mathcal{E}_N$ whose marginals are given by

$$\nu^N_{\rho_0(\cdot)}\{\eta(x) = 1\} = \rho_0(x/N)$$

It is easy to check that the sequence of probability measures $\nu^N_{\rho_0(\cdot)}$ is associated to $\rho_0$.

Denote by $W_{x,x+e_j}$ the instantaneous current of particles from $x$ to $x+e_j$. This is the rate at which a particle jumps from $x$ to $x+e_j$ minus the rate at which a particle jumps from $x+e_j$ to $x$:

$$W_{x,x+e_j} = \{\eta(x) - \eta(x+e_j)\}c_{x,x+e_j}(\eta)$$

Suppose that the mean value of the current vanishes under all stationary states $\nu^N_\alpha$. This denotes that the average displacement of each particle vanishes in the mean. In particular, in view of the central limit theorem, to observe an evolution of the density in the macroscopic scale, a diffusive rescaling of time is needed. On the other hand, if there is a net flux of particles, the evolution has to be examined in the Euler scale $tN$.

Denote by $\theta(N)$ the time rescaling: $N^2$ if the mean displacement of particles vanishes and $N$ otherwise. For each probability measure $\mu^N$ on $\mathcal{E}_N$, let $\mathbb{P}_{\mu^N}$ be the probability measure on the path space $D(\mathbb{R}_+, \mathcal{E}_N)$ induced by $\mu^N$ and the Markov process $\eta_t$ speeded up by $\theta(N)$. Expectation with respect to $\mathbb{P}_{\mu^N}$ is denoted by $\mathbb{E}_{\mu^N}$.

Denote by $\pi^N_t(\mathrm{d}u) = \pi^N(\eta_{t\theta(N)}, \mathrm{d}u)$ the empirical measure at time $t$. Fix a density profile $\rho_0: \mathbb{T}^d \to [0,1]$ and a sequence of probability measures $\mu^N$ on $\mathcal{E}_N$ associated to $\rho_0$. The goal of the theory of hydrodynamic limit of interacting particle systems is to show that for each $t > 0, \pi^N_t$ converges, as $N \uparrow \infty$, to a deterministic path $\pi(t, \mathrm{d}u) = \rho(t,u)\mathrm{d}u$ whose density $\rho$ is the solution of some partial differential equation, called the hydrodynamic equation.

The main tools available are entropy production and Dirichlet forms. Denote by $H_N(\mu^N|\nu^N)$ the entropy of a probability measure $\mu^N$ on $\mathcal{E}_N$ with respect to a reference probability measure $\nu^N$:

$$H_N(\mu^N|\nu^N) = \sup_f \left\{ \int_{\mathcal{E}_N} f\,\mathrm{d}\mu^N - \log \int_{\mathcal{E}_N} \mathrm{e}^f\,\mathrm{d}\nu^N \right\}$$

where the supremum is carried over all functions $f: \mathcal{E}_N \to \mathbb{R}$.

It follows from the general theory of Markov processes that the entropy of the state of the process with respect to an invariant state decreases in time. The rate at which the entropy production decreases can be estimated by the Dirichlet form: let $S^N_t$ be the semigroup associated to the generator $L_N$ defined in [1] speeded up by $\theta(N)$. An elementary computation gives that

$$\begin{aligned} &H_N(\mu^N S^N_t|\nu^N_\alpha) + 2\theta(N)\int_0^t \mathrm{d}s\, I^N_\alpha(\mu^N S^N_s) \\ &\quad\le H_N(\mu^N|\nu^N_\alpha) \end{aligned}$$

Here, $I^N_\alpha(\mu^N)$ is the convex and lower semicontinuous functional given by

$$I^N_\alpha(\mu^N) = -\langle f^{1/2}, L_N f^{1/2}\rangle_{\nu^N_\alpha}$$

where $f$ stands for the Radon–Nikodym derivative $\mathrm{d}\mu^N/\mathrm{d}\nu^N_\alpha$ and $\langle\cdot,\cdot\rangle_{\nu^N_\alpha}$ for the scalar product in $L^2(\nu^N_\alpha)$.

Therefore, if the initial state $\mu^N$ has entropy with respect to a reference measure $\nu^N_\alpha$ bounded by $C_0 N^d$, by convexity of $I^N_\alpha$,

$$\begin{aligned} &N^{-d} H_N(\mu^N S^N_t|\nu^N_\alpha) \\ &\quad + 2t\theta(N)N^{-d} I^N_\alpha\left(t^{-1}\int_0^t \mathrm{d}s \mu^N S^N_s\right) \le C_0 \end{aligned} \quad [4]$$

for all $t \ge 0$. This elementary estimate plays a fundamental role in the following sections.

## The Entropy Method

Consider an exclusion process with generator given by [1]. Fix $T > 0$, a density profile $\rho_0: \mathbb{T}^d \to [0,1]$ and a sequence of probability measures $\mu^N$ associated to $\rho_0$. Let $\mathbb{Q}_{\mu^N}$ be the measure on the path space $D([0,T], \mathcal{M}_+(\mathbb{T}^d))$ induced by the process $\pi^N_t$ and the initial state $\mu^N$.

To prove that $\pi^N_t$ converges to $\rho(t,u)\mathrm{d}u$ in probability, we first show that the sequence $\mathbb{Q}_{\mu^N}$ converges to the probability measure $\mathbb{Q}^*$ concentrated on the deterministic trajectory $\rho(t,u)\mathrm{d}u$, whose density is the solution of some partial differential equation with initial condition $\rho_0$. It follows from this result and general arguments that $\pi^N_t$ converges to $\rho(t,u)\mathrm{d}u$ for each $0 \le t \le T$.

To prove that $\mathbb{Q}_{\mu^N}$ converges to $\mathbb{Q}^*$, assume that we are able to prove tightness of the sequence $\mathbb{Q}_{\mu^N}$. Since there is at most one particle per site, all limit points $\mathbb{Q}^*$ of the sequence $\mathbb{Q}_{\mu^N}$ are concentrated on trajectories $\pi(t,\mathrm{d}u) = \rho(t,u)\mathrm{d}u$, which are absolutely continuous with respect to Lebesgue.

To characterize the limit points $\mathbb{Q}^*$, fix a smooth function $G: \mathbb{T}^d \to \mathbb{R}$ and consider the martingale

$$\begin{aligned} M^{G,N}_t &= \langle \pi^N_t, G\rangle - \langle \pi^N_0, G\rangle \\ &\quad - \int_0^t \theta(N) L_N \langle \pi^N_s, G\rangle\,\mathrm{d}s \end{aligned} \quad [5]$$

An elementary computation of its quadratic variation shows that $M_t^{G,N}$ vanishes in $L^2(\mathbb{P}_{\mu^N})$ as $N \uparrow \infty$.

Denote by $\mathcal{C}_0$ the space of cylinder functions which have zero mean with respect to all invariant states $\nu_\alpha^N$. Assume that the currents $W_{0,e_j}, 1 \le j \le d$, belong to $\mathcal{C}_0$ so that a diffusive scaling $\theta(N) = N^2$ is in force. Notice that

$$L_N \eta(x) = \sum_{j=1}^{d} W_{x-e_j,x} - W_{x,x+e_j}$$

In particular, after a summation by parts, the integral term on the right-hand side of [5] can be written as

$$\int_0^t N^{1-d} \sum_{j=1}^{d} \sum_{x \in \mathbb{T}_N^d} (\nabla_{u_j}^N H)(x/N) W_{x,x+e_j}(s)\, \mathrm{d}s \qquad [6]$$

where $(\nabla_{u_j}^N H)(x/N) = N\{H(x+e_j/N) - H(x/N)\}$. Notice that this sum is in principle of order $N$.

To illustrate the entropy method, consider the symmetric simple exclusion process obtained by taking $c_j = 1/2$ in [1] and observe that the current $W_{0,e_j} = (1/2)\{\eta(0) - \eta(e_j)\}$. A second summation by parts permits to rewrite the martingale [5] as

$$\langle \pi_t^N, G \rangle - \langle \pi_0^N, G \rangle - \frac{1}{2} \int_0^t \langle \pi_s^N, \Delta_N G \rangle\, \mathrm{d}s$$

where $\Delta_N$ is the discrete Laplacian.

Since the martingale $M_t^{G,N}$ vanishes in $L^2(\mathbb{P}_{\mu^N})$, as $N \uparrow \infty$, all limit points $\mathbb{Q}^*$ are concentrated on weak solutions of the linear heat equation. It remains to recall that there is a unique weak solution of the Cauchy problem for the heat equation to conclude that the sequence $\mathbb{Q}_{\mu^N}$ converges to $\mathbb{Q}^*$, the measure concentrated on the deterministic path $\pi_t(\mathrm{d}u) = \rho(t,u)\mathrm{d}u$ whose density $\rho$ is the solution of the heat equation with initial condition $\rho_0$.

The symmetric simple exclusion process has the very special property that the martingale $M_t^{G,N}$ can be written as a function of the empirical measure. This is not the case for all the other models, for which a further argument is needed to close eqn [5] in terms of the empirical measure.

To present the additional arguments needed, assume that $c_j(\eta) = 1 + [\eta(-e_j) + \eta(2e_j)]$. In this case, the current $W_{0,e_j}$ is equal to

$$\{\eta(0) - \eta(e_j)\} + \{\eta(0)\eta(-e_j) - \eta(e_j)\eta(2e_j)\} + \{\eta(0)\eta(2e_j) - \eta(-e_j)\eta(e_j)\}$$

A second summation by parts in [6] permits to rewrite it as

$$\int_0^t N^{-d} \sum_{j=1}^{d} \sum_{x \in \mathbb{T}_N^d} (\partial_{u_j}^2 H)(x/N) \tau_x h(\eta_{sN^2})\, \mathrm{d}s + o_N(1) \qquad [7]$$

where $h(\eta) = \eta(0) + 2\eta(0)\eta(-e_j) - \eta(0)\eta(2e_j)$. The remainder $o_N(1)$ appears because we replaced discrete space derivatives by continuous ones.

In contrast with the symmetric simple exclusion process, the martingale $M_t^{G,N}$ defined in [5] is not a function of the empirical measure and an argument is needed to close the equation.

For each positive integer $\ell$ and $d$-dimensional integer $x$, denote by $\eta^\ell(x)$ the empirical density of particles in a box of length $2\ell + 1$ centered at $x$:

$$\eta^\ell(x) = \frac{1}{(2\ell+1)^d} \sum_{|y-x| \le \ell} \eta(y)$$

For a cylinder function $h : \mathcal{E}_N \to \mathbb{R}$, let $\tilde{h}(\alpha)$ be the expected value of $h$ with respect to the invariant state $\nu_\alpha^N : \tilde{h}(\alpha) = E_{\nu_\alpha^N}[h(\eta)]$. For $\ell \ge 1$ and a cylinder function $h$, let

$$V_\ell(\eta) = \left| \frac{1}{(2\ell+1)^d} \sum_{|y| \le \ell} (\tau_y h)(\eta) - \tilde{h}(\eta^\ell(0)) \right|$$

**Theorem 1** *Consider a sequence of probability measures $m^N$ on $\mathcal{E}_N$ such that $I_\alpha^N(m^N) \le C_0 N^{d-2}$ for some $0 < \alpha < 1$ and some finite constant $C_0$. Then,*

$$\limsup_{\varepsilon \to 0} \limsup_{N \to \infty} \mathbb{E}_{\mu^N} \left[ N^{-d} \sum_{x \in \mathbb{T}_N^d} \tau_x V_{\varepsilon N}(\eta) \right] = 0$$

This statement, due to Guo *et al.* (1988), permits the replacement of a local function $h$ by a function of the density of particles over a macroscopic cube. It is the main step in the proof of the hydrodynamic behavior of gradient systems, defined below, and its proof can be found in Kipnis and Landim (1999, chapter 5).

Assume that the sequence $\mu^N$ has entropy with respect to a reference invariant state $\nu_\alpha^N$ bounded by $C_0 N^d$ for some finite constant $C_0$. It follows from [4] that the sequence of measures $T^{-1} \int_0^T \mathrm{d}s \mu^N S_s^N$ satisfies the assumptions of Theorem 1. Therefore, due to the presence of the time integral, we may replace the cylinder function $h$ in [7] by $\tilde{h}(\eta^{\varepsilon N}(x))$. Since $\eta^{\varepsilon N}(0)$ can be written as $\langle \pi^N, \iota_\varepsilon \rangle$, where $\iota_\varepsilon = (2\varepsilon)^{-d} 1\{[-\varepsilon, \varepsilon]^d\}$, we now have expressed the martingale [5] in terms of the empirical measure.

Repeating the arguments presented for the symmetric simple exclusion process, we may conclude that all limit points $\mathbb{Q}^*$ of the sequence $\mathbb{Q}_{\mu^N}$ are concentrated on paths $\pi_t(\mathrm{d}u) = \rho(t,u)\mathrm{d}u$, whose density $\rho$ is a weak solution of the parabolic equation

$$\begin{cases} \partial_t \rho = \Delta(\rho + \rho^2) \\ \rho(0, \cdot) = \rho_0(\cdot) \end{cases}$$

because $\tilde{h}(\alpha) = \alpha + \alpha^2$ for $h(\eta) = \eta(0) + 2\eta(0)\eta(-e_j) - \eta(0)\eta(2e_j)$. It remains to show the uniqueness of weak solutions of this differential equation to conclude.

The second integration by parts in [6] was possible because the currents could be written as the difference of local functions and their translations, a very special property not shared by most interacting particle systems. Processes with this attribute are called gradient systems.

## Nongradient Models

Consider an exclusion process with rates $c_j(\eta) = 1 + \eta(-e_j)$, in which case the current is given by

$$W_{0,e_j} = \{\eta(0) - \eta(e_j)\} + \{\eta(0) - \eta(e_j)\}\eta(-e_j)$$

a cylinder function in $\mathcal{C}_0$.

Fix $T > 0$, a density profile $\rho_0 : \mathbb{T}^d \to [0,1]$ and a sequence of probability measures $\mu^N$ associated to $\rho_0$ and having entropy with respect to a reference invariant state $\nu_\alpha^N$ bounded by $C_0 N^d$ for some finite constant $C_0$. Recall the definition of the sequence of measures $\mathbb{Q}_{\mu^N}$, assumed to be tight.

To characterize the limit points of $\mathbb{Q}_{\mu^N}$, fix a smooth function $G : \mathbb{T}^d \to \mathbb{R}$ and examine the martingale $M_t^{G,N}$ introduced in [5]. After an integration by parts, the integral term of the martingale becomes [6]. While a second integration by parts is possible for the first part of the current $\eta(0) - \eta(e_j)$, the second piece remains

$$\int_0^t N^{1-d} \sum_{j=1}^d \sum_{x \in \mathbb{T}_N^d} (\nabla_{u_j}^N H)(x/N) \tau_x w_j(\eta_{sN^2})\, \mathrm{d}s \qquad [8]$$

where $w_j = \{\eta(0) - \eta(e_j)\}\eta(-e_j)$. Notice the extra factor $N$ multiplying the sum and that $w_j$ belongs to $\mathcal{C}_0$. The next result and Theorem 4 are due to Varadhan (1994).

**Theorem 2** *Consider a sequence of probability measures $m^N$ on $\mathcal{E}_N$ such that $H_N(m^N | \nu_\alpha^N) \le C_0 N^d$ for some $0 < \alpha < 1$ and some finite constant $C_0$. Fix a smooth function $G : \mathbb{T}^d \to \mathbb{R}$ and a cylinder function $\Psi$ in $\mathcal{C}_0$. There exists a seminorm $\|\cdot\|_\alpha$ such that*

$$\limsup_{N\to\infty} \left\{ \mathbb{E}_{m^N}\left[ \left| \int_0^T \mathrm{d}s N^{1-d} \sum_{x\in\mathbb{T}_N^d} G(x/N)\tau_x \Psi(\eta_{sN^2}) \right| \right] \right\}^2 \le C_0 T \|G\|_2^2 \sup_{0\le\alpha\le 1} \|\Psi\|_\alpha^2 \qquad [9]$$

The explicit form of the seminorm $\|\cdot\|_\alpha$ can be found in Kipnis and Landim (1999, chapter 7). The proof of Theorem 2 requires a sharp estimate on the spectral gap of the generator $L_N$. Denote by $\Lambda_\ell$ the cube $\{-\ell, \ldots, \ell\}^d$ and by $L_{\Lambda_\ell}$ the restriction of the generator $L_N$ to the cube $\Lambda_\ell$, obtained by suppressing all jumps from $\Lambda_\ell$ (resp. $\Lambda_\ell^c$) to $\Lambda_\ell^c$ (resp. $\Lambda_\ell$). For $0 \le K \le |\Lambda_\ell|$, let $\nu_{\Lambda_\ell, K}$ be the uniform measure on the configurations of $\{0,1\}^{\Lambda_\ell}$ with $K$ particles. The following estimate is needed in the proof of Theorem 2:

**Theorem 3** *There exists a finite constant $C_0$ such that*

$$\langle f, f\rangle_{\nu_{\Lambda_\ell,K}} \le C_0 \ell^2 \langle f, (-L_{\Lambda_\ell}) f\rangle_{\nu_{\Lambda_\ell,K}}$$

*for all $\ell \ge 1, 0 \le K \le |\Lambda_\ell|$ and zero-mean function $f$ in $L^2(\nu_{\Lambda_\ell,K})$.*

This result is due to Quastel (1992) for symmetric simple exclusion processes. Yau developed a general method to prove sharp estimates for the spectral gap of the generator for conservative dynamics (see Lu and Yau (1993) and Yau (1997)).

Since the parallelogram identity is easy to check, by polarization we can define a semi-inner product $\ll \cdot, \cdot \gg_\alpha$ from the seminorm $\|\cdot\|_\alpha$. Denote by $\mathcal{H}_\alpha$ the Hilbert space induced by $\mathcal{C}_0$ and the semi-inner product $\ll \cdot, \cdot \gg_\alpha$ .

Denote by $L$ the generator [1] extended to $\mathbb{Z}^d$. Notice that $Lf$ belongs to $\mathcal{C}_0$ for any cylinder function $f$, and that the gradients $\eta(e_j) - \eta(0)$, and the currents $w_j, 1 \le j \le d$, also belong to $\mathcal{C}_0$. The next result states that all functions in $\mathcal{H}_\alpha$ can be written as a linear combination of gradients and cylinder functions in the image of the generator.

**Theorem 4** *Denote by $L\mathcal{C}_0$ the space $\{Lg : g \in \mathcal{C}_0\}$. For each $0 \le \alpha \le 1$,*

$$\mathcal{H}_\alpha = \overline{L\mathcal{C}_0} \oplus \{\eta(e_j) - \eta(0) : 1 \le j \le d\}$$

In particular, there exists a matrix $\{D_{i,j}(\alpha) : 1 \le i, j \le d\}$ and a sequence of functions $\{f_{i,k}(\alpha, \cdot) \in \mathcal{C}_0 : k \ge 1\}, 1 \le i \le d$, for which

$$w_i + \sum_{j=1}^d D_{i,j}(\alpha)\{\eta(e_j) - \eta(0)\} - Lf_{i,k}(\alpha, \cdot)$$

vanishes in $\mathcal{H}_\alpha$ as $k \uparrow \infty$. For reversible systems (and more generally for generators satisfying a sector condition), it can be shown that the sequence of local functions $f_{i,k}(\alpha, \eta)$ can be taken independent of $\alpha : f_{i,k}(\alpha, \eta) = f_{i,k}(\eta)$. Moreover, with a little extra effort, one obtains a bound uniform in $\alpha$:

$$\inf_{f\in\mathcal{C}_0} \sup_{0\le\alpha\le 1} \left\| w_i + \sum_{j=1}^d D_{i,j}(\alpha)\{\eta(e_j) - \eta(0)\} - Lf \right\|_\alpha = 0 \qquad [10]$$

This estimate together with some algebraic relations in $\mathcal{H}_\alpha$ give a variational formula for the matrix $D_{i,j}$:

for every vector $v$ in $\mathbb{R}^d$,

$$v \cdot D(\alpha)v = \frac{1}{\alpha(1-\alpha)} \inf_{f \in \mathcal{C}_0} \left\| \sum_{i=1}^{d} v_i w_i - Lf \right\|_{\alpha}^{2} \qquad [11]$$

It can also be shown that the matrix $D$ is continuous and strictly elliptic.

We may now complete the proof of the hydrodynamic behavior. Recall that the main difficulty was to express formula [8] in terms of the empirical measure. Fix $1 \le i \le d$ and consider a sequence of cylinder functions $\{f_{i,k} : k \ge 1\}$ satisfying [10] asymptotically as $k \uparrow \infty$. Adding and subtracting the expression $\sum_{1 \le k \le d} D_{j,k}(\eta^{\varepsilon N}(0))\{\eta^{\varepsilon N}(e_j) - \eta^{\varepsilon N}(0)\} - Lf_{j,k}$, [8] becomes the sum of three terms.

The first one is just the expression which appears inside the expectation in [9] with $G = (\nabla^N_{u_j} H)$ and $\Psi$ given by

$$w_j + \sum_{k=1}^{d} D_{j,k}(\eta^{\varepsilon N}(0))\{\eta^{\varepsilon N}(e_j) - \eta^{\varepsilon N}(0)\} - Lf_{j,k}$$

Since the sequence of measure $\mu^N$ satisfies the assumptions of Theorem 2, a modification of the proof of this theorem, to take into account the dependence of $\Psi$ on $N$ and $\varepsilon$, shows that the limit of the expectation of the absolute value of the first term in the decomposition, as $N \uparrow \infty$ and then $\varepsilon \downarrow 0$, is bounded by

$$C_0\, T \|\partial_{u_j} H\|_2^2 \sup_{0 \le \alpha \le 1} \|\Psi_{j,\alpha}\|_{\alpha}^2$$

where

$$\Psi_{j,\alpha} = w_j + \sum_{k=1}^{d} D_{j,k}(\alpha)\{\eta(e_j) - \eta(0)\} - Lf_{j,k}$$

By [10], the penultimate expression vanishes as $k \uparrow \infty$.

The second term in the decomposition is

$$\int_0^t \mathrm{d}s N^{1-d} \sum_{j,k=1}^{d} \sum_{x \in \mathbb{T}_N^d} (\nabla^N_{u_j} H)(x/N) \tau_x L f_{j,k}(\eta_{sN^2})$$

The presence of the generator $L$ and the diffusive rescaling of time permit to show that the expectation of the absolute value of this expression is of order $N^{-1}$ for each fixed $k$.

Finally, the third term is equal to

$$-\int_0^t \mathrm{d}s N^{1-d} \sum_{j,k=1}^{d} \sum_{x \in \mathbb{T}_N^d} (\nabla^N_{u_j} H)(x/N) D_{j,k} \times \left(\eta^{\varepsilon N}_{sN^2}(x)\right)\left\{\eta^{\varepsilon N}_{sN^2}(x+e_k) - \eta^{\varepsilon N}_{sN^2}(x)\right\}$$

A second integration by parts is now possible and one obtains that the previous expression is equal to

$$\int_0^t \mathrm{d}s N^{-d} \sum_{j,k=1}^{d} \sum_{x \in \mathbb{T}_N^d} \left(\partial^2_{u_j,u_k} H\right)(x/N)\, d_{j,k}\left(\eta^{\varepsilon N}_{sN^2}(x)\right) + o_N(1)$$

where $d'_{j,k} = D_{j,k}$. We have already seen in the derivation of the hydrodynamic equation for gradient systems that this sum can be expressed as a function of the empirical measure. Since all limit points are concentrated on paths $\pi_t(\mathrm{d}u)$ which are absolutely continuous, this integral converges to

$$\sum_{j,k=1}^{d} \int_0^t \mathrm{d}s \int_{\mathbb{T}^d} \mathrm{d}u \left(\partial^2_{u_j,u_k} H\right)(u)\, \mathrm{d}_{j,k}(\rho(s,u))$$

Since the martingale [5] vanishes, all limit points are concentrated on trajectories $\pi_t(\mathrm{d}u) = \rho(t,u)\mathrm{d}u$ which are weak solutions of

$$\partial_t \rho = \sum_{j,k=1}^{d} \partial_{u_j}\left\{\left[\delta_{j,k} + D_{j,k}(\rho)\right]\partial_{u_k}\rho\right\}$$

where $D$ is the strictly elliptic and continuous matrix given by the variational formula [11]. Here, the identity matrix $\delta_{j,k}$ comes from the first piece of the current which permitted a second integration by parts. A uniqueness result of weak solutions of the Cauchy problem with initial condition $\rho_0$ concludes the proof of the hydrodynamic behavior of this nongradient system.

## Hyperbolic Equations

Consider the asymmetric simple exclusion process obtained by setting $c_j(\eta) = \eta(0)[1-\eta(e_j)]$ in formula [1]. Notice that the current $W_{0,e_j} = \eta(0)[1-\eta(e_j)]$ has mean $\alpha(1-\alpha)$ with respect to the invariant state $\nu^N_\alpha$, suggesting the Euler rescaling of time $\theta(N) = N$.

Let $\le$ be the partial order on $\mathcal{E}_N$ defined by $\eta \le \xi$ if $\eta(x) \le \xi(x)$ for every $x$ in $\mathbb{T}_N^d$. The asymmetric exclusion process is attractive: there exists a stochastic evolution on $\mathcal{E}_N \times \mathcal{E}_N$ with the following two properties: (1) it preserves the order, in the sense that $\eta_t \le \xi_t$ for all $t \ge 0$ if $\eta_0 \le \xi_0$ and (2) each coordinate evolves according to the original asymmetric exclusion dynamics. This coupling, which may be constructed by letting particles jump together as much as possible, is the main tool in the derivation of the hydrodynamic equation of asymmetric processes.

Fix a smooth function $G : \mathbb{T}^d \to \mathbb{R}$ and recall definition [5] of the martingale $M_t^{G,N}$. An elementary computation shows that the quadratic variation of this martingale vanishes as $N \uparrow \infty$. On the other

hand, after an integration by parts, the integral term of the martingale becomes

$$\int_0^t N^{-d} \sum_{j=1}^{d} \sum_{x\in\mathbb{T}_N^d} (\nabla_{u_j}^N H)(x/N)\eta_{sN}(x) \times [1-\eta_{sN}(x+e_j)]\,ds$$

Assume that the state of the process at any macroscopic time $s$ is close to a product measure associated to some profile $\rho(s,\cdot)$. Since the martingale vanishes asymptotically, taking expectations in [5], we obtain that the density profile should be a weak solution of the quasilinear hyperbolic equation

$$\partial_t \rho + \sum_{j=1}^{d} \partial_{u_j} F(\rho) = 0 \qquad [12]$$

where $F(a) = a(1-a)$.

It is well known that solutions of this equation may develop shocks even if the initial profile $\rho_0(\cdot)$ is smooth and that there is no uniqueness of weak solutions. Several criteria have been introduced to select the relevant solution among the weak solutions. Kružkov (1970), for instance, in the case where density profile $\rho_0 : \mathbb{T}^d \to \mathbb{R}$ is bounded, proved that there exists a unique measurable function $\rho$ which satisfies the entropy condition

$$\partial_t|\rho - c| + \sum_{i=1}^{d} \partial_{u_i}|F(\rho) - F(c)| \le 0 \qquad [13]$$

in the sense of distributions on $(0,\infty)\times\mathbb{T}^d$, for every $c\in\mathbb{R}$, and which converges to the initial condition in $L^1(\mathbb{T}^d)$ as $t\downarrow 0$: $\lim_{t\to 0}\|\rho_t - \rho_0\|_1 = 0$.

Fix $T>0$ and a density profile $\rho_0 : \mathbb{T}^d \to [0,1]$. To couple the original process with another one starting from a different initial sate, we need to impose the initial distribution to be of product form. Consider, therefore, a sequence of "product" probability measures $\mu^N$ associated to $\rho_0$ and recall the definition of the sequence of measures $\mathbb{Q}_{\mu^N}$ given in the section "The entropy method," assumed to be tight.

We have to prove that all limit points are concentrated on entropy solutions of [12]. Coupling the original process $\eta_t$ with another one, denoted by $\xi_t$, starting from the Bernoulli product measure with density $\alpha$, and examining the time evolution of $\sum_{x\in\mathbb{T}_N^d}|\eta_{tN}(x)-\xi_{tN}(x)|$, we derive an entropy inequality at the microscopic level: let $\bar\mu^N$ be a sequence of probability measures on the product space $\mathcal{E}_N\times\mathcal{E}_N$ whose first coordinate is $\mu^N$. Denote by $\mathbb{P}_{\bar\mu^N}^N$ the measure on the path space $D([0,T],\mathcal{E}_N\times\mathcal{E}_N)$ induced by $\bar\mu^N$ and the coupling informally described at the beginning of this section. Rezakhanlou (1991) proved the following theorem:

**Theorem 5** *For every smooth positive function $H$ with compact support in $(0,\infty)\times\mathbb{T}^d$ and every $\varepsilon>0$,*

$$\lim_{\ell\to\infty}\lim_{N\to\infty}\mathbb{P}_{\bar\mu^N}^N\Bigg[\int_0^\infty dt\, N^{-d}\sum_{x\in\mathbb{T}_N^d}\Big\{\partial_t H(t,x/N)\big|\eta_t^\ell(x)-\xi_t^\ell(x)\big| + \sum_{i=1}^{d}(\partial_{u_i}H)(t,x/N)\big|F(\eta_t^\ell(x))-F(\xi_t^\ell(x))\big|\Big\}\ge -\varepsilon\Bigg] = 1$$

If we now assume that the second coordinate $\xi_t$ is initially distributed according to the stationary state $\nu_\alpha^N$, it is not difficult to replace $\xi_t^\ell$ in the above formula by $\alpha$, obtaining a microscopic version of the entropy inequality.

In the one-dimensional nearest-neighbor case, by coupling arguments, we may replace the average $\eta^\ell(0)$ over a large microscopic box by an average $\eta^{\varepsilon N}(0)$ over a small macroscopic box, deriving the entropy inequality [13]. To conclude the proof it remains to show, by means of coupling argument again, that the density profile at time $t$ converges in $L^1(\mathbb{T}^d)$ to the initial condition as $t\downarrow 0$.

In higher dimensions or in the one-dimensional non-nearest-neighbor case, it has not been proved that replacement of $\eta^\ell(0)$ by $\eta^{\varepsilon N}(0)$ is allowed. One is thus forced to consider measure-valued solutions of eqn [12]. Details can be found in Kipnis and Landim (1999, chapter 8).

## Relative Entropy Method

The relative entropy method, due to Yau (1991), is based on the analysis of the time evolution of the entropy of the state of the process with respect to the product measure associated to the solution of the hydrodynamic equation.

While the entropy method requires uniqueness of weak solutions and proves the existence of weak solutions, the relative entropy method requires the existence of a smooth solution and proves the uniqueness of such smooth solutions.

Consider the exclusion process with rates $c_j(\eta) = 1 + [\eta(-e_j) + \eta(2e_j)]$. We have seen that the hydrodynamic equation of this model is given by the nonlinear parabolic equation

$$\partial_t \rho = \Delta\{\rho + \rho^2\} \qquad [14]$$

Fix a profile $\rho_0 : \mathbb{T}^d \to [0,1]$ bounded away from 0 and 1: $0<\delta\le\rho_0(u)\le 1-\delta$. Let $\rho(t,u)$ be the solution of the hydrodynamic equation [14] with initial condition $\rho_0$ and denote by $\nu_{\rho(t,\cdot)}^N$ the product

measure with slowly varying parameter associated to the profile $\rho(t,\cdot)$:

$$\nu^N_{\rho(t,\cdot)}\{\eta;\eta(x)=1\}=\rho(t,x/N),\quad \text{for } x\in\mathbb{T}^d_N$$

**Theorem 6** *Let* $\{\mu^N : N\geq 1\}$ *be a sequence of probability measures on* $\mathcal{E}_N$ *whose entropy with respect to* $\nu^N_{\rho_0(\cdot)}$ *is of order* $o(N^d)$:

$$H_N\left(\mu^N|\nu^N_{\rho_0(\cdot)}\right)=o(N^d)$$

*Then, the relative entropy of the state of the process at the macroscopic time t with respect to* $\nu^N_{\rho(t,\cdot)}$ *is also of order* $o(N^d)$:

$$H_N\left(\mu^N S^N_t|\nu^N_{\rho(t,\cdot)}\right)=o(N^d)\quad \textit{for every } t\geq 0$$

It is not difficult to deduce from this result a strong version of the hydrodynamic limit behavior of the interacting particle system:

**Corollary 1** *Under the assumptions of the theorem, for every cylinder function* $\Psi$ *and every continuous function* $H:\mathbb{T}^d\to\mathbb{R}$,

$$\lim_{N\to\infty} E_{\mu^N S^N_t}\left[\left|N^{-d}\sum_{x\in\mathbb{T}^d_N} H(x/N)\tau_x\Psi(\eta)\right.\right.$$
$$\left.\left.-\int_{\mathbb{T}^d} H(u)\tilde{\Psi}(\rho(t,u))\,\mathrm{d}u\right|\right]=0$$

The relative entropy method can be extended to nongradient systems and to asymmetric processes, whose macroscopic evolution is described by quasilinear hyperbolic equations, up to the first shock.

The hydrodynamic behavior of an interacting particle system corresponds to a law of large numbers for the empirical measure. The central limit theorem is well understood in equilibrium, but remains to this date an important open question in nonequilibrium. The large deviations for diffusive systems have also been investigated, as well as the hydrodynamic behavior of systems in contact with reservoirs. The Navier–Stokes equations have been derived as a correction of the hydrodynamic equation of asymmetric particle systems. We refer to Kipnis and Landim (1999) for further details.

# Interacting Stochastic Particle Systems

**H Spohn**, Technische Universität München, Garching, Germany

## Introduction

According to the basic principles of mechanics, the motion of atoms and molecules is governed, in the semiclassical approximation, by the deterministic Hamiltonian equations of motion. While all evidence points in this direction, for many problems this Hamiltonian approach is so complicated that it hardly yields any useful results. A simple example are many ($10^9$) polystyrene balls (size $1\,\mu m$) immersed in water. The Hamiltonian description would have to deal with the degrees of freedom of all the fluid molecules and all the polystyrene balls. Clearly, a more useful approach is to collect the incessant bombardment of a polystyrene ball by water molecules into a stochastic force acting on the ball with postulated statistical properties. For example, following Einstein, one could regard successive collisions as independent and occurring after an exponentially distributed waiting time. In addition to such stochastic forces, the polystyrene balls are charged and interact with each other through the screened Coulomb force.

On the one-particle level, stochastic models have a long tradition within statistical physics. Considerable part of the classical theory of Markov processes is the mathematical response to such type of description. The aspect of interaction is more recent. Its origin can be traced back to the Metropolis algorithm in early computer simulations ($\cong$1953). It was recognized that the Hamiltonian dynamics is a rather slow tool to statistically sample the Gibbs equilibrium distribution $Z^{-1} \exp[-H/k_B T]$. A more efficient route is to devise a stochastic algorithm which has as its unique stationary measure the Gibbs distribution. Such schemes are now known as Markov Chain Monte Carlo and of extremely wide use, not only in statistical physics but also in quantum chromodynamics (QCD) and other quantum field theories. The time appearing in the stochastic algorithm has no physical significance; it merely counts how often a certain operation is performed.

The second clearly identifiable push toward the use of interacting stochastic particle systems came from the study of critical dynamics. Close to a point of second-order phase transition, the equilibrium properties are very effectively handled by means of statistical field theories. Thus, it was natural to search for an extension into the time domain, which then led to time-dependent Ginzburg–Landau theories, where now time refers to physical time. These are interacting stochastic models, where one keeps only a few basic fields, together with their behavior under time reversal, their vector character, and whether they are dynamically conserved or not.

In probability theory, interacting stochastic particle systems date back to the seminal papers by M Kac in 1956 and independently by R L Dobrushin and by F Spitzer in 1970. Spitzer was motivated by spin-flip and spin-exchange dynamics, while Dobrushin had the vision of many locally interacting components. In the early days, one of the prime goals was the construction of the stochastic process in infinite volume, an enterprise which had important mathematical spin-off, for example, the theory of Dirichlet forms on function spaces. Physical models offer a rich menu to the probabilist, but there is also considerable input from other areas. To give just one example: in queueing theory one considers queues in series, that is, a customer served at one counter immediately moves on to the next one. If one regards as field the number of customers at each counter, one has an interacting stochastic particle system, the interaction being mediated through the servers.

This article is split into two sections. In the first one, we list and explain a few prototypical interacting stochastic particle systems. Of course, the list is hardly exhaustive and we restrict ourselves from the outset to models from statistical physics. In the second part, we summarize prominent lines of recent research. Again the wealth of material is overwhelming and we draw the line according to the rules of mathematical physics.

## Model Systems

Our list is determined by the intrinsic mathematical properties of the stochastic particle system. Alternatively, a classification is possible according to the physical system, which would, however, be less transparent for our purposes. We restrict ourselves to models with only position-like degrees of freedom, but if needed velocity-like fields may be included. The most basic distinction is the behavior under time reversal. A model is called (statistically) "time reversible" if a particular history and its time-reversed image have the same probability. Technically, one imposes this through the condition of detailed balance. Nonreversible systems are much less explored, but currently a very active area of research.

**Reversible Models**

1. *Spin-flip, Glauber dynamics*. One considers spins attached to the sites of a regular lattice, which for symplicity we take as the hypercubic lattice $\mathbb{Z}^d$. The spin at site $x \in \mathbb{Z}^d$ is denoted by $\sigma_x = \pm 1$ and the whole spin configuration is denoted by $\sigma$. Thus, the state space of the Markov processs is $\{-1, 1\}^{\mathbb{Z}^d} = \Omega$. Spin configurations evolve in time through random spin flips, that is, through a change from $\sigma_x$ to $-\sigma_x$ according to configuration-dependent rates $c_x(\sigma)$. $c_x(\sigma)$ is local, in the sense that it depends only on the spins close to $x$, and is translation invariant, that is, if $\tau_y$ is the shift by $y$, then $c_{x+y}(\tau_y \sigma) = c_x(\sigma)$. If the current spin configuration is $\sigma(t)$, then after a short time $\mathrm{d}t$

$$\sigma_x(t+\mathrm{d}t) = \begin{cases} \sigma_x(t) & \text{with probability } 1 - c_x(\sigma(t))\,\mathrm{d}t \\ -\sigma_x(t) & \text{with probability } c_x(\sigma(t))\,\mathrm{d}t \end{cases}$$

The update is performed independently at each lattice site. Technically, it is more concise to specify the generator, $L$, of the Markov process. It acts on local functions $f : \Omega \to \mathbb{R}$ and is given by

$$Lf(\sigma) = \sum_{x \in \mathbb{Z}^d} c_x(\sigma)(f(\sigma^x) - f(\sigma)) \qquad [1]$$

where $\sigma^x$ denotes the configuration $\sigma$ with the spin at site $x$ reversed. The transition probability from the configuration $\sigma$ to the configuration $\sigma'$ in time $t \geq 0$ is given by the matrix element $(\mathrm{e}^{Lt})_{\sigma,\sigma'}$ of the Markov semigroup $\mathrm{e}^{Lt}$.

To impose time reversibility, one needs an energy function $H(\sigma)$ constructed according to the rules of equilibrium statistical mechanics. The condition of detailed balance then reads

$$c_x(\sigma) = c_x(\sigma^x)\mathrm{e}^{-\beta(H(\sigma^x) - H(\sigma))} \qquad [2]$$

with $\beta = 1/k_{\mathrm{B}}T$ the inverse temperature. Note that on the right only energy differences appear, which are always well defined. In finite volume the unique invariant measure is the Gibbs measure $Z^{-1}\mathrm{e}^{-\beta H}$.

2. *Spin-exchange, Kawasaki dynamics, stochastic lattice gases*. We model particles hopping on the lattice $\mathbb{Z}^d$ and switch to the occupation variables $\eta_x$, where $\eta_x = 0$ stands for site $x$ empty and $\eta_x = 1$ stands for site $x$ occupied. The state space is $\Omega = \{0, 1\}^{\mathbb{Z}^d}$. Since the number of particles is conserved, the basic dynamical process is a random jump of a particle from $x$ to a nearby site $y$, provided $\eta_y = 0$. Therefore, we specify the exchange rates $c_{xy}(\eta)$ between $x$ and $y$. They are local, translation invariant and symmetric, that is, $c_{xy}(\eta) = c_{yx}(\eta)$. The generator now reads

$$Lf(\eta) = \frac{1}{2}\sum_{x,y \in \mathbb{Z}^d} c_{xy}(\eta)(f(\eta^{xy}) - f(\eta)) \qquad [3]$$

where $\eta^{xy}$ is the configuration $\eta$ with the occupancies at sites $x$ and $y$ exchanged.

The condition of detailed balance refers to the exchange and reads

$$c_{xy}(\eta) = c_{xy}(\eta^{xy})\mathrm{e}^{-\beta(H(\eta^{xy}) - H(\eta))} \qquad [4]$$

In [4] we can freely add to $H$ the chemical potential $-\mu \sum_x \eta_x$. Thus for stochastic lattice gases there is a one-parameter family of invariant measures, labeled by the chemical potential $\mu$.

3. *Interacting Brownian motions*. These motions model, for example, suspensions as mentioned in the "Introduction". One considers a box $\Lambda \subset \mathbb{R}^d$ containing $N$ Brownian particles. The $j$th Brownian particle has position $x_j \in \Lambda$. Thus, the state space of the Markov process is $\Lambda^N$. We assume that the Brownian particles interact through a (sufficiently local) even pair potential $U$. Then the total potential energy is

$$H(\underline{x}) = \frac{1}{2}\sum_{i,j=1}^{N} U(x_i - x_j), \quad \underline{x} = (x_1, \ldots, x_N) \qquad [5]$$

The dynamics of the Brownian particles is given through the stochastic differential equations

$$\begin{aligned} \mathrm{d}x_j(t) = &- \sum_{i=1, i\neq j}^{N} \nabla U(x_j(t) - x_i(t))\ \mathrm{d}t \\ &+ \sqrt{2D_0}\mathrm{d}W_j(t), \quad j = 1, \ldots, N \end{aligned} \qquad [6]$$

$W_j(t), j = 1, \ldots, N$, are a collection of independent Brownian motions and $D_0$ is the diffusion coefficient of a single Brownian particle. Equation [6] has to be supplemented with suitable boundary conditions at the surface $\partial\Lambda$. Since the forces in [6] are the gradient of a potential, time reversibility is automatically satisfied with the invariant measure being $Z_N^{-1} \exp(-H(\underline{x})/D_0)\,\mathrm{d}x_1 \cdots \mathrm{d}x_N$.

4. *Ginzburg–Landau models*. Ginzburg–Landau models should be viewed as discretized versions of stochastic partial differential equations. At every lattice site $x \in \mathbb{Z}^d$, there is a real-valued field $\phi_x \in \mathbb{R}$, a field configuration being denoted by $\phi$. Formally, the state space is $\mathbb{R}^{\mathbb{Z}^d}$. Since the single-site space is noncompact, some growth condition at

infinity must be imposed. Next we give ourselves an energy, $H(\phi)$, one standard example being

$$H(\phi) = \sum_{x,y\in\mathbb{Z}^d,|x-y|=1} (\phi_x - \phi_y)^2 + \sum_{x\in\mathbb{Z}^d} V(\phi_x) \qquad [7]$$

The on-site potential increases sufficiently rapidly, so as to make large field values unlikely. The $\phi$-field evolves according to the set of stochastic differential equations

$$\mathrm{d}\phi_x(t) = -\frac{\partial H}{\partial \phi_x}(\phi(t))\mathrm{d}t + \sqrt{2/\beta}\,\mathrm{d}W_x(t), \quad x \in \mathbb{Z}^d \qquad [8]$$

where $\{W_x(t), x \in \mathbb{Z}^d\}$ is a collection of independent Brownian motions. If $V(\phi_x) = \phi_x^2$, then $\phi(t)$ is a Gaussian field theory. To have an Ising-type phase transition, one would have to choose $V(\phi_x) = \lambda\phi_x^2 + \phi_x^4$.

It is rather simple to modify [8] as to incorporate a conservation law. To each directed bond $(x, y)$, $|x - y| = 1$, one associates the current $j_{xy} = -j_{yx}$. If $e$ is a unit vector, $|e| = 1$, then

$$\mathrm{d}\phi_x(t) + \sum_{e,|e|=1} j_{xx+e}(t)\mathrm{d}t = 0, \quad x \in \mathbb{Z}^d \qquad [9]$$

The current has both a deterministic part, given through the gradient of a chemical potential, and a random part:

$$j_{xy}(t)\mathrm{d}t = -\left(\frac{\partial H}{\partial \phi_x} - \frac{\partial H}{\partial \phi_y}\right)(\phi(t))\mathrm{d}t + \mathrm{d}W_{xy}(t), \quad |x - y| = 1 \qquad [10]$$

where $W_{xy}(t) = -W_{yx}(t)$ is a collection of independent Brownian motions labeled by nearest-neighbor bonds. The conserved quantity is $\sum_x \phi_x$. Again, the dynamics has a one-parameter family of stationary measures labeled by the "magnetic field". Since in [8] and [10] the drift is the gradient of a potential, Ginzburg–Landau models are reversible.

5. *Interface dynamics*. The scalar field $\phi$ describes the location of an interface. The energy of an interface does not depend on its absolute displacements. Thus, interface models are special Ginzburg–Landau models, which have an energy $H(\phi)$ invariant under the global shift $\phi_x \to \phi_x + a$ for all $x \in \mathbb{Z}^d$. An example is

$$H(\phi) = \sum_{x,y\in\mathbb{Z}^d,|x-y|=1} V(\phi_x - \phi_y) \qquad [11]$$

with even $V$. Note that in order to have a normalizable equilibrium measure, the interface must be pinned somewhere.

6. *Several components*. For lattice gases, there may be several components. In a Ginzburg–Landau theory instead of a scalar, Ising-like field, one could consider a vector-valued, Heisenberg-like, field and require the energy to be invariant under global rotations of the field variables. The construction is as before and we do not have to repeat it.

7. *Constrained*, *glassy dynamics*. The constraint is enforced by setting some of the rates equal to zero. For example, in the case of standard Glauber dynamics, one could allow for a spin-flip only if at least two neighboring spins have the opposite sign. The Gibbs measure is still invariant, but the approach to equilibrium will be slowed down due to the constraint. It may even happen that the configuration space splits into several invariant subsets.

After this long and still incomplete list, let us turn to the nonreversible models.

### Nonreversible Models

Mathematically, one merely has to drop the condition of detailed balance. To have a more concrete example, let $L_i$ be the generator for the Glauber dynamics satisfying detailed balance with inverse temperature $\beta_i, i = 1, 2$. Then $L = L_1 + L_2$ generates a nonreversible dynamics provided $\beta_1 \neq \beta_2$. Physically, it corresponds to coupling the spins to two bulk thermal reservoirs of different temperatures. Our example leads to a general point which should be noted: While reversible models have a wide range of physical applicability, for nonreversible models nonequilibrium conditions have to be maintained over sufficiently long time spans, which poses considerable difficulties experimentally. Thus on a theoretical level, the efforts go into exploring properties of, say, semirealistic models.

Very roughly there are two broad classes of nonreversible models.

**Boundary-driven models** We consider a finite volume $\Lambda$. Inside $\Lambda$ the dynamics is reversible as explained before. At the boundary $\partial\Lambda$ the system is coupled to particle, resp. energy, reservoirs. In case the boundary chemical potential, resp. temperature, is not uniform, the dynamics is nonreversible. To be more concrete let us reconsider the lattice gas discussed in item (2) (see the discussion following eqn [2]). Inside $\Lambda$ the generator $L_\Lambda$ is given by [3] and satisfies detailed balance [4]. The boundary generator is

$$L_{\partial\Lambda} f(\eta) = \sum_{x\in\partial\Lambda} c_x(\eta)(f(\eta^x) - f(\eta)) \qquad [12]$$

where the notation is as in [1] with $\{-1, 1\}$ substituted by $\{0, 1\}$. $c_x(\eta)$ satisfies [2] with the same $\beta$ as in the bulk, but a chemical potential $\mu_x$ depending on $x \in \partial\Lambda$. $\mu_x$ controls the injection/

absorption of particles at $x$. The generator for the nonreversible dynamics is then

$$L = L_\Lambda + L_{\partial\Lambda} \qquad [13]$$

**Bulk-driven models** A prototype is the two-temperature model mentioned above. More widely studied is a nonconservative force acting globally. Here the standard example are particles moving in $\Lambda$ with periodic boundary conditions and subject to an additional uniform force field of strength $F$, which clearly cannot be written as the gradient of a potential. In the case of Brownian particles, by changing to a comoving frame of reference, one would be back to the reversible case $F=0$. For lattice gases the lattice provides a fixed frame and the driven model has properties very different from the undriven one. This leads us to:

8. *Driven lattice gases*. The generator $L$ is still given by [3]. Formally, we insert in [4] instead of $H$ the Hamiltonian $H(\eta) - \sum_x (F \cdot x)\eta_x$. The exchange rates then satisfy the condition of "local" detailed balance as

$$c_{xy}(\eta) = c_{xy}(\eta^{xy})\, e^{-\beta(H(\eta^{xy})-H(\eta))} \times e^{-\beta(F\cdot(x-y))(\eta_x-\eta_y)} \qquad [14]$$

This means, particles preferentially jump in the direction of $F$. On the infinite lattice the dynamics admits two classes of stationary measures. First, there is the Gibbs measure with particles piling up along $F$ and formally given by

$$Z^{-1}\, e^{-\beta(H(\eta)-\sum_x (F\cdot x)\eta_x)} \qquad [15]$$

With respect to this measure the dynamics is reversible. Second, there are translation invariant measures with nonzero steady-state current. This cannot happen for reversible models. A very widely studied particular case is the asymmetric simple exclusion process for which $d=1, H(\eta)=0$, and jumps are only to nearest-neighbor sites.

## Items of Interest

As there are thousands of research papers in mathematical physics alone, it is literally impossible to provide any sort of summary. On the other hand, the type of questions investigated are generic. Thus, we just explain what one would like to understand without paying much attention to the fractal boundary between "proven" and "unproven." For the construction of the stochastic processes listed above, there is a well-developed probabilistic theory available. Thus, the main focus is on "qualitative properties" of the stochastic particle system. As in the previous section, we distinguish between reversible and nonreversible models.

### Reversible Models

1. *Equilibrium state*. The most basic question concerns the classification of invariant measures in infinite volume. By construction, they are the Gibbs measures for the Hamiltonian appearing in the condition of detailed balance. In principle there could be more, which so far has been excluded only in dimension 1 or 2. Properties of the invariant measure belong to the domain of equilibrium statistical mechanics.

Thus we can turn directly to:

2. *Spectral analysis of the generator L*. We fix some extreme Gibbs measure stationary for $L$. By detailed balance, $e^{Lt}$ is a symmetric Markov semigroup in $L^2(\Omega, \mu)$. Hence, $L$ is self-adjoint and $L \leq 0$. Furthermore, it has a nondegenerate eigenvalue 0. The rate of approach to equilibrium is determined by the spectral gap of $L$. Related are log-Sobolev inequalities which serve as a stronger notion. For models with a conservation law, there is no spectral gap. Thus, the more appropriate question is to study how fast the gap vanishes as the volume $\Lambda$ increases. In the case of independent components, the spectral subspaces for $L$ are organized as single excitation, double excitation etc. Such a structure persists as the interaction is turned on which, on a mathematical level, is similar to the particle spectrum of a quantum field theory.

Physically more directly relevant are:

3. *Spacetime correlations*. To be concrete, let us consider a Ginzburg–Landau field theory $\phi_x(t)$ starting with a translation invariant Gibbs measure $\mu$. Then $\phi_x(t)$ is a spacetime stationary process. The two-point correlation function is the covariance

$$\langle \phi_x(t)\phi_0(0)\rangle - \langle \phi_0(0)\rangle^2 \qquad [16]$$

Its Fourier transform is directly linked to energy–momentum resolved scattering intensity from a probe which is modeled by the respective Ginzburg–Landau theory. For $t=0$, the expression [16] is the static correlation, again belonging to the domain of equilibrium statistical mechanics. The time decay depends on whether the field is dynamically conserved or not.

Correlation functions do not always capture the physics of the system well. This is certainly true for:

4. *Dynamics at low temperatures*. Let us consider the Glauber dynamics for the ferromagnetic Ising model in the finite but large volume $\Lambda$. Then there is a very high free energy barrier between configurations typical for the + phase and those typical for the − phase. If one starts the spin system in the + phase, one

may study through which configurations the system moves to the $-$ phase and how much time such a process will take. If the two phases are symmetric with the external magnetic field $h = 0$, the spin system tunnels, while for $h < 0$ and small the $+$ phase is metastable. Another widely studied situation, also experimentally, is the quenching from high to low temperatures. In our context this means that the initial measure is Bernoulli, while the Glauber dynamics runs at low temperatures. Then spin clusters coarsen as time proceeds developing well-defined interfaces which are governed through motion by mean curvature.

Close to a point of second-order phase transition, one has to deal with:

5. *Critical dynamics*. The usual Glauber dynamics becomes very slow at the critical point and reliable equilibrium is hard to achieve. It is thus a challenge to design faster algorithms. One proposal is the Swendsen–Wang algorithm which is based on the Fortuin–Kasteleyn representation and flips a whole cluster of spins simultaneously.

So far we concentrated on statistical properties. Researchers have been fascinated by the observation that for stochastic particle systems, the transition to a deterministic macroscopic evolution can be handled with full rigor. Such a program has been baptized:

6. *Hydrodynamic limit*, which is meaningful only for particle systems with one or several conservation laws. Let us discuss then a reversible lattice gas with Hamiltonian $H$. We start the dynamics with a state of local equlibrium which is Gibbs with a slowly varying chemical potential, that is,

$$Z^{-1} \exp\left[-\beta\left(H(\eta) - \sum_x \mu(\varepsilon x)\eta_x\right)\right], \quad \varepsilon \ll 1 \quad [17]$$

Such a measure is almost time invariant. For small $\varepsilon$, at least approximately, such a structure should persist in the course of time at the expense of properly regulating the chemical potential. For our example, the correct timescale is $\varepsilon^{-2}t$ in microscopic units, and the evolution equation for the density, related thermodynamically to the chemical potential, is a nonlinear diffusion equation of the form

$$\frac{\partial}{\partial t}\rho_t = \nabla \cdot D(\rho_t)\nabla\rho_t \quad [18]$$

We turn to the nonreversible models.

### Nonreversible Models

While for reversible models the study of the stationary Gibbs measure is its own field of inquiry, here the first entry must be:

7. *Nonequilibrium steady state*. This steady state is determined through the dynamics, since the stationary measure $\mu$ has to satisfy $\mu(Lf) = 0$ for a sufficiently large class of functions $f$. As in equilibrium, phase transitions may occur. In the nonconservative case it would mean that the infinitely extended system has several extreme stationary measures. In the conservative case, say with the density as locally conserved field, it would mean that there is an interval of densities for which there is no extreme stationary measure. Given the nonequilibrium steady state, one may wonder about its typical fluctuations and large deviations. In contrast to thermal equilibrium, weak long-range correlations are the rule.

8. *Spacetime correlations in the steady state*. Through the bulk drive the power-law decay of time correlations may change. For example for the symmetric and asymmetric exclusion process, the steady states are Bernoulli with density $\rho$, denoted by $\langle\cdot\rangle_\rho$. For the on-site density–density correlation, one finds, for large $t$,

$$\langle\eta_0(t)\eta_0(0)\rangle_{1/2} - \frac{1}{4} \cong \begin{cases} t^{-1/2} & \text{for } F = 0 \\ t^{-2/3} & \text{for } F \neq 0 \end{cases} \quad [19]$$

9. *Hydrodynamic limit*. The concept of slowly varying conserved fields remains valid; only local equilibrium must be replaced by local stationarity. Generically, there are nonzero currents in the steady state. Therefore, the macroscopic fields change on the timescale $\varepsilon^{-1}t$ (cf. item (5)) and are governed by a hyperbolic conservation law of the form

$$\frac{\partial}{\partial t}\rho_t + \operatorname{div} j(\rho_t) = 0 \quad [20]$$

in the case of a single conservation law. Here, $j(\rho)$ is the average steady state in the stationary measure at density $\rho$. Several conservation laws have an intriguing rich variety of solutions. Even on the level of continuum partial differential equations, such systems of hyperbolic conservation laws still pose unresolved basic problems.

# Interfaces and Multicomponent Fluids

**J Kim and J Lowengrub**, University of California at Irvine, Irvine, USA

## Introduction

Many important industrial problems involve flows with multiple constitutive components. Examples include extractors, separators, reactors, sprays, polymer blends, and microfluidic applications such as DNA analysis, and protein crystallization. Due to inherent nonlinearities, topological changes, and the complexity of dealing with unknown, active, and moving surfaces, multiphase flows are challenging. Much effort has been put into studying such flows through analysis, asymptotics, and numerical simulation. Here, we focus on review on studies of multicomponent fluids using continuum numerical methods.

There are many ways to characterize moving interfaces. The two main approaches to simulating multiphase and multicomponent flows are interface tracking and interface capturing. In interface-tracking methods (examples include boundary-integral, volume-of-fluid, front-tracking, immersed-boundary, and immersed-interface methods), Lagrangian (or semi-Lagrangian) particles are used to track the interfaces. In (BIMs), the flow equations are mapped from the immiscible fluid domains to the sharp interfaces separating them thus reducing the dimensionality of the problem (the computational mesh discretizes only the interface). In interface-capturing methods such as level-set and phase-field methods, the interface is implicitly captured by a contour of a particular scalar function.

The equations governing the motion of an unsteady, viscous, incompressible, immiscible two-fluid system are the Navier–Stokes equations (the subscript $i$ denotes the $i$th flow component):

$$\rho_i\left(\frac{\partial \boldsymbol{u}_i}{\partial t} + \boldsymbol{u}_i \cdot \nabla \boldsymbol{u}_i\right) = \nabla \cdot \sigma_i + \rho_i \boldsymbol{g}, \quad i = 1, 2 \qquad [1]$$

$$\sigma_i = -p_i \boldsymbol{I} + 2\eta_i \boldsymbol{D}_i \qquad [2]$$

where $\rho_i$ is the density, $\boldsymbol{u}_i$ is the fluid velocity, $p_i$ is the pressure, $\eta_i$ is the viscosity, and $\boldsymbol{g}$ is the gravitational acceleration vector. In eqn [2], $\sigma_i$ is the stress tensor, $\boldsymbol{I}$ is the identity matrix, and $\boldsymbol{D}_i$ is the rate of deformation tensor and defined as $\boldsymbol{D}_i = (1/2)(\nabla \boldsymbol{u}_i + \nabla \boldsymbol{u}_i^{\mathrm{T}})$. The velocity field is subject to the incompressibility constraint,

$$\nabla \cdot \boldsymbol{u}_i = 0 \qquad [3]$$

We let $\Gamma$ denote the fluid interface. The effect of surface tension is to balance the jump of the normal stress along the fluid interface. This gives rise to a Laplace–Young condition for the discontinuity of the normal stress across $\Gamma$:

$$[\sigma \boldsymbol{n}]_\Gamma = \tau \kappa \boldsymbol{n} \qquad [4]$$

where $[\sigma]_\Gamma$ denotes the jump $\sigma_2 - \sigma_1$ across $\Gamma, \kappa$ is the curvature of $\Gamma$ (positive for a spherical interface), $\tau$ is the surface tension coefficient which is assumed to be constant, and $\boldsymbol{n}$ is the unit normal vector along $\Gamma$ directed toward fluid 2. The fluid velocity is continuous across $\Gamma$.

In order to circumvent the problems associated with implementing the Laplace–Young calculation at the exact interface boundary, Brackbill and collaborators developed a method referred to as the continuum surface force (CSF) method. See the review by Scardovelli and Zaleski (1999). In this method, the surface tension jump condition is converted into an equivalent singular volume force that is added to the Navier–Stokes equations. Typically, the singular force is smoothed and acts only in a finite transition region across the interface. The system of equations [1]–[2] and the boundary condition, eqn [4] can be combined into the following distribution formulation that holds in both phases:

$$\rho(\boldsymbol{u}_t + \boldsymbol{u} \cdot \nabla \boldsymbol{u}) = -\nabla p + \nabla \cdot (2\eta \boldsymbol{D}) + \rho \boldsymbol{g} + \boldsymbol{F}_{\text{sing}}, \quad \nabla \cdot \boldsymbol{u} = 0 \qquad [5]$$

where the subscript $i$ is dropped (i.e., it is understood that $\boldsymbol{u} = \boldsymbol{u}_i$ in fluid $i$, etc.,) and $\boldsymbol{F}_{\text{sing}}$ is singular

surface tension force that is given by $F_{sing} = -\tau\kappa\delta_\Gamma n$, where $\delta_\Gamma$ is the surface delta-function.

## Numerical Methods for Multicomponent Fluid Flows

### Interface-Tracking Methods

**Boundary-integral methods (BIMs)** BIMs can be highly accurate for modeling free surface flows with relatively regular interface topologies. The BIM was apparently first used by Rosenhead in 1932 to study vortex sheet roll-up. In this approach, the interface is explicitly tracked, but the flow solution in the entire domain is deduced solely from information possessed by discrete points along the interface.

BIMs have been used for both inviscid and Stokes flows. For a review of Stokes flow computations, see Pozrikidis (2001), and for a review of computations of inviscid flows, see Hou *et al.* (2001). For flows with both inertia and viscosity, volume integrals must be incorporated into the formulation.

When inertial forces are negligible (left-hand side term of eqn [1] is dropped), the velocity $u(x_0)$ at a given point $x_0$ on the interface can be obtained by means of the boundary-integral formulation,

$$(\lambda+1)u(x_0) = 2u_\infty(x_0) - \frac{1}{4\pi}\int_\Gamma f(x)G(x_0,x) \times n(x)\,ds(x) \qquad [6]$$

$$-\frac{\lambda-1}{4\pi}\int_\Gamma u(x)\cdot T(x_0,x)\cdot n(x)\,ds(x) \qquad [7]$$

where $\lambda$ is the viscosity ratio, $u_\infty$ is an imposed velocity prevailing in the absence of the interfaces, and $f(x)$ is the capillary force function $f=\tau\kappa$. The tensors $G$ and $T$ are the Stokeslet and stresslet, respectively:

$$G(x_0,x) = \frac{I}{r} + \frac{\hat{x}\hat{x}}{r^3}, \qquad T(x_0,x) = -\frac{6\hat{x}\hat{x}\hat{x}}{r^5} \qquad [8]$$

$$\text{where } \hat{x} = x - x_0, \quad r = |\hat{x}| \qquad [9]$$

The boundary conditions at the interface, that is, the stress balance equation [4] and continuity of the velocity across the interface, are automatically satisfied by the boundary-integral formulation.

The normal velocity of the interface $\Gamma(x,t)$ is given by

$$\frac{dx}{dt}\cdot n(x) = u(x,t)\cdot n(x) \qquad [10]$$

The shape of the interface does not depend on the tangential velocity and there are many possible choices that can be taken, see Hou *et al.* (2001).

The principal advantages gained by using BIMs are the reduction of the flow problem by one dimension since the formulation involves quantities defined on the interface only and the potential for highly accurate solutions if the flow has topologically regular interfaces. In addition, highly efficient adaptive surface mesh refinement algorithms have recently been developed to improve the performance and accuracy of the methods (Cristini *et al.* 2001). The main disadvantages are the development of accurate quadratures of integrals with singular kernels (particularly in 3D) and the need for local surgery of the interface in the event of topological changes.

BIMs have been successfully used for simulations of complex multiphase flows: drop deformation and breakup; jets; capillary waves; mixing; drop-to-drop interaction; suspension of liquid drops in viscous flow (e.g., see Cristini *et al.* (2001), Hou *et al.* (2001), and Pozrikidis (2001) and the references therein).

**Volume-of-fluid (VOF) method** In the VOF method (see Scardovelli and Zaleski (1999) for a recent review), the location of the interface is determined by the volume fraction $c_{ij}$ of fluid 1 in the computational cell, $\Omega_{ij}$. In cells containing the interface $0 < c_{ij} < 1$, $c_{ij} = 1$ in cells containing fluid 1, and $c_{ij} = 0$ in cells containing fluid 2 as shown in Figure 1b.

A VOF algorithm is divided into two parts: a reconstruction step and a propagation step. A typical interface reconstruction is shown in Figure 1c. In the piecewise linear interface construction (PLIC) method, the true interface, as shown in Figure 1a, is approximated by a straight line perpendicular to an interface normal vector $n_{ij}$ in each cell $\Omega_{ij}$. The normal vector $n_{ij}$ is determined from the volume fraction gradient using data from neighboring cells. With given a volume fraction $c_{ij}$

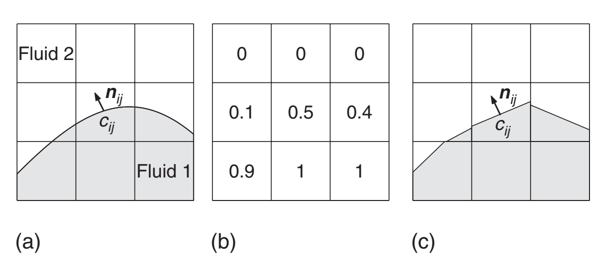

**Figure 1** VOF representation of an interface: (a) actual interface, (b) volume fraction, and (c) an approximation to the interface is produced using an interface reconstruction method such as piecewise linear approximation as shown.

and a normal vector $\boldsymbol{n}_{ij}$, the interface is given by the straight line with normal $\boldsymbol{n}_{ij}$ such that area beneath the line in cell $\Omega_{ij}$ is equal to $c_{ij}$. More recently, parabolic reconstructions of the interface have been used to gain higher-order accuracy for the surface tension force (e.g., the "parabolic reconstruction of surface tension" or PROST algorithm).

Once the interface has been reconstructed, its motion by the underlying flow field must be modeled by a suitable advection algorithm. The key here is that the explicit interface reconstruction enables fluxes to be developed that exactly conserve mass and do not diffuse the interface.

Capillary effects may be represented by the continuous surface stress (Scardovelli and Zaleski 1999),

$$\boldsymbol{T} = -\tau(\boldsymbol{I} - \boldsymbol{n} \otimes \boldsymbol{n})|\nabla\tilde{c}|, \quad \boldsymbol{F}_{\text{sing}} = -\nabla \cdot \boldsymbol{T} \qquad [11]$$

where $\tilde{c}$ is a smoothed version of the volume fraction. For the flows in which the capillary force is the dominant physical mechanism, the PROST algorithm discussed above can be used to significantly reduce spurious currents due to inaccurate representation of surface tension terms and associated pressure jump in normal stress.

The distribution form of the fluid equations [5] is typically solved using a variant of the projection method for incompressible single phase flows.

VOF methods are popular and have been used in commercial multiphase flow codes, in models of inkjet printers, flows with surfactants and in many other applications (e.g., see Scardovelli and Zaleski (1999) and James and Lowengrub (2004) and the references therein). The principal advantage of VOF methods is their inherent volume-conserving property. Nevertheless, spurious bubbles and drops may be created. The reconstruction of the interface from the volume fractions and the computation of geometric quantities such as curvature are typically less accurate than other methods discussed here since the curvature and normal vectors are obtained by differentiating a nearly discontinuous function (volume fraction).

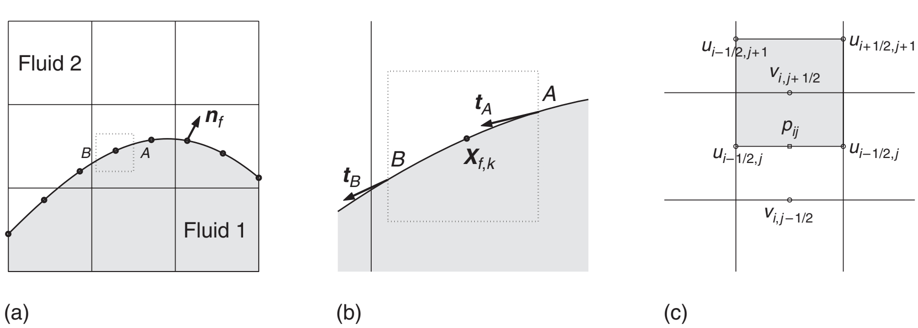
**Front-tracking methods** The basic idea behind the original front-tracking method is the use of two grids as illustrated in Figure 2. One is a standard, Eulerian finite difference mesh that is used to solve the fluid equations. The other is a discretized interface mesh that is used to explicitly track the interface and compute surface tension force which is then transferred to the finite difference mesh via a discrete delta-function. Front tracking was first proposed by Richtmyer and Morton and further developed by Glimm and co-workers.

A similar approach was taken by Unverdi and Tryggvason (see Tryggvason *et al.* (2001) and Peskin (2002) for recent reviews), who combined a moving grid description of the interface with flow computations on a fixed grid. In this immersed-boundary approach, all the fluid phases are treated together by solving a single set of governing equations. This method has its roots in the original marker-and-cell (MAC) method, where marker particles are used to identify each fluid and the immersed-boundary method of Peskin and McQueen, that was designed to track moving elastic boundaries in homogeneous fluids.

The interface is represented discretely by Lagrangian markers that are connected to form a front which lies within and moves through a stationary Eulerian mesh.

In Tryggvason's original implementation, the basic structural unit is a line segment. Since the interface moves and deforms during the computation, interface elements must occasionally be added or deleted to maintain regularity and stability. In the event of merging/breakup, elements must be relinked to effect a change in topology.

The interface is represented using an ordered list of marker particles $\boldsymbol{x}_k = ((x_1)_k, (x_2)_k), 1 \le k \le N$.



(a) (b) (c)

**Figure 2** (a) The basic idea in the front-tracking method is to use two grids – a stationary finite difference mesh and a moving Lagrangian mesh, which is used to track the interface. (b). Blow-up of the subgrid control volume in (a). (c) Control volume for the Eulerian mesh, $\Omega_{i,j+(1/2)}$.

The first step in this algorithm is the advection of the marker particles. A simple bilinear interpolation is used to find the velocity inside each grid cell (indicated in Figure 2c). The marker particles are then advected in a Lagrangian manner. Once the points have been advected, a list of connected polynomials $(p_i^x(s), p_i^y(s))$ is constructed using the marker particles. This gives a parametric representation of the interface, with $s$ typically an approximation of the arclength. Both lists are ordered and thus identify the topology of the interface. In later works, higher-order polynomials have been used (e.g., cubic splines) and semi-Lagrangian evolutions have been implemented where other tangential velocities have been used.

As the interface evolves, the markers drift along the interface following tangential velocities and more markers may be needed if the interface is stretched by the flow. Typically, the markers are redistributed along the interface to maintain an accurate interface representation.

Next, we compute the surface tension force,

$$\boldsymbol{F}_{\text{sing}}(\boldsymbol{x}, t) = \int_{\Gamma(t)} \tau \kappa_f \delta(\boldsymbol{x} - \boldsymbol{x}_f(s)) \boldsymbol{n}_f \mathrm{d}s \qquad [12]$$

where the subscript $f$ means values evaluated at the interface $\Gamma(t)$ and $s$ is arclength. The discrete numerical implementation of this distribution onto the fixed grid is in the form of a sum over interface elements, $\boldsymbol{x}_{f,k}$:

$$\boldsymbol{F}_{ij}(\boldsymbol{x}) = \sum_k \boldsymbol{f}_k \delta(\boldsymbol{x} - \boldsymbol{x}_{f,k}) \Delta s_k \qquad [13]$$

where $\Delta s_k$ is the average of the straight line distances from the point $\boldsymbol{x}_{f,k}$ to the two neighboring points $\boldsymbol{x}_{f,k+1}$ and $\boldsymbol{x}_{f,k-1}$ as indicated by the subgrid control volume shown in Figures 2a and 2b. The delta-function is typically taken to be Peskin's discrete Dirac delta-function:

$$\delta(\boldsymbol{x} - \boldsymbol{x}_{f,k}) = \begin{cases} \prod_{i=1}^{2} \dfrac{1}{4h}\left(1 + \cos\dfrac{\pi[\boldsymbol{x}_i - (\boldsymbol{x}_{f,i})_k]}{2h}\right) & \text{if } |\boldsymbol{x} - \boldsymbol{x}_{f,k}| \le 2h \\ 0 & \text{otherwise} \end{cases} \qquad [14]$$

Other higher-order alternative forms of the regularized delta-function using the product formula have recently been proposed.

Using the Frenet relation, the surface tension force on a short segment of the front is given by

$$\boldsymbol{f}_k = \int_A^B \tau \kappa_f \boldsymbol{n}_f \mathrm{d}s = \int_A^B \tau \frac{\partial \boldsymbol{t}_f}{\partial s} \mathrm{d}s = \tau(\boldsymbol{t}_B - \boldsymbol{t}_A) \qquad [15]$$

where $A$ and $B$ are the segment endpoints that lie on the boundary of the subgrid control volume (Figures 2a and 2b), and $\boldsymbol{t}_f$ is a tangent vector computed by fitting a polynomial to the endpoints of each element.

In the case of flows with varying density and/or viscosity between the fluid components, there is a need to calculate the phase indicator function $I(\boldsymbol{x}, t)$ (defined by interface geometry and position), which has the value 0 in fluid 1 and 1 in fluid 2. The indication function can be determined via the solution of the equation

$$\Delta I(\boldsymbol{x}, t) = \nabla \cdot \int_{\Gamma(t)} \boldsymbol{n}_f \delta(\boldsymbol{x} - \boldsymbol{x}_f(s, t)) \mathrm{d}s \qquad [16]$$

This equation is discretized on the Eulerian mesh and a discrete delta-function (e.g., eqn [14]) is used. The fluid properties such as density and viscosity are determined via the indicator function, that is, $\rho(\boldsymbol{x}, t) = \rho_1 + (\rho_2 - \rho_1) I(\boldsymbol{x}, t)$, etc.

As in the volume of fluid algorithm, the distribution form of the Navier–Stokes equations [5] are typically solved using a version of Chorin's projection method.

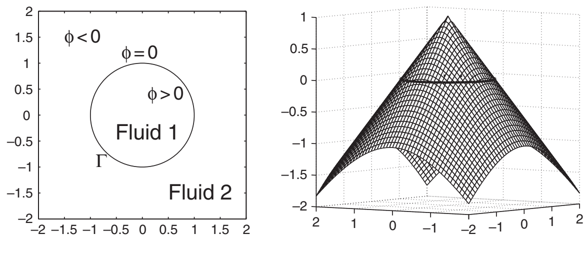
An alternative flow solver that can be used to integrate the flow equations in the presence of an interface is the immersed-interface method (IIM). The IIM was developed by Leveque and Li (see the review Li 2003), and can be used together with front-tracking as well as level-set methods.

The IIM directly incorporates jump conditions for the normal stress into the finite difference stencil. The key idea of this method is to use the jump conditions in Taylor series expansions of pressure and velocity near interfaces to derive difference equations that achieve pointwise second-order accuracy.

The principal advantage of front-tracking algorithms is their inherent accuracy, due in part to the ability to use a large number of grid points on the interface. Front-tracking methods can be complicated to implement, particularly in 3D, but give the precise location and geometry of the interface. In addition, explicit front tracking permits more than one interface to be present in a single computational cell without coalescence, which can be important in dense bubbly flows, emulsions, etc. One of major handicaps of front-tracking methods is the difficulty in modeling topological changes of the interface such as breakup and coalescence without *ad hoc* cut-and-connect and reconnecting parameterized interface (particularly, difficulties in 3D).

### Interface-Capturing Methods

**Level-set method** Level-set methods, introduced by Osher and Sethian (see the recent review papers (Osher and Fedkiw 2001, Sethian and Smereka



(a) (b)

**Figure 3** (a) Zero contour of $\phi$ representing the interface $\Gamma$. (b) Surface of $\phi$ with zero contour.

2003) and the recent texts (Osher and Fedkiw 2002, Sethian 1999)), are popular computational techniques for tracking moving interfaces. These methods rely on an implicit representation of the interface as the zero set of an auxiliary function (level-set function). The application of these methods to incompressible, multiphase flows started with the work of Osher, Merriman, Sussman, Smereka, Hou, and their collaborators.

In the level-set method, the level-set function $\phi(\boldsymbol{x}, t)$ is defined as follows (see Figure 3):

$$\phi(\boldsymbol{x}, t) \begin{cases} > 0 & \text{if } \boldsymbol{x} \in \text{fluid 1} \\ = 0 & \text{if } \boldsymbol{x} \in \Gamma \text{ (the interface between fluids)} \\ < 0 & \text{if } \boldsymbol{x} \in \text{fluid 2} \end{cases}$$

and the evolution of $\phi$ is given by

$$\phi_t + \boldsymbol{u} \cdot \nabla\phi = 0 \qquad [17]$$

which means that the interface moves with fluid.

To keep the interface geometry well resolved, the level-set function $\phi$ should be a distance function near the interface. However, under the evolution [17] it will not necessarily remain as such. We note that special velocity extensions $\boldsymbol{v}$ off the interface (i.e., $\boldsymbol{v} = \boldsymbol{u}$ at the interface, $\boldsymbol{v} \neq \boldsymbol{u}$ away from interface) have been recently developed to better maintain $\phi$ as a distance function (e.g., Sethian and Smereka (2003) and Macklin and Lowengrub (2005)). Typically, a reinitialization step (solving a Hamilton–Jacobi type equation, eqn [18]) below, is performed to keep $\phi$ as a distance function near the interface while keeping original zero-level set unchanged. More specifically, given a level-set function, $\phi$, at time t, the contours are redistributed according to the steady-state solution of the equation

$$\frac{\partial d}{\partial \tau} = S_\epsilon(\phi)(1 - |\nabla d|), \quad d(\boldsymbol{x}, 0) = \phi(\boldsymbol{x}) \qquad [18]$$

where $S_\epsilon$ is the smoothed sign function defined as

$$S_\epsilon(\phi) = \frac{\phi}{\sqrt{\phi^2 + \epsilon^2}} \qquad [19]$$

where $\epsilon$ is usually is one or two grid lengths. After solving eqn [18] to steady state $\phi(\boldsymbol{x}, t)$ is then replaced by $d(\boldsymbol{x}, \tau_{\text{steady}})$. Note that $d(\boldsymbol{x}, \tau_{\text{steady}})$ is typically a good approximation of the signed distance function.

The density and viscosity are defined as

$$\rho(\phi) = \rho_2 + (\rho_1 - \rho_2)H_\epsilon(\phi)$$

and

$$\eta(\phi) = \eta_2 + (\eta_1 - \eta_2)H_\epsilon(\phi) \qquad [20]$$

where $H_\epsilon(\phi)$ is the smoothed Heaviside function given by

$$H_\epsilon(\phi) = \begin{cases} 0 & \text{if } \phi < -\epsilon \\ \frac{1}{2}\left[1 + \frac{\phi}{\epsilon} + \frac{1}{\pi}\sin(\pi\phi/\epsilon)\right] & \text{if } |\phi| \le \epsilon \\ 1 & \text{if } \phi > \epsilon \end{cases}$$

The mollified delta-function is $\delta_\epsilon(\phi) = \mathrm{d}H_\epsilon/\mathrm{d}\phi$. The surface tension force is given as

$$\boldsymbol{F}_{\text{sing}} = -\tau\nabla \cdot \left(\frac{\nabla\phi}{|\nabla\phi|}\right)\delta_\epsilon(\phi)\frac{\nabla\phi}{|\nabla\phi|} \qquad [21]$$

The fluid equations [5] are solved using projection methods, the IIM or the ghost-fluid (GF) method (e.g., Osher and Fedkiw (2001, 2002) and Fedkiw *et al.* (2003)). The GF method is similar to the IIM in that jump discontinuities are incorporated in the finite difference stencil. In the GF algorithm, subcell resolution is used to mark the interface position and the values of discontinuous quantities are artificially extended to grid points neighboring the interface via extrapolation. A fully second order accurate GF method for moving interfaces has recently been developed (Macklin and Lowengrub 2005).

Applications of the level-set method include multiphase flows, viscoelastic fluid flows and fluid–structure interactions (e.g., see the reviews Osher and Fedkiw (2001, 2002), Sethian (1999), and Sethian and Smereka (2003)).

Advantages of the level-set algorithm include the simplicity with which it can be implemented, the ability to capture merging and breakup of interfaces automatically, and the ease with which the interface geometry can be described using the level-set function. A disadvantage of the level-set method is that mass is not conserved.

Accurate numerical simulations of multiphase flow and topology transitions require the computational mesh to resolve both the macroscales (e.g., droplet size, flow geometry) and the microscales to accurately capture local interface geometries near contact region, van der Waals forces, surfactant distribution, and Marangoni stresses. Adaptive mesh

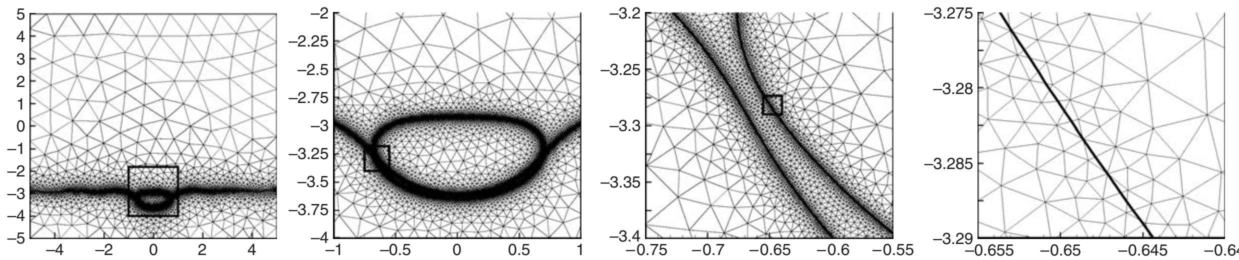


**Figure 4** Each of the first three figures has a boxed region that is magnified in the next figure. The rates of magnification are 5, 10, 40/3, respectively. The meshes in the figure are used to simulate the drop-impacting interface problem. Source: Zheng X, Anderson A, Lowengrub JS, and Cristini V (unpublished).

algorithms have recently been used greatly to increase accuracy and computational efficiency in level-set methods. Typically, the methods involve Cartesian adaptive mesh refinement. Problems tackled using this approach include droplet formation in inkjet printers and wake development behind a ship. Another approach, recently developed, is to use adaptive unstructured mesh refinement (Zheng *et al.* 2005), as shown in **Figure 4**, in which the impact of a drop onto a fluid interface is captured.

### Hybrid Methods

More recently, a number of hybrid methods, which combine good features of each algorithm, have been developed. These include coupled level-set volume-of-fluid (CLSVOF) algorithms, particle level-set methods, marker-VOF methods and level-contour front-tracking methods.

Level-set and VOF methods have recently been combined. The volume fraction is used to maintain volume conservation, while the level-set function is used to describe the interface geometry. After every time step, the volume-fraction function and level-set function are made compatible. The coupling between the level-set function $\phi$ and the VOF function $c$ occurs through the normal of the reconstructed interface and through the fact that the level-set function is reset to the exact signed normal distance to the reconstructed interface (where the area below the reconstructed interface is given by the volume-fraction function).

In the particle level-set method, Lagrangian disconnected marker particles are randomly positioned near the interface and are passively advected by the flow in order to rebuild the level-set function in under-resolved zones, such as high-curvature regions and near filaments. In these regions, the standard nonadaptive level-set method regularizes excessively the interface structure and mass is lost. The use of marker particles significantly ameliorates these difficulties.

Recently, a hybrid method has been developed, which uses both marker particles, to reconstruct and move the interface, and the volume-fraction function to conserve volume. In this approach, a smooth motion of the interface, typical of marker methods is obtained together with volume conservation, as in standard VOF methods. This work improves both the accuracy of interface tracking, when compared to standard VOF methods, and the conservation of mass, with respect to the original marker method.

Finally, a hybrid method that combines a level contour reconstruction technique with front-tracking methods has recently been developed to automatically model the merging and breakup of interfaces in three-dimensional flows.

### Phase-Field Method

Phase-field, or diffuse-interface, models are an increasingly popular choice for modeling the motion of multiphase fluids (see Anderson *et al.* (1998) for a recent review). In the phase-field model, sharp fluid interfaces are replaced by thin but nonzero thickness transition regions where the interfacial forces are smoothly distributed. The basic idea is to introduce a conserved order parameter (e.g., mass concentration) that varies continuously over thin interfacial layers and is mostly uniform in the bulk phases (see **Figure 5**).

For density-matched binary liquids (let $\rho = 1$ for simplicity), the coupling of the convective Cahn–Hilliard equation for the mass concentration with a modified momentum equation that includes a phase-field-dependent surface force is known as Model H (Hohenberg and Halperin 1977). In the case of fluids with different densities a phase-field model has been proposed by Lowengrub and Truskinovsky. Complex flow morphologies and topological transitions such as coalescence and interface breakup can be captured naturally and in a mass-conservative and energy-dissipative fashion since there is an associated free energy functional.

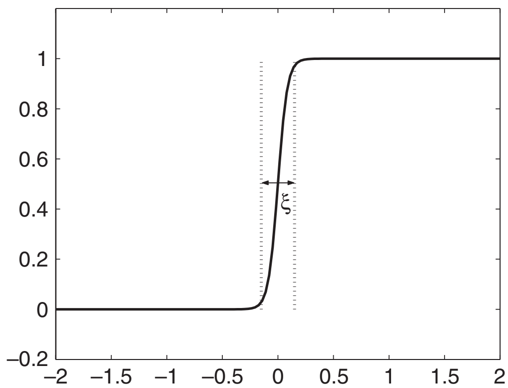

**Figure 5** A concentration prome across an interface with interface thickness, $\xi$.

The phase field is governed by the following advective Cahn–Hilliard equation:

$$\frac{\partial c}{\partial t} + \boldsymbol{u} \cdot \nabla c = \nabla \cdot (M(c)\nabla \mu) \quad [22]$$

$$\mu = F'(c) - \epsilon^2 \Delta c \quad [23]$$

where $M(c) = c(1-c)$ is the mobility, $F(c) = (1/4)c^2(1-c)^2$ is a Helmholtz free energy that describe the coexistence of immiscible phases, and $\epsilon$ is a measure of interface thickness and $\epsilon \sim \xi$ (see Figure 5). It can be shown that in the sharp interface limit $\epsilon \to 0$, the classical Navier–Stokes system equations and jump conditions are recovered.

The singular surface tension force is $\boldsymbol{F}_{\text{sing}} = -6\sqrt{2}\tau\epsilon\nabla \cdot (\nabla c \otimes \nabla c)$, where $\tau$ is the surface tension coefficient. An alternative surface tension force formulation based on the CSF is $\boldsymbol{F}_{\text{sing}} = -6\sqrt{2}\tau\epsilon\nabla \cdot (\nabla c/|\nabla c|)|\nabla c|\nabla c$.

Recently, very efficient nonlinear multigrid methods have been developed to solve implicit discretizations of the Cahn–Hilliard equation (e.g., Kim *et al.* (2004)). These schemes have been combined with projection methods to solve the Navier–Stokes equations to perform simulations of multiphase flows.

An example of simulation of liquid thread breakup using a phase-field method is shown in Figure 6. A long cylindrical thread of a viscous fluid 1 is in an infinite mass of another viscous fluid 2. If the thread becomes varicose with wavelength $\lambda$, the equilibrium of the column is unstable, provided $\lambda$ exceeds the circumference of the cylinder. This is the Rayleigh capillary instability that results in surface-tension-driven breakup of the thread.

An advantage of the phase-field approach is that it is straightforward to include more complex physical effects. For example, the binary model can be straightforwardly extended to describe three-component flows as follows.

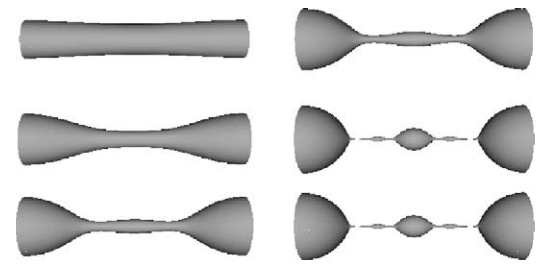

**Figure 6** Time evolution leading to multiple pinch-offs. The evolution is from top to bottom and left to right. The domain is axisymmetric, the initial velocities are zero everywhere, and the concentration field is given by $c(r,z) = 0.5(1 - \tanh((r - 0.5 - 0.05\cos(z))/(2\sqrt{2}\epsilon)))$ on $\Omega = (0,\pi) \times (0, 2\pi)$. Densities are matched and viscosity ratio is 0.5.

Consider a ternary mixture and denote the composition of components 1, 2, and 3, expressed as mass fractions, by $c_1, c_2$, and $c_3$, respectively. Therefore,

$$\sum_{i=1}^{3} c_i = 1, \quad 0 \le c_i \le 1 \quad [24]$$

The composition of a ternary mixture (A, B, and C) can be mapped onto an equilateral triangle (the Gibbs triangle (Porter and Easterling 1993)) whose corners represent 100% concentration of A, B, or C as shown in Figure 7a. Mixtures with components lying on lines parallel to $\overline{BC}$ contain the same percentage of A, those with lines parallel to $\overline{AC}$ have the same percentage of B concentration, and analogously for the C concentration. In Figure 7a, the mixture at the position marked '∘' contains 60% A, 10% B, and 30% C. Because the concentrations sum to unity, only two of them need to be determined, say $c_1, c_2$.

The evolution of $c_1$ and $c_2$ is governed by the following advective ternary Cahn–Hilliard equation:

$$\frac{\partial c_1}{\partial t} + \boldsymbol{u} \cdot \nabla c_1 = \nabla \cdot (M(c_1, c_2)\nabla \mu_1) \quad [25]$$

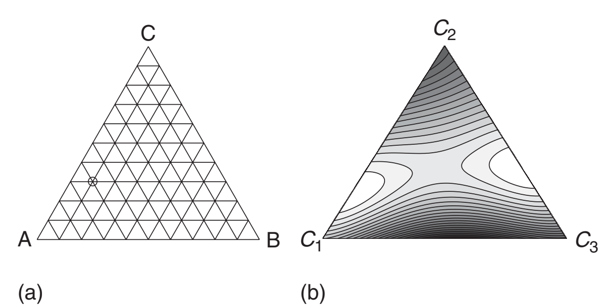

**Figure 7** (a) Gibbs triangle. (b) Contour plot of the free energy $F(c_1, c_2)$ on the Gibbs triangle.

$$\frac{\partial c_2}{\partial t} + \boldsymbol{u} \cdot \nabla c_2 = \nabla \cdot (M(c_1, c_2) \nabla \mu_2) \qquad [26]$$

$$\mu_1 = \frac{\partial F(c_1, c_2)}{\partial c_1} - \epsilon^2 \Delta c_1 - 0.5\epsilon^2 \Delta c_2 \qquad [27]$$

$$\mu_2 = \frac{\partial F(c_1, c_2)}{\partial c_2} - 0.5\epsilon^2 \Delta c_1 - \epsilon^2 \Delta c_2 \qquad [28]$$

where $M(c_1, c_2) = \sum_{i<j}^{3} c_i c_j$ is the mobility and $F(c_1, c_2)$ is the Helmholtz free energy that can be used to model the miscibility of the components. An example of a free energy (used in the simulation shown in Figure 8 below) for which fluids 1 and 3 are immiscible and fluid 2 is preferentially miscible with fluid 3 is:

$$F(c_1, c_2) = 2c_1^2(1 - c_1 - c_2)^2 + (c_1 + 0.2)(c_2 - 0.2)^2 + (1.2 - c_1 - c_2)(c_2 - 0.4)^2$$

The contours of $F$ on the Gibbs triangle are shown in Figure 7b.

The singular surface tension force is $\boldsymbol{F}_{\text{sing}} = -6\sqrt{2}\epsilon \sum_{i=1}^{3} \tau_i \nabla \cdot (\nabla c_i \otimes \nabla c_i)$, where the physical surface tension coefficients $\tau_{ij}$ between two fluids $i$ and $j$ are decomposed into the phase-specific surface tensions $\tau_i$ such that $\tau_{ij} = \tau_i + \tau_j$.

As a demonstration of the evolution possible in partially miscible liquid systems, we present an example in which there is a gravity-driven (Rayleigh–Taylor) instability that enhances the transfer of a preferentially miscible contaminant from one immiscible fluid to another in 2D. In this system, the ternary Cahn–Hilliard system is solved using nonlinear multigrid methods and a projection method (Kim and Lowengrub (in press)) is used to solve the flow equations [5].

In Figure 8 (first column), the top half of the domain initially consists of a mixture of fluids 1 and 2, and the bottom half consists of fluid 3, which is immiscible with fluid 1. The contours of $c_1, c_2$, and $c_3$ are visualized in gray-scale where darker regions denote larger values of $c_1, c_2$, and $c_3$, respectively. In the top row, the contours of fluid 1 are shown, the middle and bottom rows correspond to fluids 2 and 3, respectively.

Fluid 2 is preferentially miscible with fluid 3. Fluid 1 is assumed to be the lightest and fluid 2 the heaviest. The density of the 1/2 mixture is heavier than that of fluid 3, so the density gradient induces the Rayleigh–Taylor instability.

The evolution of the three phases is shown in Figure 8. As the simulation begins, the 1/2 mixture falls and fluid 2 diffuses into fluid 3. A characteristic Rayleigh–Taylor (inverted) mushroom forms, the

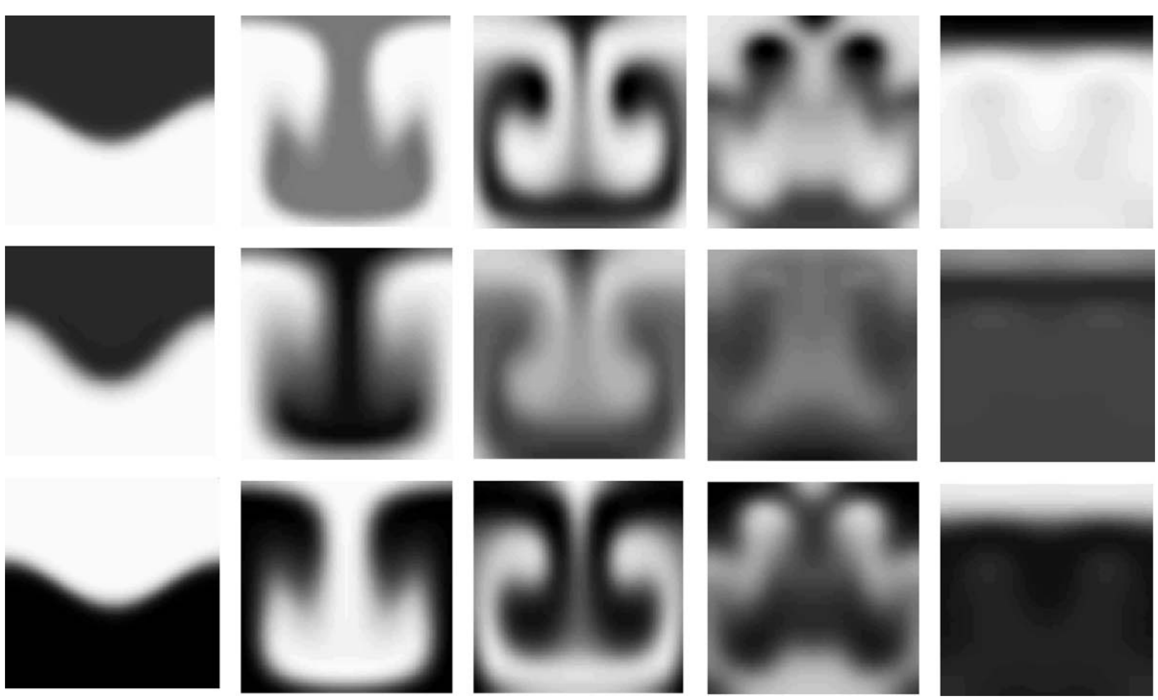

**Figure 8** Evolution of concentration of fluid 1 (top row), 2 (middle row), and 3 (bottom row). The contours of $c_1, c_2$, and $c_3$ are visualized in gray-scale where darker regions denote larger values of $c_1, c_2$, and $c_3$, respectively.

surface area of the 1/3 interface increases, and vorticity is generated and shed into the bulk. As fluid 2 is diffused from fluid 1, the pure fluid 1 rises to the top as shown in **Figure 8**. Imagining that fluid 2 is a contaminant in fluid 1, this configuration provides an efficient means of cleansing fluid 1 since the buoyancy-driven flow enhances the diffusional transfer of fluid 2 from fluid 1 to fluid 3.

The advantages of the phase-field method are: (1) topology changes are automatically described; (2) the composition field $c$ has a physical meaning not only near interface but also in the bulk phases; (3) complex physics can easily be incorporated into the framework, the methods can be straightforwardly extended to multicomponent systems, and miscible, immiscible, partially miscible, and lamellar phases can be modeled.

Associated with diffuse interfaces is a small scale $\epsilon$, proportional to the width of the interface. In real physical systems describing immiscible fluids, $\epsilon$ can be vanishingly small. However, for numerical accuracy $\epsilon$ must be at least a few grid lengths in size. This can make computations expensive. One way of ameliorating this problem is to adaptively refine the grid only near the transition layer. Such methods are under development by various research groups.

Phase-field methods have been used to model viscoelastic flow, thermocapillary flow, spinodal decomposition, the mixing and interfacial stretching, in a shear flow, droplet breakup process, wave-breaking and sloshing, the fluid motion near a moving contact line, and the nucleation and annihilation of an equilibrium droplet (see the references in the review paper Anderson *et al.* (1998)).

## Conclusions and Future Directions

In this paper we have reviewed the basic ideas of interface-tracking and interface-capturing methods that are critical in simulating the motion of interfaces in multicomponent fluid flows. The differences between these various formulations lie in the representation and the reconstruction of interfaces. The advantages and disadvantages of the algorithms have been discussed. While there has been much progress on the development of robust multifluid solvers, there is much more work to be done. Promising future directions for research include the incorporation of adaptive mesh refinement into the algorithms and the development of efficient hybrid schemes that combine the best features of individual methods.

# Intermittency in Turbulence

**J Jiménez**, Universidad Politecnica de Madrid, Madrid, Spain

## Introduction

Intermittency has several meanings in turbulence. The oldest one, now most often labeled "external" or "large-scale" intermittency, refers to the coexistence of turbulent and laminar regions in inhomogeneous turbulent flows, such as in boundary layers or in free shear layers. In those cases, the interface between laminar irrotational flow and turbulent vortical fluid is typically sharp and corrugated. An observer sitting near the edge of the layer is immersed in turbulent fluid only part of the time.

The intermittency coefficient $\gamma$ measures the fraction of turbulent fluid over the sampling universe over which the statistics are taken. For example, in a boundary layer such as that in Figure 1, the intermittency coefficient as a function of wall distance measures the fraction of turbulent fluid at a given distance from the wall. External intermittency is important in any attempt to model realistic turbulent flows, which are almost always inhomogeneous. Consider, for example, the classical homogeneous relation in eqn [1] between the mean kinetic energy $K$ of the turbulent fluctuations and the energy dissipation rate $\varepsilon$:

$$\varepsilon = C\frac{K^{3/2}}{L} \qquad [1]$$

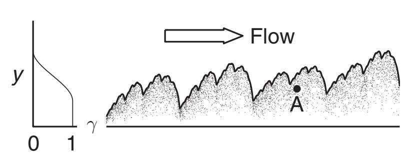

**Figure 1** Sketch of a turbulent boundary layer, and of the associated intermittency factor. An observer such as A, at a distance $y$ from the wall, only sees turbulent flow for a fraction $\gamma$ of the time.

where $L$ is the length scale of the largest eddies, and $C \approx 0.1$ is an experimentally determined constant. Such relations are often implicit in turbulent models, and they have to be modified to account for intermittency. Equation [1] only holds within the turbulent regions where the energy and the dissipation rates are $K_T$ and $\varepsilon_T$, while the overall mean values used in the modeling conservation equations are $K = \gamma K_T$ and $\varepsilon = \gamma\varepsilon_T$. The true overall relation should therefore be

$$\varepsilon = C\gamma^{-1/2}\frac{K^{3/2}}{L} \qquad [2]$$

which may differ substantially from eqn [1], especially near the edge of the layer. Experimental values and rough theoretical estimates for the distribution of the intermittency coefficient are available for most practical turbulent flows.

## Internal Intermittency

While the external intermittency just described is probably the most important one from the point of view of applications, it is not the most interesting from the theoretical point of view. Turbulence is a multiscale phenomenon which is inhomogeneous at all length scales, from the largest ones to the inner viscous cutoff (*see* Turbulence Theories). Moreover, this inhomogeneity goes beyond what could be expected just from the statistics of a random process. Consider, for example, the velocity difference $\Delta u$ between two points separated by a distance $r$. The original Kolmogorov formulation of the energy cascade assumes that the probability density function (PDF), $p(\Delta u)$, is a universal function in the inertial range of scales, whose only parameter is a velocity scale depending on $r$. It then follows from Kolmogorov's analysis that

$$p(\Delta u) = F\left[\Delta u/(\bar{\varepsilon}r)^{1/3}\right] \qquad [3]$$

where $\bar{\varepsilon}$ is the average energy transfer rate across scales per unit mass, and the average $\overline{(\ )}$ is taken either over the whole flow or over a suitably designed ensemble of experiments. In an equilibrium system,

global energy conservation implies that $\bar{\varepsilon}$ is equal to the average viscous dissipation per unit mass:

$$\bar{\varepsilon} = \nu\overline{|\nabla \boldsymbol{u}|^2} \qquad [4]$$

In eqn [4], the kinematic viscosity of the fluid is $\nu$, and $|\nabla \boldsymbol{u}|$ is the $L_2$-norm of the velocity gradient tensor. Equation [3] is valid as long as the separation $r$ is much larger than the Kolmogorov viscous cutoff $\eta = (\nu^3/\bar{\varepsilon})^{1/4}$, and much smaller than the integral scale of the largest eddies $L_\varepsilon = u'^3/\bar{\varepsilon}$, where $u'$ is the root-mean-square value of the fluctuations of one velocity component. The extent of this inertial range is a function of the Reynolds number $Re_L = u'L_\varepsilon/\nu$:

$$L_\varepsilon/\eta = Re_L^{3/4} \qquad [5]$$

The strict similarity hypothesis in eqn [3] is not well satisfied by experiments. While the velocity distribution at a given point is approximately Gaussian, Figure 2a shows that the velocity increments become increasingly non-Gaussian as the spatial separation is made much smaller than $L_\varepsilon$. It was also soon noted that the dependence of eqn [3] on a single parameter such as $\bar{\varepsilon}$ was theoretically suspect, since it is difficult to see how the PDFs of a whole set of local properties, such as the $\Delta u$ for different intervals, could depend only on a single global property. Kolmogorov himself sought to bypass that difficulty by substituting eqn [3] by a “refined similarity” hypothesis,

$$p(\Delta u) = F\left[\Delta u/(\varepsilon_r r)^{1/3}\right] \qquad [6]$$

where $\varepsilon_r$ is no longer a global average, but the mean value of the dissipation over a ball of radius of order $r$ centered at the midpoint of the interval. This refined similarity is better satisfied by experiments (see Figure 2b), although, from the practical point of view, it just transfers the problem of characterizing $\Delta u$ to that of characterizing the statistics of $\varepsilon_r$.

It has become customary to measure the behavior of $p(\Delta u)$ in terms of its structure functions,

$$S(n) = \int_{-\infty}^{\infty} \Delta u^n p(\Delta u)\,\mathrm{d}\Delta u \qquad [7]$$

which can be normalized as generalized flatness factors,

$$\sigma(n) = S(n)/S(2)^{n/2} \qquad [8]$$

It follows from the strict similarity hypothesis [3] that

$$S(n) \sim r^{n/3} \qquad [9]$$

and that all the $\sigma(n)$ should be independent of the separation.

For example, the fourth-order flatness of a Gaussian distribution is $\sigma(4) = 3$. Figure 3 shows that this is not true. The flatness increases as the separation decreases, and it only levels off at lengths of the order of the Kolmogorov viscous scale. For separations in that viscous range the flow is smooth, $\Delta u \approx (\partial_x u)r$, and

$$\sigma(n) \approx \overline{(\partial_x u)^n}/\overline{(\partial_x u)^2}^{\,n/2} \qquad [10]$$

It follows from eqn [10] and from Figure 3 that the velocity gradients become increasingly non-Gaussian as $L_\varepsilon$ and $\eta$ separate at high Reynolds numbers. The velocity differences across intervals which are large with respect to $\eta$ also become very non-Gaussian when $r \ll L_\varepsilon$.

Because the velocity difference between two points which are not too close to each other can be expressed as the sum of velocity differences over subintervals, a loose application of the central limit

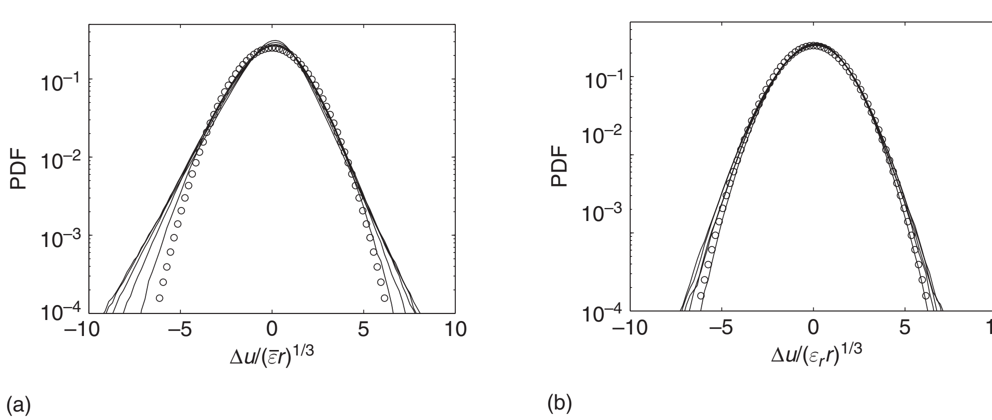

**Figure 2** PDFs of the differences of the velocity component in the direction of the separation (for separations in the inertial range of scales). $r/L_\varepsilon = 0.02-0.36$, increasing by factors of 2; equivalent to $r/\eta = 180-3000$. Nominally isotropic turbulence at Reynolds number $\mathrm{Re}_L = 10^5$.. (a) $\Delta u$ is normalized with the global energy dissipation rate $\bar{\varepsilon}$; distributions are wider as the separation decreases. (b) $\Delta u$ is scaled with the locally averaged dissipation over the separation interval. Data courtesy of H Willaime and P Tabeling.

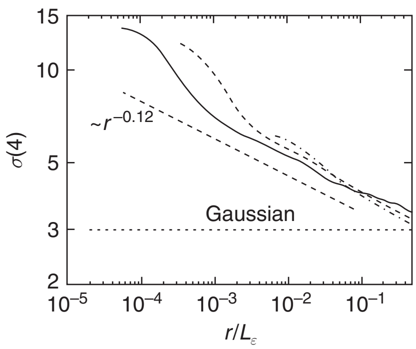

**Figure 3** Fourth-order flatness of the differences of the velocity component in the direction of the separation, for separations in the inertial range of scales, $r/L_\varepsilon = 0.5$ to $r/\eta = 2$.. The Reynolds numbers of the different flows range from $Re_L = 1800$ to $10^6$.. Data in part courtesy of H Willaime, P Tabeling, and R A Antonia.

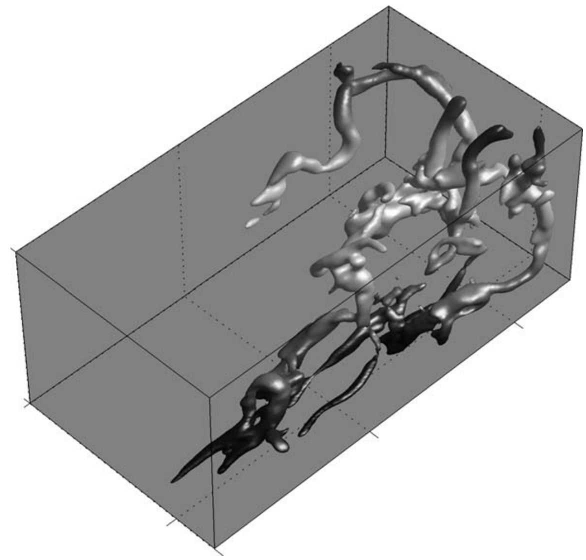

**Figure 4** Intense vortex tangle in the logarithmic layer of a turbulent channel. The vortex diameters are of the order of $10\eta$, and the size of the bounding box is of the order of the channel width. Reproduced with permission of J C del Álamo.

theorem would suggest that its PDF should be roughly Gaussian. The key conditions for that to happen are that the summands should be mutually independent, that their magnitudes should be comparable, and that each of them has a probability distribution with a finite variance. The first of those three conditions is probably a good approximation if the separation is much longer than the viscous cutoff, but the second one depends on the structure of the flow. The experimental non-Gaussian behavior suggests the existence of occasional very strong velocity jumps. In the viscous range of scales, those structures have been identified both experimentally and numerically as very strong linear vortices, in whose neighborhoods the strongest gradients are generated. An example of a tangle of such structures is shown in Figure 4.

In another example, the vorticity in decaying two-dimensional turbulence concentrates very quickly into relatively few strong compact vortices, which are stable except when they interact with each other. The velocity field is dominated by them, and the flatness of the velocity increments reaches values of the order of $\sigma(4) \approx 50$–$100$, even at moderate Reynolds numbers. That case is interesting because something can be said about the probability distribution of the velocity gradients. We have noted that the PDF of a sum of mutually comparable independent random variables with finite variances tends to Gaussian when the number of summands is large. This well-known theorem is a particular case of a more general result about sums of random variables whose incomplete second moments diverge as

$$\mu_2(s) = \int_{-s}^{s} x^2 p(x) \mathrm{d}x \sim s^{2-\alpha} \quad \text{when } s \to \infty \qquad [11]$$

When $0 < \alpha \leq 2$, the sums of such variables tend to a family of "stable" distributions parametrized by $\alpha$. The Gaussian case is the limit of that family when $\alpha = 2$. In the case of two-dimensional vortices with very small cores, the velocity gradients at a distance $R$ from the center of the vortex behave as $1/R^2$. If we take $s$ in eqn [11] to be one of those velocity derivatives, its probability distribution is proportional to the area covered by gradients with a given magnitude, and

$$\mu_2(s) \sim \int_0^{s^{1/2}} R^{-4} 2\pi R \, \mathrm{d}R \sim s^{-1} \qquad [12]$$

The velocity derivatives at any point, which are the sums of the velocity derivatives induced by all the randomly distributed neighboring vortices, should therefore be distributed according to the stable distribution with $\alpha = 1$, which is Cauchy's

$$p(s) = \frac{c}{\pi(c^2 + s^2)} \qquad [13]$$

This distribution has no moments for $n > 1$. Its tails decay as $s^{-2}$, and the distribution of the gradients essentially reflects the properties of the closest vortex. In real two-dimensional turbulent flows, the distribution [13] is followed fairly well, but its extreme tails only reach to the maximum values of the velocity gradient found within the viscous vortex cores, which are not exactly point vortices.

Other similar general results can be derived that link the behavior of the structure functions with the properties of the stable distributions corresponding to the type of flow singularities expected in the limit of infinite Reynolds number.

The common feature of the two cases just described is the presence of strong structures that live for long times because viscosity stabilizes them. They are therefore more common than what could be expected on purely statistical grounds. They are responsible for the tails of the probability distributions of the velocity derivatives, but they are not the only intermittent features of turbulent flows. The increase of the flatness in Figure 3 below $r \approx 50\eta$ is clearly connected with the presence of the coherent vortices, but even for larger separations there is a smooth evolution of $\sigma(4)$ that suggests that the formation of intense structures is a gradual process that takes place across the inertial range. Much less is known about those hypothetical inertial structures than about the viscous ones.

We can now recast the problem of intermittency in Navier–Stokes turbulence into geometric terms. The defining empirical observation for that system is that the energy dissipation given by eqn [4] does not vanish even in the infinite Reynolds number limit in which $\nu \to 0$. This means that the flow has to become singular as $\overline{|\nabla \boldsymbol{u}|}L_\epsilon/u' \sim Re_L^{1/2}$. The strict similarity approximation assumes that those singularities are uniformly distributed across the flow, but the experimental evidence just discussed shows that this is not true. The singularities are distributed inhomogeneously, and the inhomogeneity develops across the inertial cascade. The problem of intermittency is to characterize the geometry of the support of the flow singularities in the limit of infinite Reynolds number.

In the absence of detailed physical mechanisms for the dynamics of the inertial range, most intermittency models are based on plausible processes compatible with the invariances of the inviscid Euler equations. The precise power law given in eqn [9] for the structure functions depends on the strict similarity hypothesis [3], but the fact that it is a power law only depends on the scaling invariances of the equations of motion. The energies and sizes of the eddies in the inertial range are too small for the integral scales of the flow to be relevant, and too large for the viscosity to be important. They therefore have no intrinsic velocity or length scales. Under those conditions, any function of the velocity which depends on a length has to be a power. Consider a quantity with dimensions of velocity, such as $u(r) = S(n)^{1/n}$, which is a function of a distance such as $r$. On dimensional grounds we should be able to write it as

$$u(r) = UF(\rho) \qquad [14]$$

where $\rho = r/L$, and $L$ and $U(L)$ are arbitrary length and velocity scales. The value of $u(r)$ should not depend on the choice of units, and we can differentiate eqn [14] with respect to $L$ to give

$$\partial_L u = (\mathrm{d}U/\mathrm{d}L)F(\rho) - U\rho L^{-1}(\mathrm{d}F/\mathrm{d}\rho) = 0 \qquad [15]$$

which can only be satisfied if

$$\frac{\mathrm{d}F}{\mathrm{d}\rho} = \zeta F \Rightarrow F \sim \rho^{\zeta} \qquad [16]$$

and $\zeta = L(\mathrm{d}U/\mathrm{d}L)/U$ is constant. This suggests generalizing eqn [9] to

$$S(n) \sim r^{\zeta(n)} \qquad [17]$$

where the exponents are empirically adjusted. Only $\zeta(3) = 1$ can be derived directly from the Navier–Stokes equations. Equation [17] implies that $\sigma(n)$ satisfies a power law with exponent $\zeta(n) - n\zeta(2)/2$. In Figure 3, for example, the flatness follows a reasonably good power law outside the viscous range, consistent with $\zeta(4) - 2\zeta(2) \approx -0.12$. The anomalous behavior near the viscous limit, and similar limitations at the largest scales, mean that only very high Reynolds number flows can be used to measure the scaling exponents, and that the range over which they are measured is never very large. Moreover, the integrand of the higher-order structure functions peaks at the extreme tails of the probability distributions of the velocity differences, which implies that very long experimental samples have to be used to accumulate enough statistics to measure the high-order exponents. For these and for other reasons, the scaling exponents above $n \gtrsim 8-10$ are poorly known. This is unfortunate because we will see later that some of the most interesting intermittency properties of the velocity field, such as the nature of the flow singularities in the infinite Reynolds number limit, depend on the behavior of the $\zeta(n)$ for large $n$.

Experimental values for the scaling exponents are given in Table 1. They are generally smaller than the ones predicted by the strict similarity approximation, implying that the moments of the velocity differences decrease with the separation more slowly than they would if they were self-similar, and suggesting that new stronger structures become important as the scale decreases.

Note that we have included in the table values for odd-order powers. Up to now we have not specified

**Table 1** Longitudinal scaling exponents

| *Order* | *Experimental* | *Strict similarity* |
|---|---|---|
| 2 | 0..70 ± ..01 | 0.667 |
| 3 | 1.00 | 1 |
| 4 | 1..30 ± ..03 | 1.333 |
| 5 | 1..56 ± ..04 | 1.667 |
| 6 | 1..79 ± ..03 | 2.000 |
| 7 | 1..99 ± ..10 | 2.333 |
| 8 | 2..22 ± ..05 | 2.667 |

The values on the second column are averages from different experiments, and the standard deviations reflect scatter among experiments. The third column is the value from the strict similarity equation [9].

which velocity component is being analyzed, but most experiments refer to the one in the direction of the separation. That is the easiest case to measure, specially if time is used as a surrogate for distance, and those PDFs are not symmetric even in isotropic turbulence. Negative increments are more common than positive ones because of the extra energy required to stretch a vortex, and the effect is clearly visible in the distributions in Figure 2. Those longitudinal odd-order structure functions do not vanish, and their scaling exponents are the ones given in the table. The transverse structure functions are those in which the velocity component is normal to the separation, and their odd-order moments vanish by symmetry in isotropic turbulence. There has been a lot of discussion about whether the longitudinal scaling exponents of even orders differ from the transverse ones. Early results suggested that the latter are lower than the former, undermining the case for intermittency theories based on similarity arguments, and suggesting that a more mechanistic approach was needed. The present consensus seems to be that both sets of exponents are equal, but that there are residual effects of low Reynolds numbers and of flow anisotropy that are difficult to avoid experimentally. The question is still open.

## Multiplicative Models

The most successful phenomenological models for the geometry of intermittency are based on the concept of a multiplicative cascade. Consider some flow property $v$, such as the locally averaged energy transfer rate by eddies of size $r_k$, which cascades into smaller eddies of size $r_{k+1}$ which is some fraction of $r_k$. Denote by $p_k(v_k)$ the probability distribution of the value of $v$ at the step $k$ of the cascade.

Assume that the cascade is Markovian in the sense that the probability distribution of $v_k$ depends only on its value in the previous step,

$$p_{k+1}(v_{k+1}) = \int p_{\mathrm{T}}(v_{k+1}|v_k;\, k)p_k(v_k)\,\mathrm{d}v_k \qquad [18]$$

This is in contrast to some more complicated functional dependence, such as on the values of $v_k$ in some extended spatial neighborhood, or on several previous cascade stages. This assumption intuitively implies that $v_{k+1}$ evolves faster, or on a smaller scale, than $v_k$, and that it is in some kind of equilibrium with its precursor. If the cascade is deterministic in that sense, $v_k$ can be represented as a product

$$v_k/v_0 = q_k q_{k-1} \ldots q_1 \qquad [19]$$

in which the factors $q_k = v_k/v_{k-1}$ are statistically independent of each other.

If the underlying process is invariant to scaling transformations, the transition probability density function has to have the form

$$p_{\mathrm{T}}(v_{k+1}|v_k) = v_k^{-1} w(q_{k+1};\, k) \qquad [20]$$

The multiplicative model works most naturally for positive variables, and we will assume that to be the case in the following, but most results can be generalized to arbitrary distributions. We will also assume for simplicity that all the cascade steps are equivalent, so that the distribution $w(q)$ of the multiplicative factors is independent of $k$, and depends only on our choice for $r_{k+1}/r_k$.

Local deterministic self-similar cascades lead naturally to intermittent distributions, in the sense that the high-order flatness factors for $v_k$ become arbitrarily large as $k$ increases. It follows from eqns [18]–[20] that the $n$th order moment for $p_k$ can be written as

$$S_k(n) = \int \xi^n p_k(\xi)\,\mathrm{d}\xi = S_0(n)S_w(n)^k \qquad [21]$$

where $S_w(n)$ is the $n$th order moment of the multiplicative factor $q$, and $n$ is any real number for which the integral exists. If we define flatness factors as in eqn [7], we can rewrite eqn [21] as

$$\sigma_k(n) = \sigma_0(n)\sigma_w(n)^k \qquad [22]$$

It follows from Chebichev's inequality that

$$S(n) \geq S(n-2)S(2) \geq S(n-4)S(2)^2 \ldots \qquad [23]$$

from where

$$1 \le \sigma(4) \le \sigma(6) \ldots \quad [24]$$

which is true for any distribution of positive numbers. Equality only holds for trivial distributions concentrated on a single value. The product in eqn [22] therefore increases without bound with the number of cascade steps, and the flatness factors diverge.

It is tempting to substitute $k$ in [21] by a continuous variable, in which case the PDFs form a continuous semigroup generated by infinitesimal scaling steps. This leads to beautiful theoretical developments, but it is not necessarily a good idea from the physical point of view. For example, while it might be reasonable to assume that the properties of an eddy of size $r$ depend only on those of the eddy of size $2r$ from which it derives, the same argument is weaker when applied to eddies of almost equal sizes. We will restrict ourselves here to the discrete case.

### Limiting Distributions

The multiplicative process just described can be summarized as a family of distributions $p_k(v_k)$ such that the probability density for the product of two variables is

$$p(v_{k_1}v_{k_2}) = p_{k_1+k_2}(v_{k_1+k_2}) \quad [25]$$

and it is natural to ask whether there is a limiting distribution for large $k$. We know that, in the case of sums, rather than products, such distributions tend to be Gaussian under fairly general conditions, and the first attempt to analyze [25] was to reduce it to a sum by defining

$$z = k^{-1}\log(v_k/v_0) \quad [26]$$

The argument was that $z$ would tend to a Gaussian distribution, and that the limiting distribution for $v_k$ would be lognormal. This was soon shown to be incorrect. The central part of the distribution approaches lognormality, but the tails do not, because the central limit theorem says nothing about their behavior. The family of lognormal distributions is a fixed point of eqn [25], but it is unstable, and it is only attained if the individual generating distributions are themselves lognormal.

The lognormal distribution has moments

$$S_w(n) = \exp(an + bn^2) \quad [27]$$

which are conserved under [21], so that the product of lognormally distributed variables stays lognormal. The moments in eqn [27] are generated by the recursive relation

$$Q_w(n) = \frac{S_w(n+3)S_w^3(n+1)}{S_w(n)S_w^3(n+2)} = 1 \quad [28]$$

with suitable conditions for $n < 2$. Under [21], $Q_k(n) = Q_w^k(n)$, and it is clear that only when all the $Q_w(n)$ are exactly equal to 1 do they continue to be so under multiplication. Otherwise, any $Q_w$ initially larger than 1 tends to infinity after enough cascade steps, while any one initially smaller than 1 tends to 0. Only an exactly lognormal distribution of the generating factors results in a lognormal limiting distribution, and even small errors lead to very different patterns of moments. This contrasts with the situation for sums of random variables, in which the Gaussian distribution is not only a fixed point, but also has a very large basin of attraction.

### Multifractals

The problem with using the transformation [26] to find the limiting distribution of a multiplicative process is not so much the technique of analyzing the statistics of products in terms of those of sums, but the inappropriate use of the central limit theorem. It can be bypassed by using instead the theory of large deviations of sums of random variables. The key result is obtained by expanding the characteristic function of $p_k$ when $k \gg 1$, and states that

$$p_k(v_k) \approx \left(\frac{-\phi_0''}{2\pi k}\right)^{1/2} \mathrm{e}^{k[\phi(z)-z]} \quad [29]$$

where $z$ is defined as in [26] and $\phi$, which plays the role of an entropy, is a smooth function of $z$. Primes stand for derivatives with respect to $z$. Let us define $z_n$ as the point where

$$\phi_n' \equiv \phi'(z_n) = -n \quad [30]$$

which corresponds to the location of the maximum of $\phi + nz$. The entropy $\phi$ can be computed from the moments of the transition probability density. Using Laplace's method to expand the $n$th moment of $p_k$, we obtain

$$S_k(n) = \int_{-\infty}^{\infty} k\mathrm{e}^{k(n+1)z} p_k(v_k)\,\mathrm{d}z \approx \left(\frac{\phi_0''}{\phi_n''}\right)^{1/2} \mathrm{e}^{k(\phi_n + nz_n)} \quad [31]$$

from where, using [21],

$$\lambda_n \equiv \log S_w(n) = \phi(z_n) + nz_n \quad [32]$$

The essence of Laplace's approximation is that, for $k \gg 1$, most of the contribution to the integral in eqn [31] comes from the neighborhood of $z_n$, so that

it makes sense to consider each such neighborhood as a separate "component" of the cascade.

The geometric interpretation of this classification into components as a multifractal was developed in the context of three-dimensional homogeneous turbulence. We have up to now assumed very little about the nature of each cascade step, but it is natural in turbulence to interpret it as the process in which eddies decay to a smaller geometric scale. The argument works for any variable for which scale similarity can be invoked, but we have seen that most experiments are done for the magnitude of the velocity increments across a distance $r$. If we assume for simplicity that $r_k/r_{k+1} = \mathrm{e}$, so that $r_k/r_0 = \exp(-k)$, eqns [26] and [29] can be written as

$$v_k/v_0 = (r_k/r_0)^{-z_n}, \qquad p_k(z_n) \sim (r_k/r_0)^{-\phi_n} \qquad [33]$$

The multifractal interpretation is that the "component" indexed by $n$, whose velocity increments are "singular" in terms of $r$ with exponent $z_n$, lies on a fractal whose volume is proportional to its probability, and which therefore has a dimension $D(z_n) = 3 + \phi_n$.

Note that eqn [32] implies that the scaling exponents in eqn [17] can now be expressed as

$$\zeta(n) = -\log S_w(n) = -\lambda_n \qquad [34]$$

There was an enumeration there of several things which are equivalent: the exponents, the spectra, the distribution, and the limiting distribution $p_\infty(v)$ – univocally determine each other. Note however that different quantities have different scaling exponents. For example, it follows from eqn [6] that, if the scaling exponents for the local dissipation are $\zeta_\varepsilon(n)$, the exponents for $\Delta u$ would be $\zeta_{\Delta u}(n) = n/3 + \zeta_\varepsilon(n/3)$.

Some properties can be easily derived from the previous discussion. If we assume, for example, that the multiplicative factor $q$ is bounded above by $q_\mathrm{b}$, which is reasonable for many physical systems, eqn [26] implies that $z_n \leq \log q_\mathrm{b}$. In fact, if the transition probability behaves near $q_\mathrm{b}$ as $w(q) \sim (q_\mathrm{b} - q)^\beta$, the scaling exponents tend to

$$\lambda_n = n \log q_\mathrm{b} - (\beta + 1) \log n + \mathrm{O}(1) \qquad [35]$$

for $n \gg 1$. In the case in which $w(q)$ has a concentrated component at $q = q_\mathrm{b}$, the $\log n$ is missing in eqn [35]. In all cases, the singularity exponent of the set associated with $n \to \infty$ is $z_\infty = \log q_\mathrm{b}$, because the very high moments are dominated by the largest possible multiplier. In the case of a concentrated distribution the dimension of this set approaches a finite limit, but otherwise

$$D(n) \approx -(\beta + 1) \log n \qquad [36]$$

which becomes infinitely negative. This should not be considered a flaw. The set of events which only happen at isolated points and at isolated instants has dimension $D = -1$ in three-dimensional space, and those which only happen at isolated instants, and only under certain circumstances, have still lower negative dimensions. Sets with very negative dimensions are however extremely sparse, and are difficult to characterize experimentally.

The multifractal spectrum of the velocity differences in three-dimensional Navier–Stokes turbulence has been measured for several flows in terms of the scaling exponents, and appears to be universal. The probability distribution $w(q)$ of the multipliers has also been measured directly, and agrees well with the values implied by the exponents. It is also approximately independent of $r$, although not completely, perhaps due to the same experimental problems of anisotropy and limited Reynolds number which plague the measurement of the scaling exponents. There has been extensive theoretical work on the consequences of imposing various physical constraints on the multipliers, specially the conservation requirement that the average value of the dissipation has to be conserved across each cascade step. Several simple models have been proposed for the transition distribution which approximate the experimental exponents well, but the relation lacks specificity. Models that are very different give very similar results, and it is impossible to choose among them using the available data.

Multiplicative cascades and the resulting intermittency are not limited to Navier–Stokes turbulence. The equations of motion have only entered the discussion in this section through the assumption of scaling invariance. Multifractal models have in fact been proposed for many chaotic systems, from social sciences to economics, although the geometric interpretation is hard to justify in most of them. It is also important to realize that the fact that a given process can in principle be described as a cascade does not necessarily mean that such a description is a good one. Neither does a cascade imply a multiplicative process. For each particular case, we need to provide a dynamical mechanism that implements both the cascade and the transition multipliers. In three-dimensional Navier–Stokes turbulence, the basic transport of energy to smaller scales and to higher gradients is vortex stretching. The differential strengthening and weakening of the vorticity under axial stretching and compression also provide a natural way of introducing the self-similar transition probabilities of the local dissipation.

Examples of nonintermittent cascades abound. We have already mentioned that the vorticity in

decaying two-dimensional turbulence gets concentrated into stable vortex cores which eventually block the decay. The resulting enstrophy distribution is highly intermittent, but it is not well described by a multifractal. Conversely, forced two-dimensional turbulence is dominated by an inverse energy cascade to larger scales, which is not intermittent.

In addition, the intermittency of some systems is not a small-scale effect. Turbulent mixing of a passive scalar, which is the key process in turbulent heat transfer and in the atmospheric dispersion of pollutants, is an extremely intermittent phenomenon. The gradients of the scalar tend to be very localized, but they concentrate in sheets, narrow in thickness but otherwise extended. Some progress has recently been made on a simplified model due to Kraichnan for this problem, which is the linear stirring of a passive scalar by a random noise with delta correlation. Its statistics have been computed analytically, but the constraints of linearity and of uncorrelated forcing are strong, and the same methods do not appear to be extensible to mixing by real turbulence (*see* Lagrangian Dispersion (Passive Scalar)). Another problem in which intermittency is confined to large-scale surfaces is the motion of a three-dimensional pressureless gas, which has been used as a model for hypersonic turbulence and for the large-scale evolution of dark matter in the early universe.

In summary, intermittency is a fascinating property of many random systems, including three-dimensional Navier–Stokes turbulence, which interferes, sometimes strongly, with their description by simple cascade models. Significant advances have been made in its quantitative kinematic analysis. In some cases we also have a qualitative understanding of its roots. But in very few cases do we understand it well enough to make quantitative predictions.

# Intersection Theory

**A Kresch**, University of Warwick, Coventry, UK

## Introduction

Intersection theory is the theory that governs the rigorous definition of intersections of cycles. This can take place in a variety of mathematical contexts, for instance, the intersections of two cycles on an oriented manifold in algebraic topology, of two currents on a differentiable manifold in differential geometry, or of two subvarieties on a nonsingular algebraic variety in algebraic geometry.

In algebraic geometry the theory is especially well developed (Fulton 1998). A cycle on an algebraic variety (or scheme) is a formal linear combination of irreducible closed subvarieties. These are subject to an equivalence relation called rational equivalence. For every rational function on every subvariety, its zero set is deemed rationally equivalent to its poles (with appropriate multiplicities).

As an example, in the complex projective plane $\mathbb{CP}^2$, any two lines are rationally equivalent since the ratio of two linear forms will vanish on one line and have a pole along the other. Similarly, a curve of degree $d$ is rationally equivalent to $d$ lines. Any two points in $\mathbb{CP}^2$ can be joined by a line (a copy of

$\mathbb{CP}^1$), and a rational function on $\mathbb{CP}^1$ can be chosen to vanish at one point and have a pole at the other. The groups of cycles modulo rational equivalence, known as Chow groups, are

$CH_2(\mathbb{CP}^2) \cong \mathbb{Z}$, generated by the fundamental class $[\mathbb{CP}^2]$

$CH_1(\mathbb{CP}^2) \cong \mathbb{Z}$, generated by the class of a line

$CH_0(\mathbb{CP}^2) \cong \mathbb{Z}$, generated by the class of a point

Two distinct lines $\ell_1$ and $\ell_2$ meeting at a point $p$ have this point as their intersection-theoretic product:

$$[\ell_1] \cdot [\ell_2] = [p] \qquad [1]$$

Intersection theory must also provide a self-intersection $[\ell_1] \cdot [\ell_1]$. Because $\ell_1$ and $\ell_2$ are rationally equivalent, this must also be the class of a point, but symmetry precludes the choice of a distinguished point on $\ell_1$. Instead, $[\ell_1] \cdot [\ell_1]$ is declared to be the rational equivalence class of a point on $\ell_1$, an element of $CH_0(\ell_1)$ rather than a specific cycle. This example illustrates that intersections cannot generally be defined on the level of cycles.

## Algebraic Intersection Products

### Refined Intersections

For a general nonsingular variety $X$, say of dimension $m$, if $U$ and $V$ are subvarieties of $X$ of respective dimensions $c$ and $d$, then there is a refined intersection product

$$[U] \cdot [V] \in CH_{c+d-m}(U \cap V) \qquad [2]$$

The traditional definition of the intersection product is based on two ideas. First, given two cycles that intersect properly, which by definition means that no component of their intersection has codimension less than the sum of the codimensions of the given cycles, the intersection product should be a formal sum of these components, each with a multiplicity that correctly reflects the geometry of the intersection. Second, given two arbitrary cycles, it should be possible to replace one of them by a rationally equivalent cycle which intersects the other properly.

While these ideas are simple, it took several decades for them to be carried out successfully. The case of curves on a surface meeting at a point was understood in the nineteenth century. Generalizing the classically understood canonical divisor class on a variety, work in the 1930s by Severi, Todd, and others showed that there are groups of equivalence classes of cycles in which canonical invariants of higher degrees can be defined (in modern language, higher Chern classes of the tangent bundle). Weil's foundations for algebraic geometry of the 1940s included a study of intersections of cycles. It was not until the 1950s that the notion of Chow groups was formalized and intersection theory was properly developed in this context. Chevalley, Chow, Samuel, Severi, and others contributed essential components of the theory. In an interesting parallel development, an intersection theory based on intersection multiplicities in algebraic topology was put forth by Alexander and Lefschetz in the 1920s, a decade before the introduction of the cup product in cohomology.

### Deformation to the Normal Cone

In the 1970s, Fulton and MacPherson established a construction of the intersection product in algebraic intersection theory that does not require moving cycles into general position. To accomplish this, they used an elegant geometric construction known as deformation to the normal cone.

Let $i : X \to Y$ be an embedding of codimension $d$ of nonsingular varieties. Let $V$ be a subvariety of $Y$ of dimension $k$ whose intersection with $X$ is of interest. We may view $X$ as the zero set of a section $s$ of some algebraic vector bundle $E$ on $Y$. By

$$(y, \lambda) \mapsto (\lambda^{-1} s(y), \lambda)$$

we have a map of the product of $Y$ with the punctured affine line, $Y \times (\mathbb{A}^1 \setminus \{0\})$, into $E \times \mathbb{A}^1$. We denote the closure of the image by $M^\circ_X Y$. An alternative, more intrinsic description is in terms of the blowup construction of algebraic geometry:

$$M^\circ_X Y = Bl_{X \times \{0\}}(Y \times \mathbb{A}^1)$$

Geometrically, $M^\circ_X Y$ has a copy of $Y$ over each $\lambda \neq 0$ and a copy of the normal bundle $N_X Y$ over $\lambda = 0$. This is the key construction that Fulton and MacPherson make use of. The same construction applied to $V$, that is, the closure of $V \times (\mathbb{A}^1 \setminus \{0\})$ in $M^\circ_X Y$, has over 0 a sort of singular normal bundle known as the normal cone

$$C_{X \cap V} V \subset N_X Y|_{X \cap V}$$

One of the properties of Chow groups is that they are unchanged upon pullback to the total space of a vector bundle (apart from the obvious dimension shift). The refined intersection of $V$ with $X$, denoted $i^![V]$, is defined to be the unique element of $CH_{k-d}(X \cap V)$ whose pullback to $N_X Y$ is equal to $[C_{X \cap V} V]$.

This single construction encompasses and interpolates between two extreme cases of intersections:

$$i^![V] = [X \cap V] \quad \text{when } X \text{ and } V \text{ meet transversely} \qquad [3]$$

$$i^![V] = c_d(N_X Y) \cap [V] \quad \text{when } V \subset X \qquad [4]$$

Equation [3] makes reference to transverse intersection, a notion that is stronger than proper intersection. In situations when it applies, for example, in eqn [1], it signifies that intersection operations behave as one might expect. Equation [4] includes the self-intersection formula which says that $[X] \cdot [X]$ is equal to the top Chern class of $N_X Y$.

With this construction, which is well documented in Fulton (1998), the general refined intersection in eqn [2] is obtained by reduction to the diagonal. Let $\Delta_X$ denote the diagonal inclusion $X \to X \times X$ of the nonsingular variety $X$. For subvarieties $U$ and $V$ of $X$, we define

$$[U] \cdot [V] = \Delta_X^![U \times V] \qquad [5]$$

Equation [5] makes the Chow groups of $X$ into a ring, the Chow ring $CH^*(X)$, which is graded by codimension by setting

$$CH^k(X) = CH_{m-k}(X)$$

## Links with Topology

### Cycle Map to Homology

For algebraic varieties over the complex numbers, there is a cycle map which links the Chow groups with a topological homology group. If $X$ is an algebraic variety over $\mathbb{C}$, then let $H_*(X)$ denote the Borel–Moore homology of $X$, that is, the homology of locally finite singular chains on $X$ (viewed as a topological space with the classical topology). If $X$ is embedded as a closed subset of an oriented differentiable manifold $M$, then there are identifications

$$H_i(X) \cong H^{n-i}(M, M \setminus X) \qquad [6]$$

where $n$ is the dimension of $M$. There is a cycle class map

$$CH_k(X) \to H_{2k}(X)$$

which sends the class of each irreducible subvariety $Z$ of dimension $k$ in $X$ to its fundamental class $[Z] \in H_{2k}(X)$.

Let $M$ be an oriented differentiable manifold of dimension $n$ and let $X$ and $Y$ be closed subsets of $M$. Then the cup product $H^i(M, M\setminus X) \otimes H^j(M, M\setminus Y) \to H^{i+j}(M, M\setminus(X \cap Y))$ induces, via eqn [6], an intersection product

$$H_i(X) \otimes H_j(Y) \to H_{i+j-n}(X \cap Y)$$

which is the topological analog of the refined intersection product of eqn [5]. The products are compatible via the cycle class map. The topology of complex algebraic varieties and the compatibilities between algebraic and topological intersections are discussed in Fulton (1998). An interesting application of this interplay of intersection theories is the convolution product in Borel–Moore homology, which is important in geometric representation theory (see Chriss and Ginzburg (1997)).

### Riemann–Roch Theorems

The classical Riemann–Roch theorem relates the dimensions of linear systems on an algebraic curve (algebraic quantities) with their degrees and the curve's genus (topological quantities). The Hirzebruch–Riemann–Roch theorem states that on a nonsingular projective variety $X$, if $E$ is an algebraic vector bundle on $X$ and $\chi(E)$ denotes its Euler characteristic (the alternating sum of the ranks of the sheaf-theoretic cohomology groups), then

$$\chi(E) = \int_X \mathrm{ch}(E) \cdot \mathrm{td}(T_X) \qquad [7]$$

where $\int_X$ denotes the degree of the zero-dimensional component of the quantity that follows, and the Chern character $\mathrm{ch}(E)$ and Todd class $\mathrm{td}(T_X)$ are certain standard universal polynomials of Chern classes.

Grothendieck had the inspired idea that eqn [7] could be generalized to a covariance property for the Chern character times the Todd class. If $X$ and $Y$ are nonsingular varieties and $f : X \to Y$ is a projective morphism (or, more generally, a proper morphism), then there is a well-defined push-forward $f_*$ on Chow groups. There is also a kind of push-forward for vector bundles. The Grothendieck group of vector bundles on $X$, denoted $K^0(X)$, is the group of formal linear combinations of vector bundles, modulo the relations $[E] = [E'] + [E'']$ whenever $E'$ is a sub-bundle of $E$ with quotient bundle $E''$. Every coherent sheaf $\mathcal{F}$ has a well-defined class in $K^0(X)$, namely, the alternating sum of $[E_i]$ where $E_\bullet$ is any finite resolution of $\mathcal{F}$ by vector bundles (locally free sheaves). The push-forward $f_*[E]$ is defined as the alternating sum of the classes in $K^0(Y)$ of the higher direct images $R^i f_* E$. The Grothendieck–Riemann–Roch theorem states that

$$\mathrm{ch}(f_*[E]) \cdot \mathrm{td}(T_Y) = f_*(\mathrm{ch}(E) \cdot \mathrm{td}(T_X)) \qquad [8]$$

in $CH_*(Y) \otimes \mathbb{Q}$. Notice that eqn [7] represents the case that $Y$ is a point.

There is an even more general formulation valid for singular varieties. It is necessary to work with a homology version of the Grothendieck group, namely, the Grothendieck group $K_0(X)$ of coherent sheaves on $X$. The Baum–Fulton–MacPherson version of the Grothendieck–Riemann–Roch theorem prescribes transformations

$$\tau_X : K_0(X) \to CH_*(X) \otimes \mathbb{Q} \qquad [9]$$

which are covariant for proper morphisms. When $X$ is nonsingular, $\tau_X$ is given by the "Chern character" times the "Todd class", and covariance becomes eqn [8].

In the case of varieties over the complex numbers, there is also a transformation from the algebraic Grothendieck group $K_0(X)$ to a topological analog, satisfying various compatibilities. The composition with the homology Chern character gives Riemann–Roch transformations $K_0(X) \to H_*(X; \mathbb{Q})$ satisfying properties akin to those of eqn [9].

### The Analytic Setting

The Atiyah–Singer index theorem stands as an important generalization of the Hirzebruch–Riemann–Roch theorem. The index of an elliptic differential operator on a differentiable manifold plays the role of the Euler characteristic, and is equated with a topological quantity. One of the consequences of the index theorem is the validity of eqn [7] for general compact complex manifolds.

More in the domain of pure analysis is the question of intersecting two currents on a differentiable manifold. Currents arise naturally out of Chern–Weil theory. To each current is associated a wave front, a subset of the cotangent bundle that reflects the geometry of the singular set of the current. A current can be pulled back to an embedded submanifold whenever the embedding is transverse to the wave front. By reduction to the diagonal, this gives an intersection of two currents with transverse wave fronts which reduces to the usual wedge product in the case of smooth differential forms (see Hörmander (1990)).

## Applications of Intersection Theory

### Enumerative Geometry

Intersection theory has proved to be a useful tool in diverse areas such as enumerative geometry, singularity theory, and moduli problems. Enumerative problems have intrigued generations of geometers. Chasles, Maillard, Schubert, and Zeuthen are among the geometers of the second half of the nineteenth century who solved an impressive array of problems, including, as a notable example, Steiner's five conics problem to determine the number of plane conics tangent to five given conics in general position.

In modern terms, the successful solution to an enumerative problem involves setting up a space which parametrizes the geometric objects being counted, suitably compactified, and carrying out an intersection-theoretic computation on this space. Steiner's problem illustrates how "excess intersection" can occur and cause difficulty. Inside the $\mathbb{CP}^5$ of plane conics, including degenerate conics, those tangent to a given conic constitute a sextic hypersurface. So $6^5 = 7776$ would appear plausible; this was, in fact, the originally proposed solution. However, the most degenerate conics, the double lines, all appear as limits of families of conics tangent to any given conic. The refined intersection of five of these sextics has a cycle class of degree 4512 supported on the Veronese surface of double lines. This leaves 3264, the correct answer given by Chasles in 1864. The issue of providing rigorous foundations for these kinds of calculations was recognized by Hilbert, who set it as the 15th of his 23 major mathematical problems outlined in 1900. A good survey of early and modern efforts in enumerative geometry can be found in Kleiman and Thorup (1987).

### Singularity Theory and Degeneracy Loci

In any situation where a geometric object is described by parameters, there will be values of the parameter at which the geometry changes qualitatively. The significance of this is evident in the space of conics above. Singularity theory is concerned with the loci in parameter spaces on which these transitions can occur. Let $\pi : Y \to P$ be a map of differential manifolds, or of nonsingular algebraic varieties, which is generally (but not everywhere) submersive, so that there are singular fibers. Let $d$ denote the dimension of $P$, which can be considered as a parameter space, and let $c$ be the dimension of $Y$. Consider the loci

$$\bar{S}_k(\pi) = \{y \in Y \mid \operatorname{rk}(T_{y,Y} \to T_{\pi(y),P}) \le d - k\}$$

of singularity theory. Thom made an influential study of these in the 1950s, and Porteous in 1971 gave the following formula, now called the Thom–Porteous formula:

$$[\bar{S}_k(\pi)] = s_{((k+c-d)^k)}(\pi^* T_P - T_Y) \qquad [10]$$

The symbol on the right is shorthand for $s_{(k+c-d,\dots,k+c-d)}$, the case $a_1 = \cdots = a_k = k + c - d$ of the Schur determinant $s_{(a_1,\dots,a_k)} = \det(s_{a_i+j-i})_{1 \le i,j \le k}$, and for vector bundles $E$ and $F$ the $s_i(F - E)$ are

defined by the formula $s(F-E)=\sum_i(-1)^i c_i(E)/\sum_i(-1)^i c_i(F)$. In algebraic intersection theory, eqn [10] has the precise meaning that when $\bar{S}_k(\pi)$ has the expected codimension $k(k+c-d)$ in $Y$ (or is empty), its cycle class is equal to the given polynomial in Chern classes. The Thom–Porteous formula applies to the degeneracy loci of arbitrary maps of vector bundles $E \to F$. Degeneracy loci constitute an active area of research in intersection theory, and there are generalizations, for example, to cases where there are more bundles or bundle maps with symmetry (see Fulton and Pragacz (1998)).

### Moduli Spaces

The parameter spaces that have appeared often admit interpretations as moduli spaces. Moduli problems start with geometric objects to be classified, and ask for families of these objects over an arbitrary base space to be represented as faithfully as possible by maps from the base space to some space called a moduli space. For enumerative applications it is most useful for the moduli space to be compact. One of the principal examples is the moduli of algebraic curves of given genus $g$: for $g \geq 2$, the moduli space of smooth curves $M_g$ has a compactification $\bar{M}_g$ by stable curves, as defined and studied by Deligne and Mumford. While the $M_g$ are singular, the singularities are mild enough to permit the definition of an intersection theory for $M_g$ and $\bar{M}_g$, as was done by Mumford in the 1980s. More generally, if $X$ is a complex projective variety, Kontsevich's spaces of stable maps $\bar{M}_{g,n}(X,\beta)$ compactify the moduli of genus $g$ curves with $n$ marked points together with algebraic maps to $X$ having image in homology class $\beta \in H_2(X)$. These spaces, and some high-powered intersection theory that takes place on them, are vitally important in Gromov–Witten theory. $K$-theory also provides an alternative approach to intersection products in algebraic geometry.

## Extensions and Related Theories

### Motives and Higher Chow Groups

Intersection theory has evolved into a mature theory with numerous extensions and offshoots. Many of these are a result of endeavors to forge links with other branches of mathematics. One of the extensions, higher Chow groups, has its roots in a basic property of intersection theory, the excision property, which states that if $X$ is a variety and $U \subset X$ an open subvariety, with $Z = X \setminus U$, then the inclusion and restriction maps fit into a right exact sequence

$$CH_*Z \to CH_*X \to CH_*U \to 0$$

This is reminiscent of the long exact homology sequence of a pair in algebraic topology. Indeed, there is a corresponding long exact sequence of Borel–Moore homology groups, but the elementary algebraic theory lacks such a long exact sequence. Bloch introduced higher Chow groups in the 1980s to fill this gap. The theory, which is quite complicated, provides groups $CH_*(X,j)$, with $CH_*(X,0)=CH_*X$, such that there is a long exact sequence

$$\cdots \to CH_*(U,j+1) \to CH_*(Z,j) \to CH_*(X,j) \to CH_*(U,j) \to \cdots$$

These groups are closely connected to algebraic $K$-theory and also to a related theory called motivic cohomology.

Motives, a sort of universal cohomology theory envisaged by Grothendieck, conjecturally form a category which can be extended to a bigger category of mixed motives that reflects mixed structures in cohomology, such as mixed Hodge structures. Recently, Voevodsky *et al.* (2000) have introduced motivic cohomology groups which form an integral part of a homotopy theory for algebraic varieties. Voevodsky's work, including a proof of the Milnor conjecture of $K$-theory, earned him a Fields Medal in 2002.

### Arithmetic Intersection Theory

There is an arithmetic version of intersection theory which applies to an arithmetic scheme $X$, which is, informally, a scheme defined over every prime field (all finite fields $\mathbb{F}_p$ and also $\mathbb{Q}$) in a consistent way. This means that $X$ can be base-extended to any field. In situations where the complex variety $X(\mathbb{C})$ is nonsingular, there is an arithmetic Chow ring $\widehat{CH}^*(X)$, introduced by Gillet and Soulé in 1990. Elements of $\widehat{CH}^*(X)$ are equivalence classes of pairs $(Z,g)$ where $Z$ is an algebraic cycle on $X$ and $g$ is known as a Green current for $Z$, a current on $X(\mathbb{C})$ satisfying the relation

$$\frac{\mathrm{i}}{2\pi}\partial\bar{\partial}g + \delta_{Z(\mathbb{C})} = \omega \qquad [11]$$

for some smooth differential form $\omega$ satisfying some conditions. Here, $\delta_Z(\mathbb{C})$ denotes the current of integration along $Z(\mathbb{C})$. The point to notice is that eqn [11] relates analysis (the Green current) and algebra (the cycle) on $X$ on one side with topology on the other, as $\omega$ will be a closed form whose class in de Rham cohomology is Poincaré dual to $[Z(\mathbb{C})]$.

Arithmetic intersection theory is used to define arithmetic height functions. Height functions have important applications to Diophantine problems, and were an essential component of the proof by Faltings of the Mordell conjecture, which earned him a Fields Medal in 1986. Arithmetic intersection theory grew

out of an earlier theory of Arakelov, in which $X(\mathbb{C})$ is endowed with a Kähler metric, and the form $\omega$ in eqn [11] is required to be harmonic. The Arakelov Chow group is only a ring when harmonic forms are closed under wedge product, which is not the case generally but which is true in some interesting cases, for example, for Grassmannian varieties. Arakelov treated the case of arithmetic surfaces, that is, the case when $X(\mathbb{C})$ is an algebraic curve ("surface" refers to a second dimension in the arithmetic direction), and introduced a pairing of arithmetic divisors, in analogy with the usual pairing of divisors on an algebraic surface. Arakelov's work, its subsequent generalizations, and more recent developments are covered in Faltings (1992).

### Equivariant Theories and Stacks

Moduli problems such as those mentioned previously are often best represented not by traditional varieties, but by a more sophisticated sort of object called a stack. Taking inspiration from Mumford's intersection theory on $M_g$, intersection theory on algebraic stacks has grown into a mature theory in its own right. Examples of stacks include orbifolds, for which there is the Chen–Ruan (orbifold) cohomology theory as well as an algebraic analog due to Abramovich, Graber, and Vistoli (see Abramovich, *et al.* (2002)). Another class of examples are quotient stacks of a variety by the action of an algebraic group. In these cases the Chow groups of the stack are equivariant Chow groups, part of a rich theory modeled on equivariant cohomology in algebraic topology. Behrend (2002) provides a nice survey of stacks, equivariant intersection theory, and their uses in Gromov–Witten theory. The Bott residue formula is an important tool in equivariant intersection theory which is particularly well suited to making concrete calculations, for example, in enumerative geometry. A description with nice examples can be found in Ellingsrud and Strømme (1996).

# Inverse Problem in Classical Mechanics

**R G Novikov**, Université de Nantes, Nantes, France

## Formulation of the Problem

Consider the Newton equation

$$\ddot{x} = F(x), \quad F(x) = -\nabla v(x), \qquad x \in \mathbb{R}^d \qquad [1]$$

where

$$v \in C^2(\mathbb{R}^d, \mathbb{R})$$
$$|\partial_x^j v(x)| \le c_{|j|}(1 + |x|)^{-\alpha-|j|} \qquad [2]$$
$$\text{for } x \in \mathbb{R}^d, |j| \le 2, \text{and some } \alpha > 1, c_{|j|} \ge 0$$

(where $j$ is the multi-index $j \in (\mathbb{N} \cup \{0\})^d, |j| = \sum_{n=1}^d j_n$). In classical mechanics, eqn [1] describes the dynamics of a particle with the mass $m = 1$ in the force field $F$ with the potential $v$. For eqn [1] the energy $E = (1/2)(\dot{x}(t))^2 + v(x(t))$ is an integral of motion.

Under the assumptions [2], it follows that (Reed and Simon 1979): for any $(p_-, x_-) \in \mathbb{R}^{2d}, p_- \ne 0$, eqn [1] has a unique solution $x \in C^2(\mathbb{R}, \mathbb{R}^2)$ such that

$$x(t) = p_- t + x_- + y_-(t)$$
$$y_-(t) \to 0, \quad \dot{y}_-(t) \to 0, \qquad \text{as } t \to -\infty \qquad [3]$$

in addition, for almost any $(p_-, x_-)$

$$x(t) = a(p_-, x_-)t + b(p_-, x_-) + y_+(t)$$
$$a(p_-, x_-) \neq 0,\ y_+(t) \to 0,\ \dot{y}_+(t) \to 0 \quad [4]$$
$$\text{as } t \to +\infty$$

furthermore, the set $\mathcal{D}$ of all $(p_-, x_-) \in \mathbb{R}^{2d}, p_- \neq 0$, for which [4] holds for fixed $v$, is an open subset of $\mathbb{R}^{2d}$ and $\mathcal{M}es(\mathbb{R}^{2d}\backslash\mathcal{D}) = 0$.

We say that $a, b$ arising in [4] (and defined on $\mathcal{D}$) are the scattering data for eqn [1]. In addition, the scattering data $a, b$ at fixed energy $E > 0$ means $a, b$ on $\{(p_-, x_-) \in \mathcal{D} \,|\, p_-^2/2 = E\}$. Roughly speaking, for a particle moving according to [1], the functions $a, b$ relate the free motion at time $t \to -\infty$ with the free motion at time $t \to +\infty$.

Note that

$$a(p_-, x_- + t_0 p_-) = a(p_-, x_-)$$
$$b(p_-, x_- + t_0 p_-) = b(p_-, x_-) + t_0 a(p_-, x_-) \quad [5]$$
$$(p_-, x_-) \in \mathcal{D}, \quad t_0 \in \mathbb{R}$$

Formula [5] imply that $a, b$ on $\mathcal{D}$ are uniquely determined by $a, b$ on $\{(p_-, x_-) \in \mathcal{D} \,|\, p_- x_- = 0\}$, where $p_- x_-$ is the scalar product of $p_-$ and $x_-$.

If $v(x) \equiv 0$, then $a(p_-, x_-) = p_-, b(p_-, x_-) = x_-, (p_-, x_-) \in \mathbb{R}^d, p_- \neq 0$. Therefore, it is convenient to use for $a$, $b$ the following representation:

$$a(p_-, x_-) = p_- + a_{\text{sc}}(p_-, x_-)$$
$$b(p_-, x_-) = x_- + b_{\text{sc}}(p_-, x_-), \quad (p_-, x_-) \in \mathcal{D} \quad [6]$$

where the subscript sc is an abbreviation of the word "scattering."

The direct scattering problem for eqn [1], under the assumptions [2], consists in the following: given $v$, find $a, b$.

The inverse-scattering problem for eqn [1], under the assumptions [2], consists in the following: given $a, b$ (or some partial information about $a, b$), find $v$.

In the present article, we discuss, mainly, the aforementioned inverse-scattering problem.

## Abel's Result of 1826

Consider the Newton equation [1] in dimension $d = 1$ for $x \in ]-\infty, x_1], x_1 > 0$, where

$$v \in C^2(]-\infty, x_1], \mathbb{R})$$
$$v(x) = 0 \quad \text{for } x < 0 \quad [7]$$
$$\frac{dv(x)}{dx} > 0 \quad \text{for } 0 < x < x_1$$

Under the assumptions [7], for any $p_- > 0$, where $E = p_-^2/2 < v(x_1)$, eqn [1] has a unique solution $x \in C^2(\mathbb{R}, ]-\infty, x_1])$ such that

$$x(t) = p_- t \quad \text{for } t \leq 0 \quad [8]$$

in addition,

$$x(t) = -p_- t + b(p_-) \quad \text{as } t \to +\infty \quad [9]$$

Let

$$T(E) = \frac{b(\sqrt{2E})}{\sqrt{2E}}, \quad 0 < E < v(x_1),\ \sqrt{2E} > 0 \quad [10]$$

($T(E)$ is the time during which a particle starting at $x = 0$ with the impulse $p_- = \sqrt{2E}$ returns to $x = 0$).

Let $x(v)$, $v \in [0, v(x_1)]$, be the inverse function to $v(x)$, $x \in [0, x_1]$. Then (under the assumptions [7]),

$$T(E) = \sqrt{2}\int_0^E (E - v)^{-1/2}\frac{dx(v)}{dv}dv$$
$$0 < E < v(x_1) \quad [11]$$

$$x(v) = \frac{1}{\sqrt{2}\pi}\int_0^v (v - E)^{-1/2}T(E)dE$$
$$0 < v < v(x_1) \quad [12]$$

Actually, the formulas [11], [12] relating the travel time $T$ and the potential $v$ are the results from Abel (1826) (see also Keller (1976) for a discussion of this result). Formula [11] is a result on direct scattering, whereas [12] is a result on inverse scattering. In addition, if $T(E), 0 < E < v(x_1)$, is given, then [11] is the Abel integral equation for $x(v), 0 < v < v(x_1)$, and [12] solves this equation.

Concerning further results on inverse scattering for the one-dimensional Newton equation, see Keller (1976) and Astaburuaga *et al.* (1991). Note that for the one-dimensional case the scattering data $a$, $b$ do not in general determine $v$ uniquely.

The Abel integral equation and the Abel formula solving this equation were used also, in particular, by Firsov (1953) and Keller *et al.* (1956), where inverse scattering was considered for the three-dimensional Newton equation at fixed energy for the case of spherically symmetric monotonous decreasing potential in $|x|$.

Note also that the Abel method for solving the integral equation [11] was used by Radon (1917) for finding the inversion formula for the Radon transformation. In the next section, we reduce the inverse-scattering problem for the Newton equation [1] in dimension $d \geq 2$, under the assumptions [2], to the inversion problem for the X-ray transformation (i.e., the Radon transformation along straight lines).

## Inverse Scattering for the Multidimensional Newton Equation

Consider

$$T\mathbb{S}^{d-1} = \{(\theta, x) \in \mathbb{S}^{d-1} \times \mathbb{R}^d \mid \theta x = 0\} \qquad [13]$$

Consider the X-ray transformation $P$ defined by the formula

$$Pf(\theta, x) = \int_{\mathbb{R}} f(t\theta + x)\mathrm{d}t, \quad (\theta, x) \in T\mathbb{S}^{d-1} \qquad [14]$$

where

$$f \in C(\mathbb{R}^d, \mathbb{R}^m)$$
$$f(x) = O(|x|^{-\beta}) \quad \text{as } |x| \to \infty \text{ for some } \beta > 1 \qquad [15]$$

Consider the functions $a_{sc}, b_{sc}$ of [6]

**Theorem 1** (Novikov 1999). *For the Newton equation* [1], *under the assumptions* [2], *the following formulas hold*:

$$PF(\theta, x) = \lim_{s\to+\infty} s a_{sc}(s\theta, x), \quad (\theta, x) \in T\mathbb{S}^{d-1} \qquad [16]$$

$$Pv(\theta, x) = \lim_{s\to+\infty} s^2 \theta b_{sc}(s\theta, x), \quad (\theta, x) \in T\mathbb{S}^{d-1} \qquad [17]$$

*in addition*,

$$|PF(\theta, x) - s a_{sc}(s\theta, x)| \le \frac{d^3 c^2 2^{2\alpha+4}}{\alpha(\alpha-1)(1+|x|/\sqrt{2})^{2\alpha-1}} \frac{s^3}{(s/\sqrt{2}-1)^4} \qquad [18]$$

$$|Pv(\theta, x) - s^2\theta b_{sc}(s\theta, x)| \le \frac{d^3 c^2 2^{2\alpha+4}}{\alpha(\alpha-1)^2(1+|x|/\sqrt{2})^{2\alpha-2}} \frac{s^4}{(s/\sqrt{2}-1)^5} \qquad [19]$$

*for* $(\theta, x) \in T\mathbb{S}^{d-1}, s \ge z(d, c, \alpha, |x|)$, *where* $\theta b_{sc}$ *is the scalar product of* $\theta$ *and* $b_{sc}$, $z$ *is the root of the equation*

$$\frac{d^2 c 2^{\alpha+2}}{(\alpha-1)(1+|x|/\sqrt{2})^{\alpha-1}} \frac{z^2}{(z/\sqrt{2}-1)^3} = 1$$
$$z \in ]\sqrt{2}, +\infty[ \qquad [20]$$

$c = \max(c_1, c_2)$ (*and* $\alpha, c_1, c_2$ *are the constants of* [2]).

Theorem 1 gives a method for finding $PF$ and $Pv$ from $a_{sc}$ and $b_{sc}$ at high energies. It has been proved in Novikov (1999) by means of analysis of the following nonlinear integral equation for the function $y_-$ of [3]:

$$y_-(t) = A_{p_-, x_-}(y_-)(t)$$

where

$$A_{p_-, x_-}(u)(t) = \int_{-\infty}^{t} \int_{-\infty}^{\tau} F(p_- s + x_- + u(s))\mathrm{d}s\, \mathrm{d}\tau$$
$$p_- \neq 0$$

In dimension $d \ge 2$, Theorem 1 and methods for the reconstruction of $f$ from $Pf$ (Gelfand *et al.* 1980, Natterer 1986, Novikov 1999) give a method for the reconstruction of $F$ and $v$ from the scattering data $a$, $b$ at high energies. Note that for $d = 1$ Theorem 1 is valid but $f$ cannot be uniquely reconstructed from $Pf$.

Theorem 1 is an analog of the Born formula for the Schrödinger equation at high energies (see, e.g., Faddeev (1956), Enss and Weber (1995), and Novikov (1998) as regards this Born formula and its variations). On the other hand, Theorem 1 was preceded by a result of Gerver and Nadirashvili (1983) on the high-energy asymptotics for the travel time between boundary points for the Newton equation in a bounded strictly convex domain with smooth boundary. There is a considerable similarity between this result and Theorem 1.

We continue our review on inverse scattering for the multidimensional Newton equation, and make the following well-known observation.

**Observation 1** *Suppose that* $v(x) > E > 0$ *for* $x \in \mathcal{U}$, *where* $\mathcal{U}$ *is a compact subset of* $\mathbb{R}^d$. *Then the scattering data* $a, b$ *for energies smaller than or equal to* $E$ *contain no information about* $v(x)$ *for* $x \in \mathcal{U}$.

In addition to Theorem 1 and Observation 1, one has the following conjecture.

**Conjecture 1** (Novikov 1999). *Suppose that* $v$ *satisfies* [2], $d \ge 2$, *and the energy* $E$ *is sufficiently large*, $E > E(v)$. *Then the scattering data* $a, b$ *at fixed energy* $E$ *uniquely determine* $v$.

Gerver and Nadirashvili (1983) proved a result similar to Conjecture 1 for the case of the Newton equation in a bounded strictly convex domain $G$ with smooth boundary. Their proof of this result contains no reconstruction method but does contain a stability estimate. It is based on the Maupertuis principle and the results of Muhometov and Romanov (1978), Beylkin (1979), and Bernstein and Gerver (1980). For the case $v \in C^2(\mathbb{R}^d, \mathbb{R})$, $\operatorname{supp} v \subset G$ (where $G$ has the properties mentioned above), in Novikov (1999) a connection between the boundary-value data of Gerver and Nadirashvili (1983) and the scattering data $a, b$ is given and it is shown that for $d \ge 2$ the scattering data $a, b$ and the domain $G$ uniquely determine $v$ at fixed sufficiently large energy $E > E(v, G)$.

For more information concerning results mentioned above, see Novikov (1999) and Gerver and Nadirashvili (1983). One can see from the review of this section that very few results on inverse scattering for the multidimensional Newton equation are given in the literature, at present. It should

be remarked that the inverse-scattering theory in multidimensions is much more developed for the Schrödinger equation than for the Newton equation.

## Inverse Scattering for the Schrödinger Equation in Multidimensions

The inverse-scattering theory for the multidimensional Schrödinger equation has been developed by many authors (see, e.g., surveys given in Grinevich (2000) and Novikov (2001)).

Quantum-mechanical analogs of Theorem 1 appear, for example, in Faddeev (1956), Enss and Weder (1995), Novikov (1998) (see also references therein). Similarly, the quantum-mechanical analogs of Conjecture 1 have been proved, for example, in Novikov (1992, 1994) and Grinevich and Novikov (1995) (see also references therein). On the other hand, as a rule, classical-mechanical analogs of results of the works on inverse Schrödinger scattering in multidimensions are unknown. This leads to many open problems. For the one-dimensional case some results on finding classical limits of results on inverse Schrödinger scattering are given in Lax and Levermore (1983) and Bogdanov (1985). Note that inverse scattering for the two-dimensional Schrödinger equation at fixed energy (see Novikov (1992), Grinevich and Novikov (1995), and Grinevich (2000) and references therein) has considerable similarity with inverse scattering for the one-dimensional Schrödinger equation. Therefore, an interesting open problem consists in extending the aforementioned study of Lax and Levermore (1983) and Bogdanov (1985) to the case of inverse scattering for the two-dimensional Schrödinger equation at fixed energy. Perhaps, in this way one can find proper two-dimensional analogs of the Abel formulas [11] and [12].

# Inviscid Flows

**R Robert**, Université Joseph Fourier, Saint Martin D'Hères, France

## Introduction

The equations governing the motion of an ideal (inviscid) fluid were derived by Euler in 1755. They were, together with the equation of vibrating strings, the first partial differential equations introduced in the field of mathematical physics. While several partial differential equations, coming from the modeling of physical phenomena, have had a satisfactory mathematical solution, it is piquant to note that the old Euler equations remain essentially unsolved. Together with the Navier–Stokes equations of viscous fluids, the Euler equations play a central role in the modern analysis of partial differential equations.

The mathematical difficulties encountered in the study of Euler equations seem to be deeply linked with the understanding of turbulence, which remains one of the great open problems in the field of macroscopic physics.

The relevance of Euler equations as a model of fluid flow is rather subtle, and the discussion is far from closed. On the one hand, Euler equations have disturbing aspects, which, in their most visible form, yield paradoxes. On the other hand, the systematic recourse to some viscosity seems to put a serious obstacle to a proper understanding of turbulence. In this article we will try to give some insight into this issue.

To be rigorous, every fluid has some compressibility, that is to say the density varies with the pressure. Compressibility gives rise to pressure waves, which propagate in the fluid with some finite speed. When the velocity of the fluid particles is slow relative to the speed of the pressure waves, it is legitimate to make the approximation that the flow is incompressible; it is the case for meteorological flows, for example. Then, there are no more pressure waves; nevertheless the motion can be very unstable and intricate (turbulent). Although very often in physical flows these two features coexist, following the tradition, we clearly separate the compressible and incompressible cases.

## The Equations of the Perfect Fluid

Until now a rigorous derivation of the fluid equations from a system of interacting particles governed by Newton's laws is not known. Thus, the mathematical models of fluid motion result from heuristic considerations.

Let us specify some notations.

The fluid motion is supposed to take place in some domain (not necessarily bounded) $\Omega$ of the physical space $\Re^3$.

We shall use the so-called Eulerian description of the fluid motion: $\rho(t,\boldsymbol{x})$ denotes the local density of the fluid at time $t$ and position $\boldsymbol{x}$, and $\boldsymbol{u}(t,\boldsymbol{x})$ the velocity of the fluid particle located at $\boldsymbol{x}$ at time $t$.

The first equation (conservation equation) expresses the conservation of mass:

$$\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho \boldsymbol{u}) = 0 \qquad [1]$$

The second equation (momentum equation) expresses Newton's law (in the absence of internal friction):

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u}\right) = -\nabla p \qquad [2]$$

where the scalar function p($t$, $\boldsymbol{x}$) is the pressure inside the fluid, and

$$(\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = \sum_i u_i \partial_i \boldsymbol{u}$$

With [1] and [2], we have five scalar unknown functions $(\rho, u_i, p)$ and only four equations. To get a

closed set of equations, we need to add a supplementary relationship:

$$\operatorname{div}(\boldsymbol{u}) = 0, \quad \text{for the incompressible flows} \qquad [3]$$

In the case of compressible flows, eqns [1] and [2] must be completed by a thermodynamical description of the fluid, which yields a relationship between $\rho, p$, the internal energy, the specific entropy, etc. We will only consider here the simple case of an isentropic gas which is modeled by the relationship

$$p = p(\rho) \qquad [4]$$

with $p(\rho) = c\,p^{\gamma}$ for a perfect gas ($c > 0, \gamma > 1$).

#### Condition at the Boundary $\partial\Omega$ of the Domain

In the case of a perfect fluid, we simply have to write that the velocities of the fluid particles at the boundary are tangent to the boundary, that is,

$$\boldsymbol{u} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial\Omega \qquad [5]$$

where $\boldsymbol{n}$ denotes the unit normal vector to the boundary (pointing outward).

### The Incompressible Perfect Fluid: Main Properties of Smooth Flows

We shall suppose $\rho = 1$. Equations [1]–[3] and [5] then yield the classical Euler system:

$$\begin{aligned} &\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = -\nabla p \quad \text{on } \Omega \\ &\operatorname{div} \boldsymbol{u} = 0, \quad \boldsymbol{u} \cdot \boldsymbol{n} = 0 \text{ on } \partial\Omega \end{aligned} \qquad [6]$$

#### The Constants of the Motion

Let us examine the constants of the motion of the dynamical system defined by [6], that is, the functionals which are conserved by the motion of the fluid.

First we have the classical constants of motion associated with the natural symmetries by Noether's theorem.

The time translational invariance of the system implies that the kinetic energy is conserved:

$$E_c = \frac{1}{2}\int_{\Omega} \boldsymbol{u}^2 \,\mathrm{d}\boldsymbol{x}$$

In the case $\Omega = \Re^3$, the homogeneity of space implies the conservation of the impulsion:

$$\int_{\Omega} \boldsymbol{u} \,\mathrm{d}\boldsymbol{x}$$

The space isotropy, on the other hand, yields the conservation of the angular momentum:

$$\int_{\Omega} \boldsymbol{x} \wedge \boldsymbol{u} \,\mathrm{d}\boldsymbol{x}$$

There is a more hidden constant of the motion, called helicity, which was discovered in 1961 by J J Moreau (1961) (see, e.g., Serre (1979)).

Let us define the vorticity of the flow:

$$\omega = \operatorname{curl} \boldsymbol{u}$$

then the helicity is

$$\int_{\Omega} \omega \cdot \boldsymbol{u} \,\mathrm{d}\boldsymbol{x}$$

Of course, here, we suppose $\boldsymbol{u}$ to be vanishing at infinity in such a manner that the above integrals make sense.

One may wonder about the existence of other constants of the motion of the form (first-order functionals):

$$\int F(\boldsymbol{x}, \boldsymbol{u}(\boldsymbol{x}), \nabla \boldsymbol{u}(\boldsymbol{x}))\mathrm{d}\boldsymbol{x}$$

The answer, due to Serre (1979), is that any functional of the above form which is conserved by the flow is a linear function of the energy, the impulsion, the angular momentum, the helicity plus a trivial term (i.e., taking the same value for any field $\boldsymbol{u}$ such that $\operatorname{div} \boldsymbol{u} = 0$).

#### Beltrami Equation and Kelvin's Theorem

Another important issue is to know how the vorticity field evolves in a regular flow. If we apply the operator curl to the equation [6] in order to eliminate the pressure term, we get:

$$\frac{\partial \omega}{\partial t} + (\boldsymbol{u} \cdot \nabla)\omega - (\omega \cdot \nabla)\boldsymbol{u} = 0 \qquad [7]$$

which is the Beltrami equation.

To exploit the Beltrami equation, we need the Lagrangian flow $\varphi(t, \boldsymbol{x})$, associated with the field $\boldsymbol{u}$, which is defined by the differential equation:

$$\frac{\partial \varphi}{\partial t}(t, \boldsymbol{x}) = \boldsymbol{u}(t, \varphi(t, \boldsymbol{x})), \quad \varphi(0, \boldsymbol{x}) = \boldsymbol{x}$$

Then we can state the following proposition.

**Proposition** *During the smooth motion of an incompressible perfect fluid, we have:*

$$\omega(t, \varphi(t, \boldsymbol{x})) = D\varphi(t, \boldsymbol{x})[\omega(0, \boldsymbol{x})], \quad \text{for all } t, \boldsymbol{x}$$

*where $D\varphi(t, \boldsymbol{x})$ denotes the derivative at the point $\boldsymbol{x}$ ($t$ fixed) of the mapping $\boldsymbol{x} \to \varphi(t, \boldsymbol{x})$.*

The first consequence of this result is to point out the class of irrotational flows, for which

$\omega(t, \boldsymbol{x}) = 0$. Indeed, if the vorticity vanishes initially, it follows from the proposition that it will vanish for ever.

Another consequence is the behavior of vortex lines. By definition, a vortex line is any integral curve of the vorticity field. More precisely, a vorticity line at time $t$, $C(s)$ is defined by the differential equation

$$\frac{\mathrm{d}C}{\mathrm{d}s}(s) = \omega(t, C(s))$$

Now we can check that vortex lines are merely transported by the flow: if $C(s)$ is a vortex line at time $t = 0, \varphi(t, C(s))$ is a vortex line at time $t$.

We end this section with the famous Kelvin's circulation theorem (1869) (see, e.g., Marchioro and Pulvirenti (1994)).

**Theorem** *Let L be a closed (oriented) contour drawn inside the fluid. We suppose that L is transported by the flow; $\varphi_t(L)$ denotes the contour at time t. Then the circulation of the velocity field $\boldsymbol{u}(t, \boldsymbol{x})$ along $\varphi_t(L)$ is independent of t.*

### Stationary Solutions: D'Alembert's Paradox

Let us focus now on the flow around a bounded body $\overline{\Omega}$, whose complement $\overline{\Omega}^c$ will be supposed to be simply connected.

A stationary solution $u(\boldsymbol{x}), p(\boldsymbol{x})$ satisfies:

$$(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = -\nabla p$$
$$\operatorname{div} \boldsymbol{u} = 0, \quad \boldsymbol{u} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial\Omega$$

But since $(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = \nabla(\frac{1}{2}\boldsymbol{u}^2) + (\operatorname{curl} \boldsymbol{u}) \wedge \boldsymbol{u}$, any stationary field $\boldsymbol{u}(\boldsymbol{x})$ satisfying curl $\boldsymbol{u} = 0$, div $\boldsymbol{u} = 0$, $\boldsymbol{u} \cdot \boldsymbol{n} = 0$ on $\partial\Omega$, defines a stationary solution with associated pressure $p = -\frac{1}{2}\boldsymbol{u}^2$.

We also need to specify a condition at infinity for the field $\boldsymbol{u}$. We impose that the velocity is equal (at infinity) to some constant value $U$. Since $\overline{\Omega}^c$ is simply connected, the condition curl $\boldsymbol{u} = \boldsymbol{0}$ implies that the flow is potential, that is, there is a scalar function $F(\boldsymbol{x})$ such that $\boldsymbol{u} = U + \nabla F$.

Thus, the determination of an irrotational flow around an obstacle amounts to solving the following exterior Neuman problem.

Find $F$ satisfying:

$$\Delta F = 0 \quad \text{in } \overline{\Omega}^c$$
$$\frac{\partial F}{\partial n} = -\mathrm{U} \cdot \boldsymbol{n} \quad \text{on } \partial\Omega$$
$$\nabla F = 0 \quad \text{at infinity}$$

This problem is well known and has a unique solution, which satisfies, at infinity:

$$F(\boldsymbol{x}) = \mathrm{O}(1/|\boldsymbol{x}|^2) \qquad \nabla F(\boldsymbol{x}) = \mathrm{O}(1/|\boldsymbol{x}|^3)$$

Then a classical calculation (integration by parts) gives the resulting force exerted by the flow on the body:

$$R = -\int_{\partial\Omega} \mathrm{p}\boldsymbol{n} \,\mathrm{d}\sigma = \int_{\partial\Omega} \frac{1}{2}\boldsymbol{u}^2\boldsymbol{n} \,\mathrm{d}\sigma = 0$$

This property of inviscid potential flows was first noticed by Jean Le Rond d'Alembert (1717–1783). Furthermore, d'Alembert performed a series of experiments to measure the drag on a sphere in a flowing fluid and he expected that the force would go to zero as the viscosity of the fluid approached zero. But this was not the case: the drag seemed to converge toward a nonzero value. Hence, this property was called d'Alembert's paradox.

Of course, d'Alembert's paradox tells us that something is going wrong: this model of flow around a body is not physically relevant. But it is not obvious to identify precisely what is going wrong.

Physics tells us that in a flow around a flying airplane, the viscous term (as measured by an dimensionless number called Reynolds number) is very small. The main effect of the viscosity is then to alter the limit condition at the boundary of the body. The relevant boundary condition is no longer $\boldsymbol{u} \cdot \boldsymbol{n} = 0$, but the purely viscous condition $\boldsymbol{u} = 0$, or more realistically a condition of friction type (turbulent boundary condition).

A common approach is to disqualify the perfect-fluid model in arguing that this modification of the boundary condition has important consequences on the flow near the body (giving rise to a turbulent boundary layer, for example).

It seems to us that such a disqualification of the perfect-fluid model discards prematurely interesting issues. Indeed, we must notice first that the stationary solution on which d'Alembert's reasoning is based is highly unstable and not acceptable physically. Thus, a realistic solution would necessarily be either nonstationary or with some vorticity. On this basis, we can imagine other scenarios to explain the existence of a resulting force exerted on the body. For example, we may imagine a stationary solution with a discontinuous velocity field (i.e., with a vortex sheet). The process conducive to such a stationary solution is called Prandtl's scenario (Batchelor 1967). The mathematical proof that Prandtl's scenario does exist is a difficult (open) issue, which seems closely related to the (probable) nonuniqueness of weak solutions of the Cauchy problem.

## The Cauchy Problem for the Incompressible Perfect Fluid

### The Case $\Omega \subset \Re^3$

In the Cauchy problem, given an initial velocity field $\boldsymbol{u}_0(\boldsymbol{x})$, we want to determine the corresponding solution $\boldsymbol{u}(t,\boldsymbol{x})$ of [6] at each time $t$.

The first significant result on the Cauchy problem for three-dimensional Euler equations was given by Kato (1975).

**Theorem** *For $\boldsymbol{u}_0$ in the Sobolev space $H^s(\Re^3)$, for $s > 5/2$, there is $T > 0$ and a unique classical solution (of the Cauchy problem) $\boldsymbol{u}(t,\boldsymbol{x})$ on $[0,T] \times \Re^3$. $\boldsymbol{u}$ depends continuously on t in the space $H^s$.*

By a classical solution we mean that the field $\boldsymbol{u}(t,\boldsymbol{x})$ is derivable in terms of the variables $t$, $\boldsymbol{x}$ and satisfies the equations in the usual sense.

Here $H^S(\Re^3)$ denotes the Sobolev space of the fields $\boldsymbol{u}$, which are square integrable and with spatial derivatives of order $s$ (in the case where $s$ is an integer) also square integrable.

**Remark** These results have been generalized to some extent during the last few decades, but the following issues are still open:

1. Do singularities occur at a finite time for such regular solutions?
2. For a less regular initial datum, do weak solutions exist (in the sense of distributions)?

### The Case $\Omega \subset \Re^2$

This case is better understood, the first mathematical results trace back to Lichtenstein (1925) and Wolibner (1933); they take a plain form with the famous theorem of Youdovitch 1963 (see, e.g., Chemin (1995)).

In two dimensions, the vorticity $\omega = \operatorname{curl} \boldsymbol{u}$ identifies with a scalar function, and the Beltrami equation becomes

$$\frac{\partial \omega}{\partial t} + \operatorname{div}(\omega \boldsymbol{u}) = 0 \quad [8a]$$

$$\operatorname{curl} \boldsymbol{u} = \omega \quad [8b]$$

$$\operatorname{div} \boldsymbol{u} = 0, \quad \boldsymbol{u} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial\Omega \quad [8c]$$

This formulation, which appears as a transport equation [8a] for $\omega$, coupled with the elliptic system [8b]–[8c], which determines $\boldsymbol{u}$ from $\omega$, is particularly convenient.

The constants of motion associated with the usual symmetries, of course, persist; notice, however, that the helicity degenerates since, in two dimensions, $\omega \cdot \boldsymbol{u} = 0$. But now from [8a] we see that $\omega$ is merely convected by the incompressible velocity field $\boldsymbol{u}$. We deduce that, for any continuous function $f$, the functional

$$\int_\Omega f(\omega(t,\boldsymbol{x}))\mathrm{d}\boldsymbol{x}$$

is a constant of motion.

Thus, a specific feature of the two-dimensional case is to introduce an infinite set of constants of motion. By a skilful exploitation of this fact, Youdovitch succeeded in proving the following result.

**Theorem** *For a given $\omega_0$ in the space $L^\infty(\Omega)$, there is a unique weak solution $\omega(t,\boldsymbol{x})$ of [8], such that $\omega(t,\boldsymbol{x})$ is in $L^\infty(\Omega)$ for all $t$, and $\omega$ depends continuously on t in the space $L^p, 1 \le p < \infty$.*

$L^p$ denotes, in a standard way, the Lebesgue space of the functions $f$ such that $|f|^p$ is integrable over $\Omega$ and $L^\infty(\Omega)$, the space of measurable bounded functions on $\Omega$.

Thus, if we limit ourselves to initial data with bounded scalar vorticity, the Cauchy problem for the two-dimensional incompressible perfect fluid is satisfactorily solved. The situation is much more intricate if we consider a less regular initial datum (e.g., if $\omega_0$ is a measure supported by a curve (vortex sheet)).

#### Arnol'd's Work on Two-Dimensional Inviscid Flows

Youdovitch's theorem implies that the incompressible Euler equations, with $\omega_0$ in $L^\infty(\Omega)$, is a satisfactory model of two-dimensional flows – an important issue to study further the properties of this model.

A famous result due to Arnol'd (see Arnol'd and Khesin (1998) and Marchioro and Pulvirenti (1994)) deals with the nonlinear stability of the stationary solutions.

Let us determine the smooth stationary solutions of the two-dimensional Euler equations in a bounded domain $\Omega$ of the plane. We have to solve:

$$(\boldsymbol{u} \cdot \nabla)\omega = \boldsymbol{0} \quad [9a]$$

$$\operatorname{curl} \boldsymbol{u} = \omega \quad [9b]$$

$$\operatorname{div} \boldsymbol{u} = 0, \quad \boldsymbol{u} \cdot \boldsymbol{n} = 0 \quad \text{on } \partial\Omega \quad [9c]$$

Since we have $\operatorname{div} \boldsymbol{u} = 0$, we may introduce the stream function of $\boldsymbol{u}$, $\psi$, which is given by the Dirichlet's problem:

$$-\Delta\psi = \omega, \quad \psi = 0 \text{ on } \partial\Omega$$

so that $\boldsymbol{u} = \operatorname{curl} \psi$.

The system [9] becomes:

$$\nabla\psi \wedge \nabla\omega = 0, \quad -\Delta\psi = \omega, \quad \psi = 0 \text{ on } \partial\Omega$$

Let us focus on solutions which are characterized by a relationship $\omega = f(\psi)$, where $f$ is a smooth function. Such solutions are given by the resolution of the following nonlinear elliptic problem:

$$-\Delta\psi = f(\psi), \quad \psi = 0 \text{ on } \partial\Omega \qquad [10]$$

This problem has always at least a solution, for example, if $f$ is a bounded function of $\psi$.

Let $\psi^*$ be a solution of [10], and $\omega^* = f(\psi^*)$ the corresponding vorticity function. We shall say that the stationary solution $\omega^*$ is stable in the $L^2$-norm if:

For all $\varepsilon > 0$, there is a $\delta > 0$, such that for all initial datum $\omega_0$ in $L^\infty(\Omega)$ satisfying

$$\int_\Omega (\omega^* - \omega_0)^2 \mathrm{d}\boldsymbol{x} \le \delta, \text{ we have :}$$
$$\int_\Omega (\omega^* - \omega(t))^2 \,\mathrm{d}\boldsymbol{x} \le \varepsilon, \text{for all } t$$

where $\omega(t)$ denotes the solution of the Cauchy problem associated with the initial datum $\omega_0$ by Youdovitch's theorem.

Now we can state the following result.

**Theorem** (Arnol'd) *Let $\omega$ be a stationary solution given by [10]. We assume that one of the following assumptions holds*:

(C1) *There are positive constants $c_1, c_2$, such that*

$$c_1 \le f' \le c_2$$

(C2) *There are positive constants $c_1, c_2$, with $c_2 < \lambda_1$ (first eigenvalue of the Dirichlet problem on the domain $\Omega$) such that*:

$$c_1 \le -f' \le c_2$$

*Then $\omega$ is stable in the $L_2$-norm.*

**Remarks**

(i) This result was the first nonlinear stability result for stationary flows.
(ii) The proof makes use of the conservation of the functionals of the vorticity field.

Another significant contribution of Arnol'd to hydrodynamics was to reveal the geometrical aspect of the instability of the perfect-fluid motion. We give a brief insight into this issue.

Let us come back to the Lagrangian description of motion. We want to determine the function $\varphi(t, \boldsymbol{x})$. Each mapping $\varphi_t(\boldsymbol{x}) = \varphi(t, \boldsymbol{x})$ is, for $t$ fixed, a diffeomorphism of $\bar{\Omega}$ preserving the Lebesgue measure and the orientation (equivalently stated, it is an element of $\mathrm{SDiff}(\bar{\Omega})$).

In other words, a fluid motion is a curve $t \to \varphi_t$ drawn on the "manifold" $M = \mathrm{SDiff}(\bar{\Omega})$ (the configuration space of the system).

At time $t$, the relationship

$$\frac{\partial\varphi}{\partial t}(t, \boldsymbol{x}) = \boldsymbol{u}(t, \varphi(t, \boldsymbol{x}))$$

states that the velocity field $\boldsymbol{u}(t, \varphi_t(\boldsymbol{x}))$ belongs to the space tangent to $M$ at $\varphi_t$. The tangent space at $\varphi$ to $M$ is the space of vector fields $\boldsymbol{v}(\varphi(\boldsymbol{x}))$, where $\boldsymbol{v}(\boldsymbol{x})$ is an incompressible vector field on $\bar{\Omega}$ satisfying $\boldsymbol{v}\cdot\boldsymbol{n} = 0$ on $\partial\Omega$. This space is naturally endowed with a norm given by the kinetic energy

$$\frac{1}{2}\int_\Omega \boldsymbol{v}(\boldsymbol{x})^2 \mathrm{d}\boldsymbol{x}$$

and thus $M$ is endowed with a Riemannian structure.

It is easy to check that the perfect-fluid motions correspond to the curves $\varphi_t$ drawn on $M$ which are the critical points of the action integral:

$$\frac{1}{2}\int_{t_1}^{t_2} \mathrm{d}t \int_\Omega \left|\frac{\partial\varphi}{\partial t}(t, \boldsymbol{x})\right|^2 \mathrm{d}\boldsymbol{x}, \quad \text{for all } t_1 < t_2$$
$$\text{(with the constraints } \varphi(t_1, .) = \varphi_1, \varphi(t_2, .) = \varphi_2)$$

That is to say, the perfect-fluid motions are the geodesics of the Riemannian manifold $M$.

The main interest of this geometric framework is to bring back, at least formally, the perfect-fluid motions to well-known objects. Indeed, we know that the Riemannian curvature of a manifold has a profound impact on the behavior of geodesics on it. If the Riemannian curvature is positive, then nearby geodesics oscillate about one another, and if the curvature is negative, geodesics rapidly diverge from one another. More precisely, the stability of geodesics is expressed in terms of the curvature by means of Jacobi's equation [1]. If $\varphi_t$ is a geodesic curve starting from $\varphi_0$, with velocity field $\boldsymbol{v}(t)$ (whose norm is supposed equal to 1), if the sectional curvature of the manifold in all the 2-planes containing $\boldsymbol{v}(t)$ is less than $-c(<0)$, a perturbation of the initial datum will increase at least as $\exp(ct)$:

$$d(\varphi_t, \tilde{\varphi}_t) \ge d(\varphi_0, \tilde{\varphi}_0)\exp(ct)$$

where $\tilde{\varphi}_0$ denotes the perturbed initial datum and $d$ the geodesic distance on the manifold. Moreover, if the curvature at every point and for all the sections is less than $-c$, and if $M$ is compact, then the geodesic flow, that is, the one-parameter group of transformations $(\varphi_0, \boldsymbol{v}(0)) \to (\varphi_t, \boldsymbol{v}(t))$, is mixing (in the usual meaning of ergodic theory). Arnol'd succeeded in calculating the sectional curvature for flows on the two-dimensional torus; he showed that the

curvature is negative for "most" of the sections. This gives an enlightening geometrical picture of the instability of Lagrangian flows.

It was tempting to connect the above considerations on the instability of two-dimensional flows with the problem of weather forecast. In 1963 EN Lorenz stated that a two-week forecast would be a theoretical bound for predicting the atmospheric motion. Lorenz's assertion was based on numerical simulations. He took as model for the large-scale atmospheric motion the two-dimensional Euler equations on the torus, which he truncated to a small number of Fourier modes (about 20). This model is highly unstable and displays exponential sensitivity with respect to the initial datum. However, the parallel between the behavior of this system and the instability of the Lagrangian flow is misleading. On the one hand, if we again do the Lorenz computations on Euler equations, taking into account a large number of Fourier modes, we note a striking phenomenon: the flow has a tendency to self-organize into large vortices, called coherent structures, and simultaneously the exponential sensitivity, as measured in terms of the energy norm of the velocity field, disappears. On the other hand, the problem of predicting the Lagrangian flow is very different, the Lagrangian flow can be exponentially unstable, while the corresponding velocity field quietly converges, in the energy norm, towards some equilibrium. We must keep in mind that the meteorologist aims to predict the values of the velocity field at some future time and not the trajectories of the fluid particles. In fact, it appears that Lorenz has ignored phenomena of a statistical nature which occur when a large number of degrees of freedom are considered; thus, his theoretical bound for the prediction of the atmospheric motion has no definite basis. More detailed reflections on this issue can be found in Robert and Rosier (2001).

## The Cauchy Problem for the Euler Equations for Compressible Inviscid Fluids

As remarked in the introduction, compressible flows yield pressure waves. The equations of motion being nonlinear, these waves interact in an intricate manner giving rise to shocks. This is the main feature of compressible fluid flows. Compressible flows are situated in the more general domain of nonlinear hyperbolic systems, which were intensively studied during the last decades. We only give here an example of the kind of result which can be obtained.

The following theorem, which states that for a set of regular initial data, shocks do not occur till some finite time, is a consequence of a more general result on hyperbolic systems due to Majda (1984).

We consider $\Omega = \Re^3$ and the system [1], [2], [4].

**Theorem** *Assume* $p_0, \boldsymbol{u}_0 \in H^S \cap L^\infty(\Re^3)$, *with* $s > 5/2$ *and* $p_0(\boldsymbol{x}) > 0$. *Then there is a finite time* $T > 0$, *depending on the* $H^s$ *and* $L^\infty$ *norms of the initial data, such that the Cauchy problem for* [1], [2], [4] *has a unique bounded smooth solution* $p$, $\boldsymbol{u} \in C^1([0, T] \times \Re^3)$, *with* $p(t, \boldsymbol{x}) > 0$ *for all* $t, \boldsymbol{x}$.

## Inviscid Flows and Turbulence

Loosely speaking, turbulence is the intricate motion of a slightly viscous flow. Going back to the first half of the last century, there are two main approaches to turbulence. The first is due to Leray. The dissipation of energy is a characteristic feature of three-dimensional turbulence, and Leray thought that, even if very small, the viscosity of the fluid plays an important role, so that to understand turbulence the first step is to study the Navier–Stokes equations. A radically different approach is due to Onsager. Onsager (1949) started with the fundamental remark that the 4/5 law of turbulence, which relates the dissipation of energy to the increments of the velocity field, does not involve viscosity. Furthermore, he observed that the proof of the conservation of energy for the solutions of Euler equations uses an integration by parts which supposes some regularity of the velocity field. He then imagined that an inviscid dissipation mechanism, due to a lack of regularity of the solutions, was at work in Euler equations. In modern terminology, he suggested to model turbulent flows by nonregular (weak) solutions satisfying the Euler equations in the sense of distributions. He also conjectured that if a solution satisfies a Hölder regularity condition of order $>1/3$, then the energy would be conserved.

Onsager's views were revolutionary and forgotten for a long time. Recent works, such as the proof of Onsager's conjecture, the construction of weak solutions with energy dissipation, and the discovery of the explicit local form of the energy dissipation for weak solutions, show a renewed interest in these views (see, e.g., Constantin and Titi (1994), Eyink (1994), Robert (2003), and Shnirelman (2003)).

# Isochronous Systems

**Francesco Calogero**, University of Rome, Rome, Italy and Institute, Nazionale de Fisica Nucleare, Rome, Italy

## Introduction

This paper reviews recent developments, following closely (sometimes *verbatim*) the review paper Calogero F (2004c) (see the Bibliography below); for more traditional investigations of *isochronous* systems see other entries of this Encyclopedia (and for the mathematical investigation of isochronous centers in the plane, related to the 16th Hilbert problem, see for instance the survey paper referred to at the end of this entry).

The *isochronous* systems treated herein are characterized by the property to possess an *open* domain having full dimensionality in their phase space such that *all* the motions evolving from a set of initial data in it are *completely periodic* with the same fixed period. The natural measure of this *open* domain might, or it might not, be *infinite* when the measure of the entire phase space is itself *infinite*: for instance, if the entire phase space is the two-dimensional Euclidian plane, such a domain might be the exterior, or the interior, of a circle of finite radius.

It is justified to call such systems *superintegrable*, or perhaps *partially superintegrable* inasmuch as the property of *isochronicity* of all their motions holds only in a subregion of the entire phase space. This terminology is justified by the observation that, roughly speaking, all confined motions of a *superintegrable* system – in which all but one of the degrees of freedom are constrained by the existence of the *maximal* possible number of constants of motion – are *completely periodic*, although not necessarily all with a fixed period – entailing that *isochronicity* entails *superintegrability*, while the converse is not the case (see the entry *Integrable systems* in this Encyclopedia).

A simple trick – amounting essentially to a change of independent, and possible as well of dependent, variables, allows to deform a largely arbitrary dynamical system so that the deformed system obtained from it be *isochronous*. This "trick", which is now explained, entails therefore that *isochronous systems are not rare*. Below we provide several examples; others can be found in the further reading suggested at the end of this entry, and/or can be manufactured *ad libitum* using the trick.

## The Trick

We now show that, given a largely arbitrary dynamical system, it is possible to introduce a deformed version of it featuring a *real* constant $\omega$, that has the following properties: for $\omega = 0$, it coincides with the original, undeformed system; for $\omega > 0$, it possesses an *open* region having full dimensionality in its phase space such that *all* solutions evolving from an initial datum in it are *completely periodic* with a period $\tilde{T}$ which is a finite integer multiple, or perhaps a simple fraction, of the basic period

$$T = \frac{2\pi}{\omega} \qquad [1]$$

Let us indeed, consider a quite general dynamical system which we write as follows:

$$\zeta' = F(\zeta; \tau) \qquad [2]$$

Here $\zeta \equiv \zeta(\tau)$ is the dependent variable, which might be a scalar, a vector, a tensor, a matrix, you name it. The independent variable is $\tau$, and the main limitation on the dynamical system [2] is that it be permissible to treat this variable as *complex*; this requires that the derivative with respect to this *complex* variable $\tau$ that appears in the left-hand side of the evolution equation [2] make sense, namely that this dynamical system be *analytic*, entailing that the dependent variable $\zeta$ be an *analytic* function of the complex variable $\tau$ (but this does not require $\zeta(\tau)$ to be a holomorphic nor a meromorphic function of $\tau; \zeta(\tau)$ might feature all sorts of singularities, including branch points, in the complex $\tau$-plane, indeed this will generally happen since we generally assume the evolution equation (??) to be *nonlinear*). The quantity $F$ in the right-hand side of [2] – which has of course the same scalar, vector, matrix... character as $\zeta$ – might depend (arbitrarily but analytically) on $\zeta$ as well as on $\tau$. (Let us also emphasize that this approach is as well applicable to more general dynamical systems that also feature other, "spacelike", independent variables, for instance are a system of PDEs rather than ODEs; the interested reader is referred to the literature cited below).

In spite of the generality of this dynamical system, [2], there generally holds a result ("Theorem of existence, uniqueness and analyticity") that characterizes the solution $\zeta(\tau)$ of its initial-value problem determined by the assignment

$$\zeta(0) = \zeta_0$$

Here, for notational simplicity, we assign the initial datum $\zeta_0$ at $\tau = 0$; and we assume of course that the right-hand side of [2] is not singular for $\tau = 0$ and $\zeta = \zeta_0$. The relevant result guarantees, not only for the initial datum $\zeta_0$, but for a (sufficiently small but open) set of initial data in its neighborhood, the existence of a circular disk in the complex $\tau$-plane, centered at $\tau = 0$ (where the initial data are assigned) and having a *nonvanishing* radius $\rho$, such that the solutions $\zeta(\tau)$ corresponding to these initial data are *holomorphic* in it, namely for $|\tau| < \rho$ (and note that if $\zeta(\tau)$ is a multicomponent object, the property to be *holomorphic* is featured by each and everyone of its components).

Let us now introduce the following changes of dependent and independent variables:

$$z(t) = \exp(i\lambda\omega t)\zeta(\tau) \qquad [3a]$$

$$\tau \equiv \tau(t) = \frac{\exp(i\omega t) - 1}{i\omega} \qquad [3b]$$

This transformation is called "the trick". The essential part of it is the change of *independent* variable [3b]: and let us re-emphasize that, here and hereafter, the new *independent* variable $t$ is considered as the *real*, "physical time" variable. Note that [3b] entails

$$\tau(0) = 0, \ \dot{\tau}(0) = 1$$

and, most importantly, that $\tau(t)$ is a periodic function of $t$ with period $T$, see [1]. More specifically, as the time $t$ increases from zero onwards, the complex variable $\tau$ travels counterclockwise round and round on the circle $C$ the diameter of which, of length $2/\omega$, lies on the imaginary axis in the complex $\tau$-plane, with one extreme at the origin, $\tau = 0$, and the other at the point $\tau = 2i/\omega$, making a full circle in the time interval $T$. As for the prefactor $\exp(i\lambda\omega t)$ that multiplies $\zeta(\tau)$ in the right-hand side of [3a], its purpose is to allow, via an appropriate choice of the parameter $\lambda$, the deformed system, see below, to have a neater look; however this choice is hereafter restricted by the condition that $\lambda$ be *real* and *rational*, say

$$\lambda = \frac{p}{q}$$

with $p$ and $q$ two coprime integers and $q > 0$. This restriction is essential to guarantee, via [3], that if $\zeta(\tau)$ is *holomorphic* in $\tau$ in the (closed) disk encircled by the circle $C$, then $z(t)$ is *completely periodic* (namely, each and everyone of its components is *periodic*) with the period

$$\tilde{T} = qT \qquad [4]$$

The deformed dynamical system is the one that obtains from [2] via the trick [3]. It clearly reads as follows:

$$\dot{z} = i\lambda\omega z + \exp[i(\lambda+1)\omega t] \times F\left(\exp(-i\lambda\omega t)z; \frac{\exp(i\omega t)-1}{i\omega}\right) \quad [5]$$

And it is plain, on the basis of the arguments we just gave, that this system is *isochronous*, a sufficient condition for the *complete periodicity* with period $\tilde{T}$, see [4], of its solutions being provided by the inequality

$$\frac{2}{\omega} < \rho$$

which can clearly be satisfied by initial data situated inside an *open* domain of such data, at least provided $\omega$ is sufficiently large (actually, in all the examples reported below no restriction on the value of $\omega$ is required, namely such an open domain exists for any arbitrary value of $\omega > 0$).

## Examples

In this subsection we report tersely several examples of *isochronous* dynamical systems; in each case we also provide the reference where more information can be found. Except when explicitly otherwise mentioned, these dynamical systems are to be considered in the *complex* context.

The first example we report is a Hamiltonian $N$-body problem which is a generalization of a well-known *integrable* (indeed, *superintegrable*) system (*see* Integrable Systems: Overview). It is characterized by the (normal) Hamiltonian

$$H(\underline{z},\underline{p}) = \frac{1}{2}\sum_{n=1}^{N}\left(p_n^2+\omega^2 z_n^2\right) + \frac{1}{4}\sum_{m,n=1;m\neq n}^{N}\sum_{k=1}^{K}\frac{f_{nm}^{(k)}}{k(z_n-z_m)^{2k}} \quad [6a]$$

and correspondingly by the Newtonian equations of motion

$$\ddot{z}_n + \omega^2 z_n = \sum_{m=1,m\neq n}^{N}\sum_{k=1}^{K}\frac{f_{nm}^{(k)}}{(z_n-z_m)^{1+2k}} \quad [6b]$$

Here the $\frac{1}{2}N(N-1)K$ "coupling constants" $f_{nm}^{(k)}$ are arbitrary, except for the symmetry restriction $f_{nm}^{(k)} = f_{mn}^{(k)}$ (see [6a]).

The next example we report is a *real* $N$-body problem in the horizontal plane, characterized by the Newtonian equations of motions

$$\ddot{\vec{r}}_n = \omega\hat{k}\wedge\dot{\vec{r}}_n + 2\sum_{m=1,m\neq n}^{N}\left(\alpha_{nm}+\beta_{nm}\hat{k}\wedge\right) \times \frac{\left[\dot{\vec{r}}_n\left(\dot{\vec{r}}_m\cdot\vec{r}_{nm}\right)+\dot{\vec{r}}_m\left(\dot{\vec{r}}_n\cdot\vec{r}_{nm}\right)-\vec{r}_{nm}\left(\dot{\vec{r}}_n\cdot\dot{\vec{r}}_m\right)\right]}{r_{nm}^2} \quad [7]$$

Here $\vec{r}_n \equiv (x_n, y_n, 0)$ is a *real* two-vector in the horizontal plane, $\hat{k} \equiv (0,0,1)$ is the unit vector orthogonal to the horizontal plane, the symbol $\wedge$ denotes the (three-dimensional) vector product so that $\hat{k}\wedge\vec{r}_n = (-y_n, x_n, 0)$, and we use the short-hand notation $\vec{r}_{nm} = \vec{r}_n - \vec{r}_m$ entailing $r_{nm}^2 = r_n^2 + r_m^2 - 2\vec{r}_n\cdot\vec{r}_m$. Note that these equations are *translation-* and *rotation-invariant*; and they are *Hamiltonian*, although the corresponding Hamiltonian function is *not* of normal type (kinetic plus potential energy).

The $N(N-1)$ "coupling constants" $\alpha_{nm}$ and $\beta_{nm}$ are of course real, but they are otherwise *arbitrary* except for the symmetry restrictions $\alpha_{nm} = \alpha_{mn}$, $\beta_{nm} = \beta_{mn}$ which are required in order that this system be *Hamiltonian*. If *all* these coupling constants *vanish*, this dynamical system has a clear physical interpretation: it describes the motion of $N$ equal, electrically charged, point particles, moving in the horizontal plane under the effect of a magnetic field orthogonal to that plane (in the approximation in which the electrostatic interparticle interaction is neglected). In that case each particle moves on a circle, the center and radius of which depend on the initial data, while the time taken to go round it is, in all cases, $T$, see [1]. If the $\frac{1}{2}N(N-1)$ coupling constants $\beta_{nm}$ vanish, $\beta_{nm} = 0$, and the $\frac{1}{2}N(N-1)$ coupling constants $\alpha_{nm}$ all equal unity, $\alpha_{nm} = 1$, the system is a well-known *integrable* (indeed *solvable*) system; and this is as well the case if the $\frac{1}{2}N(N-1)$ coupling constants $\beta_{nm}$ vanish, $\beta_{nm} = 0$, and the $\frac{1}{2}N(N-1)$ coupling constants $\alpha_{nm}$ equal minus one half, and only act among "nearest neighbors", $\alpha_{nm} = -\frac{1}{2}(\delta_{m,n+1}+\delta_{m,n-1})$ (see the entry *Integrable systems* in this Encyclopedia).

Because of its many interesting features as well as the neatness of its equations of motion (especially in their complex version, see below) the honorary title of "goldfish" has been attributed to this model, characterized by the Newtonian equations of motion in the plane [7]. A more detailed discussion of it – in particular of its behavior for initial data *outside* of the region yielding *isochronous* motions – is made in the next section.

Several interesting classes of *isochronous* dynamical systems are reported in Calogero F. (2004b).

We only mention here a remarkably general example, characterized by the Newtonian equations of motion

$$\ddot{\underline{z}} + i\omega\dot{\underline{z}} = \sum_{k=1}^{K} \underline{f}^{(-k)}(\underline{z}, \dot{\underline{z}} + i\omega\underline{z})$$

where $\underline{z} \equiv (z_1, \ldots, z_N)$ is the $N$-vector whose *complex* components $z_n \equiv z_n(t)$ are the dependent variables, while the "forces" $\underline{f}^{(-k)}(\underline{z}, \tilde{\underline{z}})$ are required to be *analytic* in all their arguments and to satisfy the scaling properties

$$\underline{f}^{(-k)}(\alpha\underline{z}, \tilde{\underline{z}}) = \alpha^{-k}\underline{f}^{(-k)}(\underline{z}, \tilde{\underline{z}})$$

which however entail no restriction on the velocity-dependence of these forces, namely on the dependence of $\underline{f}^{(-k)}(\underline{z}, \tilde{\underline{z}})$ on the (components of the) second, $\tilde{\underline{z}}$, of its two $N$-vector arguments.

The next example we report is characterized by the Newtonian equations of motion

$$\ddot{\vec{r}}_n + i\omega\dot{\vec{r}}_n + 2\omega^2\vec{r}_n = \sum_{m=1, m\neq n}^{N} \frac{M_m \vec{r}_{mn}}{r_{mn}^3}$$

where we assume the $N$ dependent variables $\vec{r}_n \equiv \vec{r}_n(t)$ to be three-vectors (although the property of *isochronicity* of this deformed system would hold no less if these were $S$-vectors, with $S$ an arbitrary positive integer) and we use the short-hand notation $\vec{r}_{mn} = \vec{r}_m - \vec{r}_n$. This system is (perhaps) remarkable inasmuch as it represents a (*complex*) deformation of the classical $N$-body gravitational problem, to which it clearly reduces for $\omega = 0$.

The next example we report is characterized by the following (first-order) equations of motion of oscillator type:

$$\dot{x}_n - ip_n\omega x_n = f_n(\underline{x}, \underline{y}), \;\; n = 1, \ldots, N$$
$$\dot{y}_m + iq_m\omega y_m = g_m(\underline{x}, \underline{y}), \;\; m = 1, \ldots, M \qquad [8]$$

Here the $N$-vector $\underline{x}$, respectively the $M$-vector $\underline{y}$, have as components the $N + M$ *complex* dependent variables $x_n \equiv x_n(t), y_m \equiv y_m(t)$; the $N + M$ parameters $p_n, q_m$ are all *nonnegative integers* (or they could be *nonnegative rational* numbers); and the $N + M$ *complex* functions $f_n, g_m$ are restricted by the following conditions (which are sufficient to guarantee the *isochronicity* of this dynamical system):

(1) $f_n(\underline{x}, \underline{y})$ and $g_m(\underline{x}, \underline{y})$ are *holomorphic* at $\underline{x} = 0, \underline{y} = 0$;
(2) $\lim_{\varepsilon\to 0}[\varepsilon^{-1}\underline{f}(\varepsilon\underline{x}, \varepsilon\underline{y})] = \underline{0}$, $\lim_{\varepsilon\to 0}[\varepsilon^{-1}\underline{g}(\varepsilon\underline{x}, \varepsilon\underline{y})] = \underline{0}$;
(3) $\underline{f}(\underline{x}, \underline{y})$ and $\underline{g}(\underline{x}, \underline{y})$ are *polynomial* in the $y_m$;
(4a) $\lim_{\varepsilon\to 0}[\varepsilon^{-1-p_n} f_n(\varepsilon^{\underline{p}}\underline{x}, \varepsilon^{-\underline{q}}\underline{y})] = \text{nondivergent}, n = 1, \ldots, N$;
(4b) $\lim_{\varepsilon\to 0}[\varepsilon^{-1+q_m} g_m(\varepsilon^{\underline{p}}\underline{x}, \varepsilon^{-\underline{q}}\underline{y})] = \text{nondivergent}, m = 1, \ldots, M$.

In the conditions (4a) and (4b) the notation $\varepsilon^{\underline{p}}\underline{x}$ indicates of course the $N$-vector of components $\varepsilon^{p_n}x_n$, and likewise $\varepsilon^{-\underline{q}}\underline{y}$ is the $M$-vector of components $\varepsilon^{-q_m}y_m$.

Note that this dynamical system, [8], includes the *Hamiltonian* case characterized by the restrictions

$$N = M, p_n = q_n, f_n(\underline{x}, \underline{y}) = \frac{\partial V(\underline{x}, \underline{y})}{\partial y_n}, g_n(\underline{x}, \underline{y}) = -\frac{\partial V(\underline{x}, \underline{y})}{\partial x_n}$$

which imply that the equations of motion [8] are just the Hamiltonian equations entailed by the Hamiltonian function

$$H(\underline{x}, \underline{y}) = i\omega \sum_{n=1}^{N} p_n x_n y_n + V(\underline{x}, \underline{y})$$

*isochronicity* being now guaranteed by the following conditions on the function $V(\underline{x}, \underline{y})$:

(1) $V(\underline{x}, \underline{y})$ is *holomorphic* at $\underline{x} = 0, \underline{y} = 0$;
(2) $\lim_{\varepsilon\to 0}[\varepsilon^{-2} V(\varepsilon\underline{x}, \varepsilon\underline{y})] = \underline{0}$;
(3) $V(\underline{x}, \underline{y})$ is *polynomial* in the $y_n$;
(4) $\lim_{\varepsilon\to 0}[\varepsilon^{-1} V(\varepsilon^{\underline{p}}\underline{x}, \varepsilon^{-\underline{p}}\underline{y})] = \text{nondivergent}$.

The last two examples we report can be characterized as assemblies of *non-linear harmonic oscillators*, inasmuch as these two dynamical systems (which are actually special cases of more general systems) have the remarkable property that their *generic* solutions (namely, *all* their solutions, except for a lower-dimensional set of *singular* solutions in which one or more of the "moving particles" shoot off to infinity at a finite time) are *completely periodic* with the fixed period $T$, see [1]. Their Newtonian equations of motion read

$$\ddot{\vec{z}}_{nm} - 3i\omega\dot{\vec{z}}_{nm} - 2\omega^2\vec{z}_{nm} = c\sum_{\nu=1}^{N}\sum_{\mu=1}^{M} \vec{z}_{n\mu}(\vec{z}_{\nu\mu}\cdot\vec{z}_{\nu m})$$

$$\ddot{\vec{z}}_{nm} - 3i\omega\dot{\vec{z}}_{nm} - 2\omega^2\vec{z}_{nm} = c\sum_{\nu=1}^{N}\sum_{\mu=1}^{M} \vec{z}_{\nu\mu}(\vec{z}_{\nu\mu}\cdot\vec{z}_{nm})$$

These are two (different) systems of $NM$ Newtonian equations of motion satisfied by the $NM$ *complex* $S$-vectors $\vec{z}_{nm}$ (with $S$ an *arbitrary* positive integer); hence here the index $n$ runs from 1 to $N$, and the index $m$ runs from 1 to $M$, with $N$ and $M$ two *arbitrary* positive integers, while $c$ is of course an *arbitrary* complex constant (which might actually be rescaled away). The dot sandwiched between two

$S$-vectors denotes the standard (Euclidian) scalar product, entailing the rotation-invariant character, in $S$-dimensional space, of these equations of motion. Since these systems only feature *linear* and *cubic* forces, these models are remarkably close to physics; and they become even more applicable if they are written in their *real* versions, that obtain in an obvious manner by setting

$$\vec{z}_{nm} = \vec{x}_{nm} + i\vec{y}_{nm}, c = a + ib$$

In contrast to what we did for the previous examples, let us outline here the derivation of these results. Actually the two systems of Newtonian equations written above are merely special subcases, corresponding to appropriate parametrizations of a square matrix $M$ (of appropriate rank) in terms of $S$-vectors, of the following nonlinear *matrix* evolution equation:

$$\ddot{M} - 3i\omega\dot{M} - 2\omega^2 M = cM^3 \qquad [9]$$

Hence the findings reported above are merely special cases of the more general result according to which the *generic* solution of this nonlinear *matrix* evolution equation – with $M \equiv M(t)$ a square matrix of *arbitrary* rank – is *periodic* with period $T$, see [1]:

$$M(t + T) = M(t)$$

And this result is an immediate consequence, via the following *matrix* version of the trick

$$M(t) = \exp(i\omega t)\Psi(\tau), \tau = \frac{\exp(i\omega t) - 1}{i\omega} \qquad [10]$$

of a previous result due to V. I. Inozemtsev, according to which the matrix evolution equation

$$\Psi'' = c\Psi^3$$

which clearly corresponds to [9] via [10], is *integrable* and *all* its solutions $\Psi(\tau)$ are *meromorphic* functions of the independent variable $\tau$.

## The Transition to Deterministic Chaos

In this section we illustrate, using the *real* $N$-body problem in the plane characterized by the Newtonian equations of motion [7], the behavior of an *isochronous* system of the kind described above when the initial data fall *outside* of the region yielding *isochronous* motions.

To do this it is convenient to use the *complex* version of the equations of motion [7], that obtain from [7] by setting

$$z_n = x_n + iy_n, \vec{r}_n = (x_n, y_n, 0),$$
$$\hat{k} = (0, 0, 1), a_{nm} = \alpha_{nm} + i\beta_{nm} \qquad [11]$$

and read as follows:

$$\ddot{z}_n = i\omega\dot{z}_n + 2\sum_{m=1, m\neq n}^{N} \frac{a_{nm}\dot{z}_n\dot{z}_m}{z_n - z_m} \qquad [12]$$

The main tool of our analysis is the (particularly simple) version of the trick appropriate to this model,

$$z_n(t) = \zeta_n(\tau), \tau = \frac{\exp(i\omega t) - 1}{i\omega} \qquad [13a]$$

entailing

$$z_n(0 = \zeta_n(0), \dot{z}_n(0) = \zeta'_n(0) \qquad [13b]$$

that relates our equations of motion [12] to the equations of motion

$$\zeta''_n = 2\sum_{m=1, m\neq n}^{N} \frac{a_{nm}\zeta'_n\zeta'_m}{\zeta_n - \zeta_m} \qquad [14]$$

These equations of motion, together with the initial data $\zeta_n(0), \zeta'_n(0)$ (see [13b]) define the solutions $\zeta_n \equiv \zeta_n(\tau)$ in the *complex* $\tau$-plane. The "physical" evolution of the points $z_n \equiv z_n(t)$ as functions of the *real* time variable $t$ is then given by the evolution of the corresponding coordinates $\zeta_n(\tau)$, see [13a], as the *complex* variable $\tau$ travels round and round on the circle $C$ in the *complex* $\tau$-plane, the diameter of which of length $2/\omega$, has one extreme at the origin $\tau = 0$ and the other on the positive imaginary axis at $\tau = 2i/\omega$. It is therefore clear that the behavior of $z_n(t)$ as a function of the *real*, "physical time" variable $t$ depends on the analytic structure of $\zeta_n(\tau)$ as function of the *complex* variable $\tau$, in particular of the singularities, if any, of this function $\zeta_n(\tau)$ that fall in the disk $D$ encircled by the circle $C$ in the *complex* $\tau$-plane.

Let us tersely review the relevant analysis. We recall first of all that (it can be proven that) there exists in phase space an *open* region of initial data $z_n(0), \dot{z}_n(0)$, characterized by *large* values of the moduli $|z_n(0) - z_m(0)|$ of the initial interparticle distances and by *small* values of the moduli of the initial particle velocities $|\dot{z}_n(0)|$ (see [14] and [13b]), that guarantees (all components $\zeta_n(\tau)$ of) the corresponding solution $\underline{\zeta}(\tau)$ of [14] to be *holomorphic* in (a disk of radius $\rho$ centered at the origin $\tau = 0$ of the *complex* $\tau$-plane that includes) the circle $C$, hence the corresponding solution $\underline{z}(t)$ to be *completely periodic* with period $T$, see [13a] and [1]. This result guarantees the *isochronous* character of this model, [12], for any arbitrarily given assignment of the coupling constants $a_{nm}$.

Next, let us restrict, for simplicity, our consideration to models [12] in which the coupling constants $a_{nm}$ are *real* and *nonnegative*,

$$a_{nm} \geq 0 \qquad [15]$$

Then the singularities of the generic solution $\underline{\zeta}(\tau)$ of [14] – which occur at values $\tau_b$ of $\tau$ where *two* coordinates $\zeta_n(\tau)$ coincide, say $\zeta_\mu(\tau_b) = \zeta_\nu(\tau_b) = b$ (see the right-hand side of [14]) – are *branch points* characterized by the exponent, say,

$$\gamma = \gamma_{\mu\nu} = \frac{1}{1 + a_{\mu\nu}} \qquad [16]$$

so that in their neighborhood, namely for $\tau \approx \tau_b$,

$$\zeta_s(\tau) = b \pm c(\tau - \tau_b)^\gamma + v(\tau - \tau_b) + \sum_{k=1}^{\infty} \sum_{\ell, m=0 \, \ell+m \geq 1}^{\infty} \varphi_{k\ell m}^{(s)} (\tau - \tau_b)^{k + \ell\gamma + m(1-\gamma)}, \quad s = \mu, \nu \qquad [17a]$$

$$\zeta_n(\tau) = b_n + v_n(\tau - \tau_b) + \sum_{k=1}^{\infty} \sum_{\ell=\delta_{k1}}^{\infty} \sum_{m=0}^{\infty} \varphi_{k\ell m}^{(n)} (\tau - \tau_b)^{k + \ell\gamma + m(1-\gamma)}, \quad n \neq \mu, \nu \qquad [17b]$$

The $\pm$ sign in front of $c$ in the right- hand side of the first, [17a], of these formulas indicates that one sign must be chosen for $s = \mu$, the opposite for $s = \nu$. Note that here the $4 + 2(N-2) = 2N$ constants $\tau_b, b, c, v, b_n, v_n$ are *a priori* arbitrary – except for the obvious restrictions $b_n \neq b, b_n \neq b_m$ – while the coefficients $\varphi_{k\ell m}^{(s)}, \varphi_{k\ell m}^{(n)}$ can be computed from these constants, recursively, by inserting this *ansatz*, [17], in the equations of motion [14]. The fact that the number, $2N$, of *a priori* undetermined coupling constants equals the number of arbitrary initial data for this system of ODEs, [14], indicates that this kind of branch points, characterized by the exponents $\gamma_{nm}$, see [16], is the typical singularity featured by the generic solution $\underline{\zeta}(\tau)$ of [14]. (Branch points with different exponents may appear, but only in *nongeneric* solutions $\underline{\zeta}(\tau)$ which, at some value $\tau_b$ of $\tau$, feature the coincidence of more than two components, say $\zeta_\mu(\tau_b) = \zeta_\nu(\tau_b) = \zeta_\lambda(\tau_b)$).

We conclude therefore that the *generic* solution $\underline{\zeta}(\tau)$ of [14] features a, generally infinite, number of branch points, that generally affect each of its components $\zeta_n(\tau)$, and which are characterized, for the class of models to which we are restricting attention here, see [15]) by (*real*) exponents $\gamma_{nm}$, see [16], which are then clearly characterized by the inequalities

$$0 < \gamma_{nm} \leq 1$$

What does this tell us about the *generic* solution $\underline{z}(t)$ of the equations of motions of primary interest to us, [12], in particular about its evolution as function of the *real* "time" variable $t$?

To the solution $\underline{\zeta}(\tau)$ is associated a Riemann surface the structure of which is determined by the character and distribution of the branch points of $\underline{\zeta}(\tau)$ in the complex $\tau$-plane (each of which is generally featured by each component $\zeta_n(\tau)$ of $\underline{\zeta}(\tau)$, although generally not in the same way: see [17]), and we know from [13a] that the values taken by $\underline{z}(t)$ as $t$ evolves from $t = 0$ towards $t = \infty$ coincide with the values taken by $\underline{\zeta}(\tau)$ as the independent variable $\tau$ travels, on that Riemann surface associated with $\underline{\zeta}(\tau)$, counterclockwise round and round on the circle $C$ defined above (the diameter of which lies on the imaginary axis in the complex $\tau$-plane, with one end at $\tau = 0$ and the other at $\tau = 2i/\omega$), employing a period $T$, see [1], to make each full round. Hence the behavior of the solution $\underline{z}(t)$ of [12] depends on the structure of the Riemann surface associated with the corresponding solution $\underline{\zeta}(\tau)$ of [14], and specifically on the number of different sheets of that surface that are visited as one travels on it before returning, if ever, to the main sheet from which the travel started at $t = \tau = 0$.

If no other sheet is visited besides the main one, the corresponding solution $\underline{z}(t)$ is of course periodic with period $T$, see [1] and [13a],

$$\underline{z}(t + T) = \underline{z}(t) \qquad [18]$$

This happens provided no branch point is featured by $\underline{\zeta}(\tau)$ on its main sheet *inside* the circle $C$; and, as already indicated above, it has been proven (even in the more general case with arbitrary coupling constants $a_{nm}$) that there is an *open* region having full dimensionality in the phase space of initial data, see [13b], that yields such an outcome, implying the *isochronicity* of the model characterized by the Newtonian equations of motion [12]. This region $R$ of initial data has a boundary – a lower-dimensional domain in the phase space of initial data – out of which emerge motions leading, at a time $t_b$ smaller than $T$, to a "particle collision", say $z_\nu(t_b) = z_\mu(t_b)$.

The character of the solution $\underline{z}(t)$ yielded by initial data *outside* of the region $R$ depends on the structure of the Riemann surface associated with the corresponding solution $\underline{\zeta}(\tau)$. This is mainly determined by the values of the branch point exponents $\gamma_{nm}$, which are themselves determined by the values of the coupling constants $a_{nm}$, see [17] and [16]. Let us focus on the (more interesting) case in which these constants $a_{nm}$ are *rational* numbers, entailing that the coefficients $\gamma_{nm}$ determining the

character of the branch points are as well *rational*, see [16], so that each of the cuts associated with them opens the way, in the Riemann surface, to a *finite* number of sheets. There are then two possibilities, each generally characterized by *open* regions of initial data having full dimensionality in phase space, the boundaries of which always are (lower-dimensional) domains out of which emerge motions leading, in a time $t_b$ smaller than $T$, to a "particle collision".

One possibility is that the number $B$ of sheets visited before returning to the main sheet be *finite*, $B < \infty$; the corresponding solutions $\underline{z}(t)$ are then *completely periodic* with period $\tilde{T} = (B+1)T$, $\underline{z}(t+\tilde{T}) = \underline{z}(t)$.

Another possibility is that the number of new sheets visited be *unlimited*, namely that the structure of the Riemann surface be such that, by traveling round and round on it along the circle $C$ one *never* returns back to the main sheet. This can happen, even if the exponents $\gamma_{nm}$ are *all rational* so that via the cuts associated to each of them access is gained to only a *finite* number of new sheets, because of the possibility that an *infinity* of branch points be located inside the circle $C$ on the *infinite* sheets associated to these branch points, via a never ending mechanism of branch points nesting. Whenever this happens the corresponding solution $\underline{z}(t)$ is *aperiodic*; and it is moreover likely that it then be *chaotic*, in the sense of displaying a *sensitive dependence* on its initial data. Indeed this will happen whenever some ones out of this infinity of branch points fall arbitrarily close to the contour $C$, because then a *minute* change in the initial data, to which there will correspond a *minute* change in the pattern of these branch points of $\underline{\zeta}(\tau)$ in the complex $\tau$-plane, will cause some relevant branch point to cross over from outside the circle $C$ to inside it, or viceversa, and this will eventually affect quite significantly the time evolution of $\underline{z}(t)$, by causing a change in the sequence of sheets that get visited by traveling along the circle $C$ on the Riemann surface associated to the corresponding $\underline{\zeta}(\tau)$.

This phenomenology has a clear "physical interpretation", which can be qualitatively understood as follows. The $N$-body problem characterized by the Newtonian equations of motion [12] generally yields confined motions, the trajectory of each particle tending to wind round and round – it would indeed reduce to a circle were it not for the interaction with the other particles. A possibility, as we know, is that this $N$-body motion be *completely periodic*, with the same period $T$ that characterizes the circular motion of each particle when the two-body interparticle interaction is altogether missing ($a_{nm} = 0$). Another possibility, in the case discussed above with *rational* coupling constants, is that there exist other motions which are as well *completely periodic*, but with periods which are *integer multiples* of $T$. A third possibility, which cannot *a priori* be excluded, is that there also exist motions which are *aperiodic* but in some way overall *ordered*, perhaps featuring trajectories that eventually wind up around *limit cycles*. And still another possibility is that the motions described by the solution $\underline{z}(t)$ be *aperiodic* and *disordered*. In this case the physical mechanism causing a sensitive dependence on the initial data can be understood as follows. Such disordered motions necessarily feature *near misses*, in which, typically, two particles pass *quite close* to each other (while the probability that an actual collision occur among *point particles* moving *in a plane* is of course *a priori* nil). Such a *near miss* in the motion described by $\underline{z}(t)$ corresponds – see the discussion above – to a branch point of the corresponding solution $\underline{\zeta}(\tau)$ occurring *quite close* to the circle $C$ in the complex $\tau$-plane (which is the one-dimensional region of the two-dimensional complex $\tau$-plane in which the values of $\underline{\zeta}(\tau)$ correspond to the values $\underline{z}(t)$ describing the motion of physical particles moving as functions of the time $t$); and in the generic case of a *two-body* near miss, there is a correspondence between the fact that such a branch point occur *just inside*, or *just outside*, the circle $C$, and the way the particles pass, on one or the other side, by each other. Likewise, the tiny change in the initial data that causes, in the context of the solutions $\underline{\zeta}(\tau)$ – see the discussion above – a branch point of $\underline{\zeta}(\tau)$ to pass from inside to outside the circle $C$, or viceversa, corresponds, in the context of the "physical" solutions $\underline{z}(t)$, to a change occurring in the corresponding *near miss*, from the case in which the two particles involved in it slide by each other on one side to the case in which they instead slide by each other on the other side – entailing a significant change in the subsequent motion (indeed, the closer a near miss, the more it affects the motion, due to the singularity of the two-body interaction at zero separation, see [12]).

The phenomenology outlined here does indeed occur in this goldfish model. It also occurs – rather similarly if more simply, since in this case only square-root branch points occur, irrespective of the values of the coupling constants – in the model [6] with $K = 1$. Indeed, it is clear that this phenomenology provides a paradigm of rather general applicability for the transition from *isochronicity* to *deterministic chaos*, indeed perhaps for the generic *onset* of *deterministic chaos*.

# Isomonodromic Deformations

**V P Kostov**, Université de Nice – Sophia Antipolis, Nice, France

## Introduction

In this article we consider families of linear differential equations whose monodromy data do not depend on the parameters. Such families are called isomonodromic deformations of any of the equations of the family (for the definitions of a regular and Fuchsian linear system and of their monodromy groups, see Riemann–Hilbert Problem).

## Schlesinger's Equation

The best-studied example of an isomonodromic deformation is the Fuchsian system on Riemann's sphere $\mathbf{C}P^1 = \mathbf{C} \cup \infty$ considered by L Schlesinger:

$$\frac{\mathrm{d}X}{\mathrm{d}t} = \left(\sum_{j=1}^{p+1} \frac{A_j}{t - a_j}\right) X \qquad [1]$$

Here the poles $a_j \in \mathbf{C}$ are free parameters and the matrices-residua $A_j$ depend analytically on $a := (a_1, \ldots, a_{p+1})$; therefore, system [1] is in fact a family of linear systems which is an analytic deformation of the system obtained for $a_j = a_j^0$.

One can think of system [1] as defined by the Pfaffian system

$$\mathrm{d}X = \omega_{\mathrm{s}} X, \quad \omega_{\mathrm{s}} = \sum_{j=1}^{p+1} \frac{A_j}{t - a_j} \mathrm{d}(t - a_j) \qquad [2]$$
